FIGURE 95-9 Granuloma gluteal infantum with two large nodules in the diaper area. While these nodules are brown they can also have a red or purplish hue. In this case, topical steroids were one factor in this nodular granulomatous response. (*Used with permission Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 3-5, McGraw-Hill, 2009*.)

3. Pseudoverrucous papules and nodules are shiny, smooth, red, moist, flat-topped perianal lesions that occur with chronic diarrhea. They are commonly confused with the genital warts and can occur with Hirschsprung disease (**Figure 95-10**).

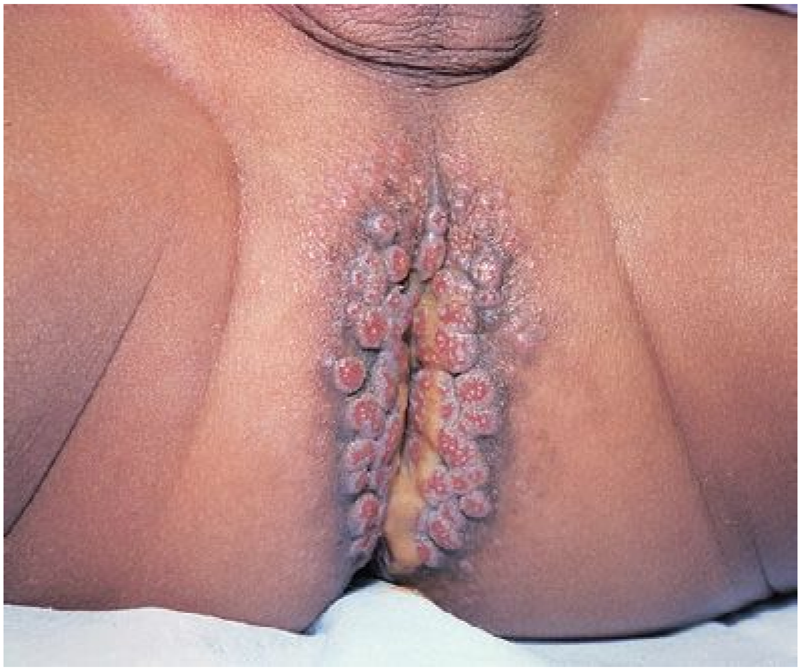

FIGURE 95-10 Pseudoverrucous papules and nodules. The flat-topped or round lesions are shiny, erythematous and moist. This unique diaper dermatitis was originally described in the skin surrounding urostomies, but can occur as a result of chronic diarrhea (sometimes from Hirschsprung's disease), encopresis or urinary incontinence. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 8-45, New York, NY: McGraw-Hill, 2008*.)

Secondary diaper dermatitis is an eruption in the diaper area with a defined etiology. Atopic dermatitis, seborrheic dermatitis, and psoriasis are examples of rashes that can appear anywhere on the body and can be exaggerated in the groin as a result of wearing diapers (**Figure 95-11**). Family history of atopy or psoriasis and rash in other locations besides the groin can be helpful. Look on the scalp for seborrheic dermatitis (cradle-cap) (see Chapter 135, Seborrheic dermatitis).

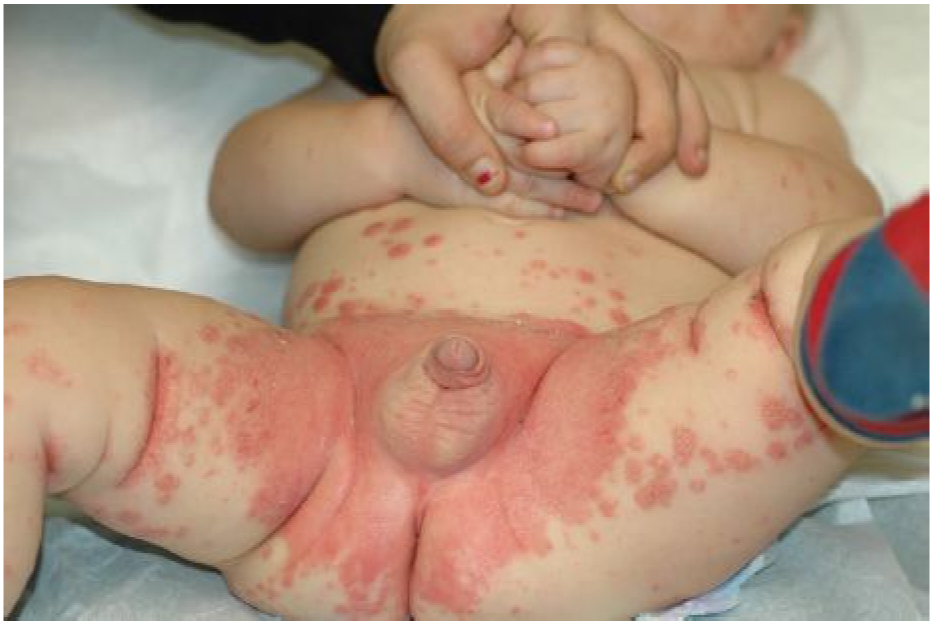

FIGURE 95-11 Severe seborrheic dermatitis in a 1-year-old boy. Note that this condition is not just confined to the diaper area. The whitish-yellow scale is characteristic of seborrhea and the child had involvement on the cheeks and "cradle cap" in the scalp. No satellite pustules of candidiasis are noted. This is not irritant dermatitis as it does not spare the deep folds and the distribution strongly suggests seborrheic dermatitis not candida diaper dermatitis, which would be restricted largely to diaper area or other skin folds. (*Image used with permission from Robert Brodell, MD.*)

Congenital syphilis, scabies, HIV, Langerhans cell histiocytosis (**Figure 95-12**), and acrodermatitis enteropathica (**Figure 95-6**) are examples of rashes in the diaper area unrelated to the diaper. Allergic contact dermatitis as a result of an allergen in the diaper itself is possible but rare. Suspect acrodermatitis enteropathica caused by zinc deficiency when the diaper dermatitis is severe and accompanied by perioral dermatitis (**Figure 95-6**). The serum zinc level will be low and zinc supplementation will be needed.

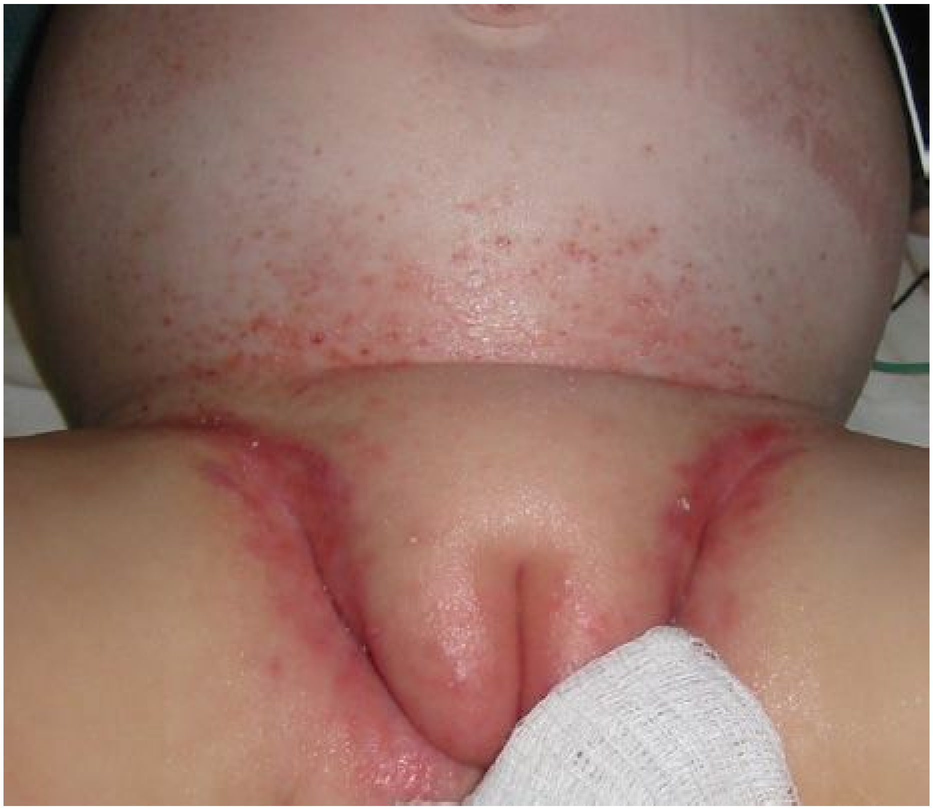

FIGURE 95-12 Langerhans cell histiocytosis in the diaper area. This presented as a refractory diaper rash with scattered erythematous papules and a petechial component. Note the petechiae are particularly prominent on the lower abdomen and the eruption is not only confined to the diaper area. A skin biopsy revealed Langerhans' cells to confirm the diagnosis. (*Used with permission Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 3-6, McGraw-Hill, 2009*.)

Intertrigo is an inflammatory condition that occurs in intertriginous areas such as in the inguinal folds (**Figure 95-13**). Other areas involved may be under the neck, in the axillae, or in the gluteal cleft. The term is nonspecific as to the etiology and one should always look for causes such as candida, seborrhea, and psoriasis.

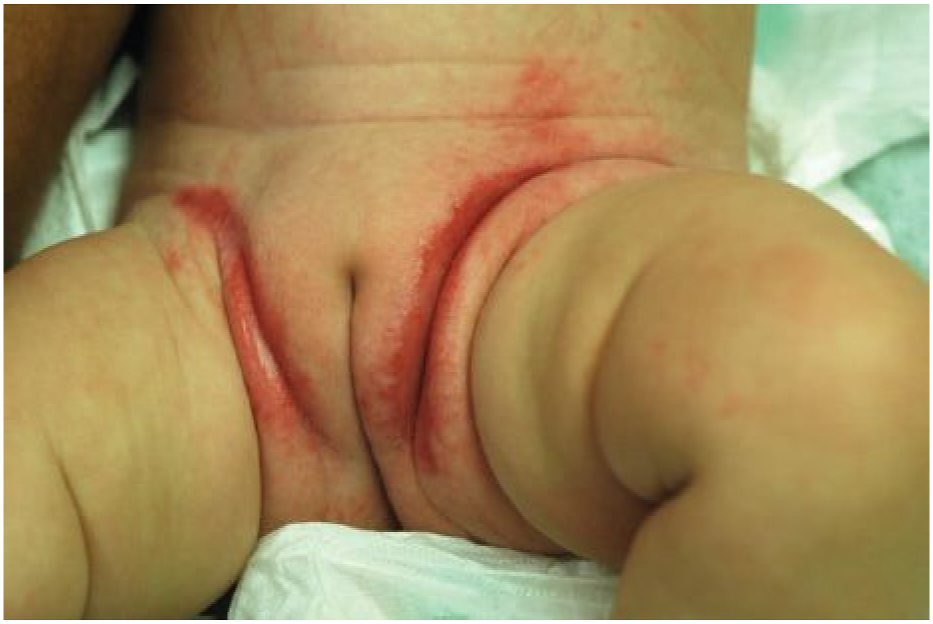

FIGURE 95-13 Intertrigo with bright red erythema in the inguinal folds. One should always look for the contributing factors in any case of intertrigo. Three etiologies to consider are: (1) Irritant dermatitis: This is NOT the classic appearance of an irritant from urine and feces that effects outer skin and spares the deep fold. (2) Candida: Note the papules and papulovesicles on the left abdomen and a few on the thighs (satellite papules and papulovesicles) (3) Seborrheic dermatitis: Look on the scalp and face as this could be a principle cause of this rash. (*Image used with permission from Robert Brodell, MD.*)

MANAGEMENT

TREATMENT

- Parental behavior change to keep the skin as exposed and dry as possible. SOR Ⓑ Frequent diaper changes (as soon as they are wet or soiled and at least every 3 to 4 hours); use disposable diapers.SOR Ⓑ Frequent gentle cleaning of the affected area with lukewarm tap water instead of commercial wipes containing alcohol and pat dry. A squeeze bottle with lukewarm water can be used to avoid rubbing the delicate skin.

- Superabsorbent diapers that pull moisture away from the skin are helpful.[1] SOR B
- Apply barrier preparations, including zinc oxide paste, petroleum jelly, Vitamin A & D ointment, or Burow solution to affected area after each diaper change.[1] SOR B Pastes are better than ointments, which, in turn, are better than creams or lotions. Avoid products with fragrances or preservatives to minimize allergic potential. Apply thickly like "icing on a cake." These barrier preparations should be used *on top* of other indicated therapies.
- For moderate to severe inflammation, consider a nonfluorinated, low-potency topical steroid such as 1 percent hydrocortisone ointment (up to 3 times daily) to the affected area until the dermatitis is gone. To avoid skin erosions, atrophy, and striae, it is best to not go beyond 2 weeks of therapy with any topical steroid on a baby's bottom.
- For *Candida*, use topical nonprescription antifungal creams such as clotrimazole, miconazole after every diaper change until the rash resolves. SOR B For concomitant oral thrush, treat with oral nystatin swish and swallow 4 times daily.
- Avoid combination antifungal–steroid agents that contain steroids stronger than hydrocortisone (e.g., Lotrisone). Potent topical steroids can cause striae and skin erosions, hypothalamus–pituitary–adrenal axis suppression, and Cushing syndrome.[1]
- For mild bacterial infections, use topical antibiotic ointments such as bacitracin or mupirocin after every diaper change until the rash resolves. SOR B
- For more severe bacterial infections, consider a broad-spectrum oral antibiotic such as amoxicillin-clavulanate. Perianal bacterial dermatitis has been reported to be predominantly caused by *S. aureus*.[6] Oral cephalexin is a good choice because it covers *S. aureus* and group A β-hemolytic streptococcus. If methicillin-resistant *S. aureus* (MRSA) is suspected, consider trimethoprim-sulfamethoxazole. SOR B
- Ciclopirox 0.77 percent topical suspension (Loprox), a broad-spectrum agent with antifungal, antibacterial, and antiinflammatory properties, was

used safely and effectively in 1 trial of 44 children to treat diaper dermatitis caused by *Candida*.[1] SOR B

- Recommend dye-free diapers for allergic contact dermatitis. SOR B

PREVENTION AND ROUTINE SKIN CARE

- Keep the diaper region as dry and clean as possible.
- Promote the use of barrier preparations daily to maintain skin integrity.
- There is no evidence to suggest that topical vitamin A prevents diaper dermatitis.[7] SOR B
- Disposable diapers—Although many individual trials show benefits, a 2006 Cochrane Review found that there is not enough evidence from good quality, randomized, controlled trials to support or refute the use and type of disposable diapers for the prevention of diaper dermatitis in infants.[8] SOR B

PROGNOSIS

Diaper dermatitis has an excellent prognosis when treated as previously described.

FOLLOW-UP

No follow-up needed unless the rash worsens or persists. The exception is severe bacterial infection where follow-up is recommended because recurrences are common.

PATIENT EDUCATION

Prevention and early treatment are the best strategies. Keep the child's diaper area as clean, cool, and dry as possible with frequent diaper changes. Do *not* use creams that contain boric acid, camphor, phenol, methyl salicylate, compound of benzoin, or talcum powder or cornstarch. Reassure parents that, although this common condition is sometimes distressing for parents and uncomfortable for children, it is rarely dangerous.

SECTION 2 ACNEIFORM DISORDERS

96 ACNE VULGARIS

Richard P. Usatine, MD

PATIENT STORY

A 16-year-old boy (**Figure 96-1**) with severe nodulocystic acne and scarring presents for treatment. After trying oral antibiotics, topical retinoids, and topical benzyl peroxide with no significant benefit, the patient and his mother request isotretinoin (Accutane). After 4 months of isotretinoin, the nodules and cysts cleared, and there remained only a few papules (**Figure 96-2**). He is much happier and more confident about his appearance. The skin fully cleared after the last month of isotretinoin.

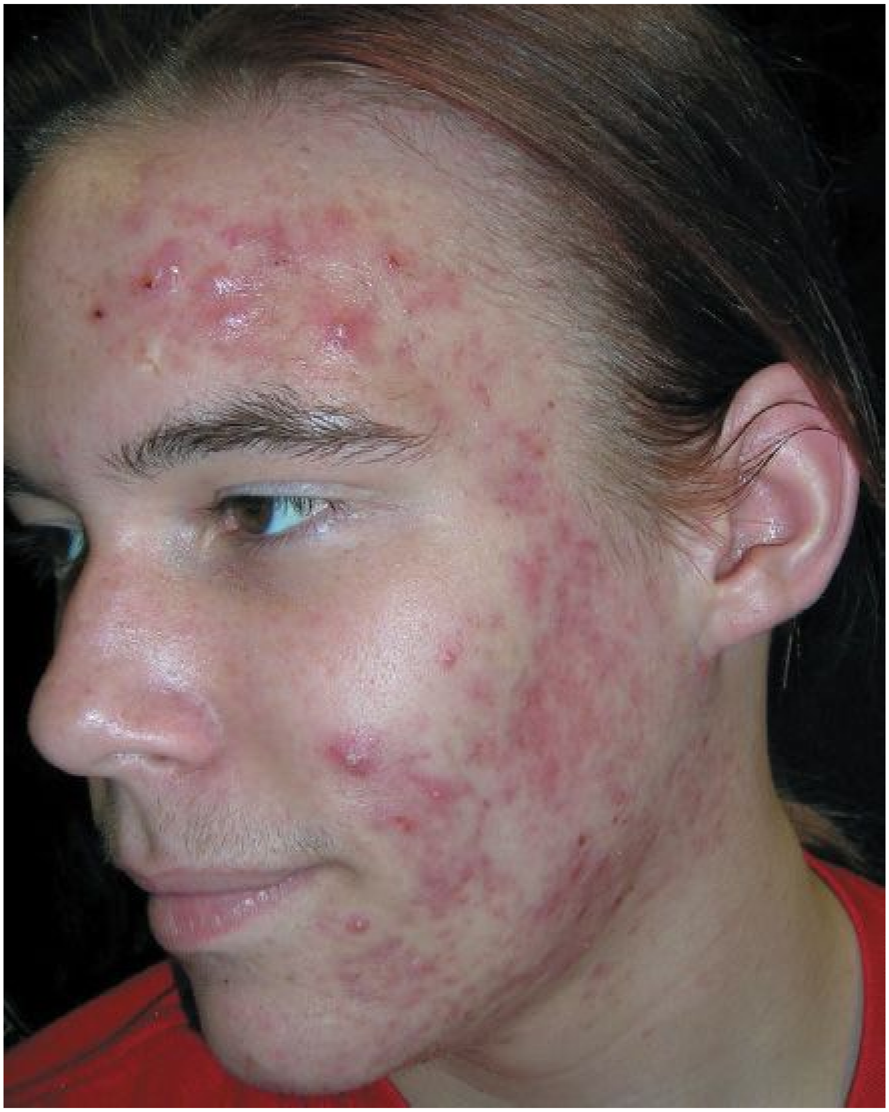

FIGURE 96-1 Severe nodulocystic acne with scarring in a 16-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

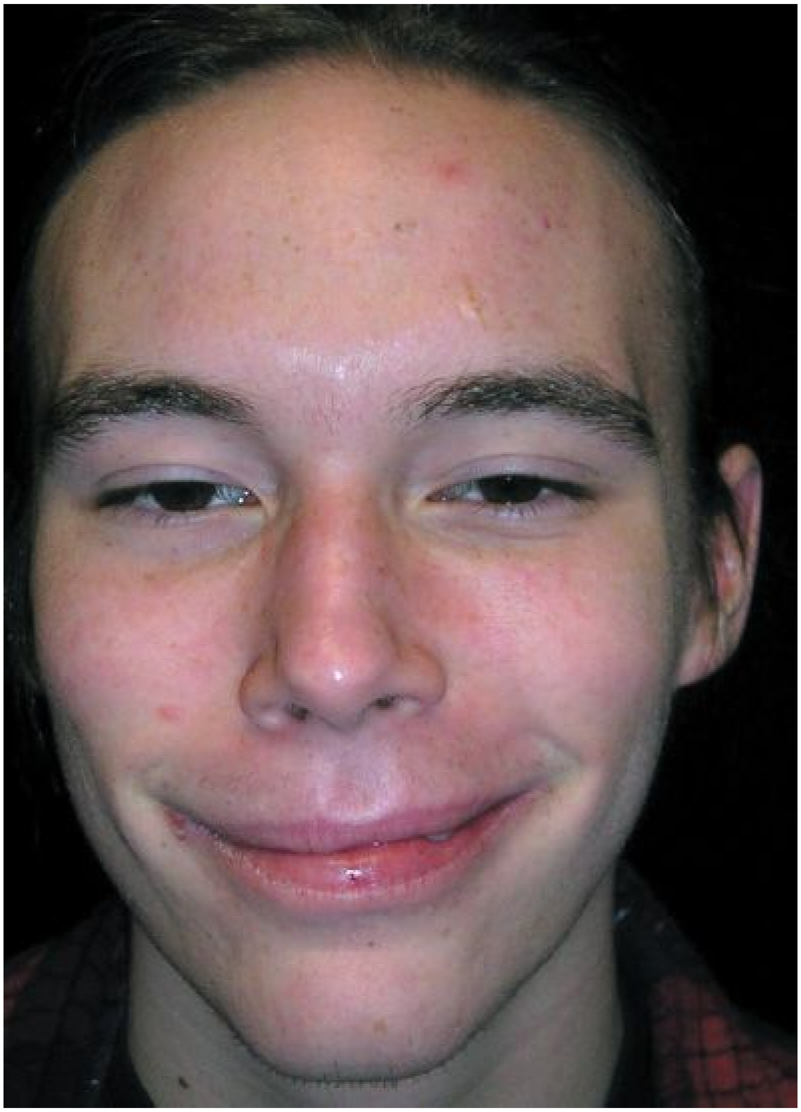

FIGURE 96-2 A happier boy now that his nodules and cysts have cleared at the start of the fifth month of isotretinoin treatment. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Acne is an obstructive and inflammatory disease of the pilosebaceous unit predominantly found on the face of adolescents. However, it can occur at any age and often involves the trunk in addition to the face.

EPIDEMIOLOGY

Acne vulgaris affects more than 80 percent of teenagers, and persists beyond the age of 25 years in 3 percent of men and 12 percent of women.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

The four most important steps in acne pathogenesis:

1. Sebum overproduction related to androgenic hormones and genetics.
2. Abnormal desquamation of the follicular epithelium (keratin plugging).
3. *Propionibacterium acnes* proliferation.

4. Follicular obstruction, which can lead to inflammation and follicular disruption.

Neonatal acne is thought to be related to maternal hormones and is temporary (**Figure 96-3**).

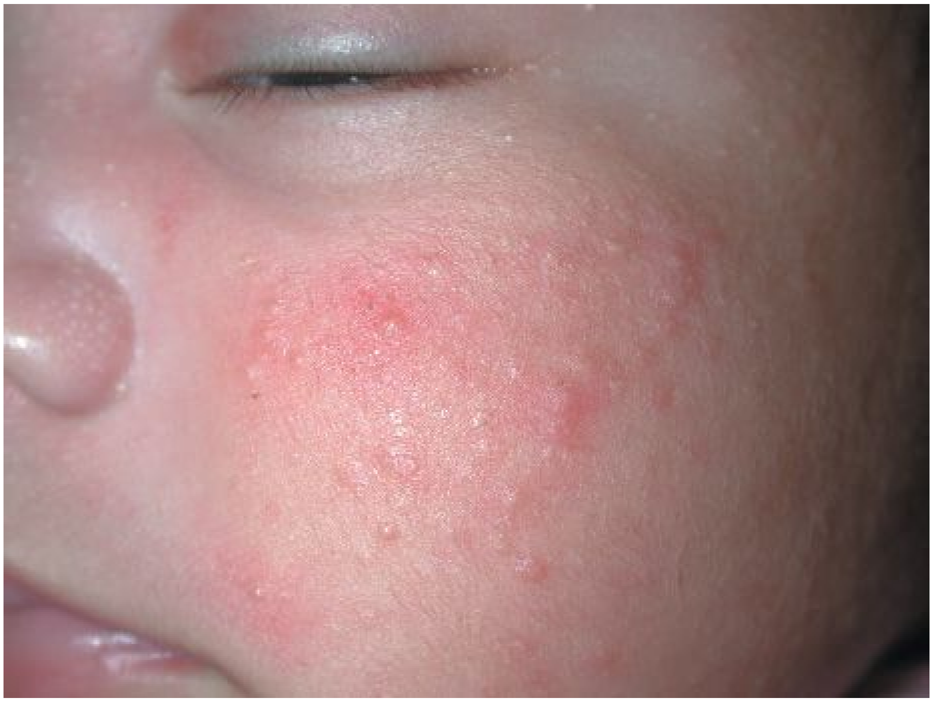

FIGURE 96-3 Neonatal acne in a healthy 2-week-old infant that resolved without treatment. (*Used with permission from Richard P. Usatine, MD.*)

Acne can be precipitated by mechanical pressure as with a helmet strap (**Figure 96-4**) and medications such as phenytoin and lithium (**Figure 96-5**).

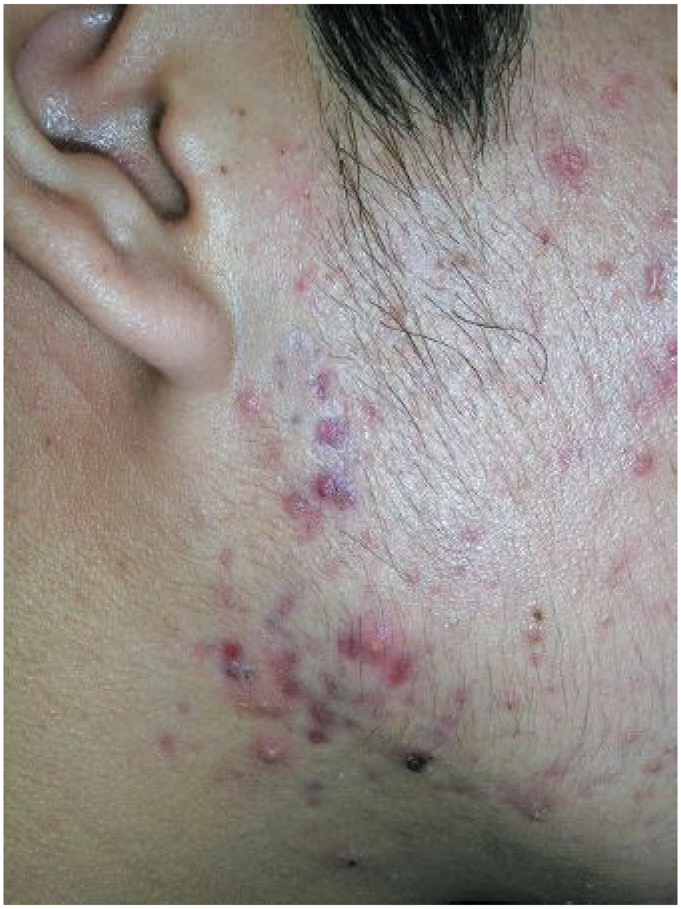

FIGURE 96-4 Inflammatory acne showing pustules and nodules in a 17-year-old boy who uses a helmet while playing football in high school. (*Used with permission from Richard P. Usatine, MD.*)

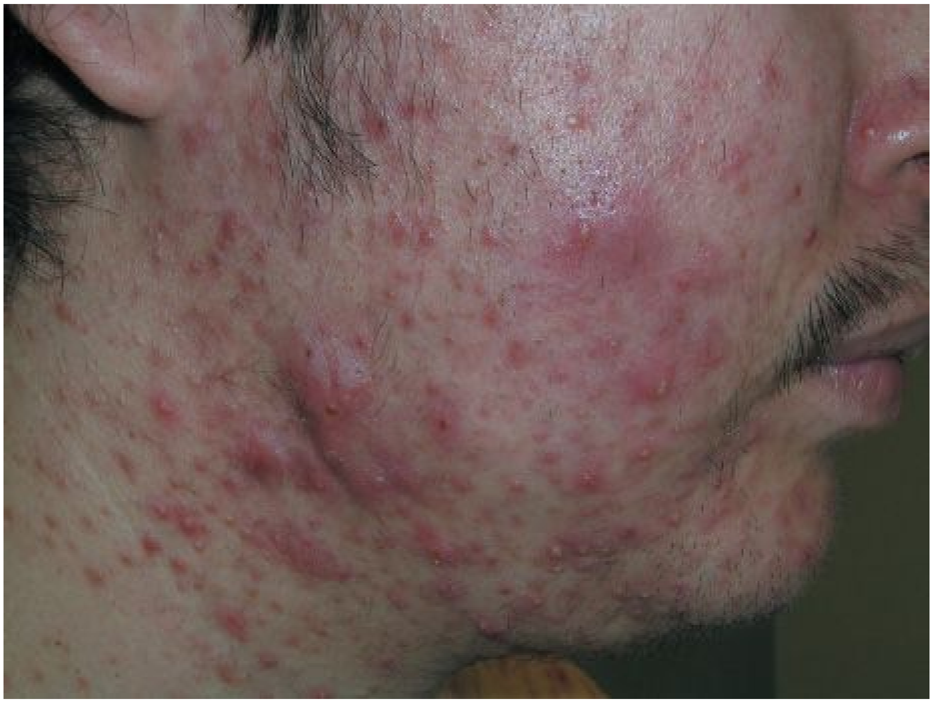

FIGURE 96-5 Severe inflammatory acne in a young adult. His acne worsened when he was started on phenytoin for his seizure disorder. (*Used with permission from Richard P. Usatine, MD.*)

There are some studies that suggest that consumption of large quantities of milk (especially skim milk) increase the risk for acne in teenagers.[2]

DIAGNOSIS

CLINICAL FEATURES

Morphology of acne includes comedones, papules, pustules, nodules, and cysts.

- Obstructive acne = comedonal acne = noninflammatory acne and consists of only comedones (**Figure 96-6**).

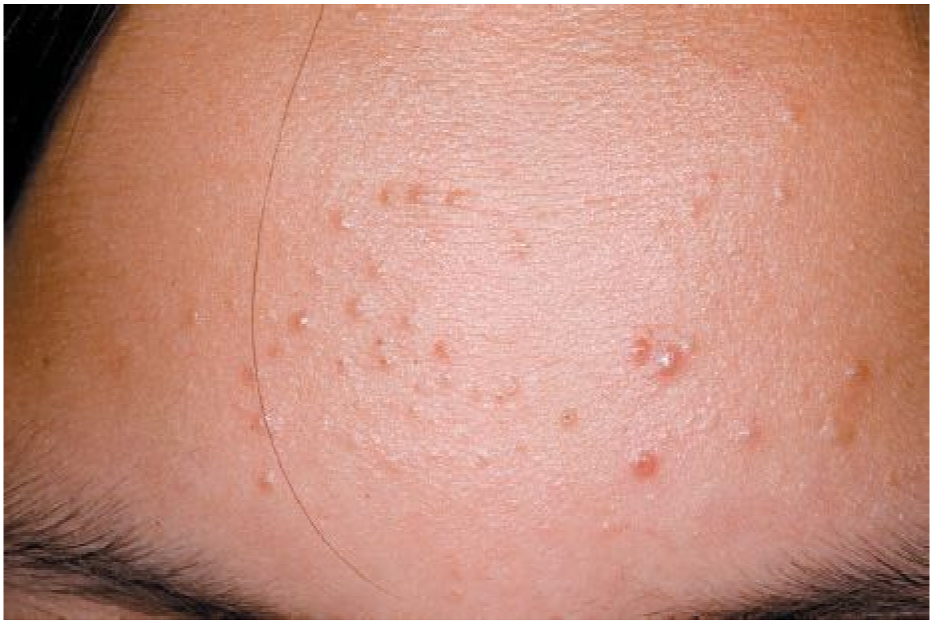

FIGURE 96-6 Comedonal acne in a 15-year-old girl. Open comedones (blackheads) and closed comedones (whiteheads) are visible on her forehead. (*Used with permission from Richard P. Usatine, MD.*)

- Open comedones are blackheads (**Figure 96-7**) and closed comedones are called whiteheads and look like small papules.

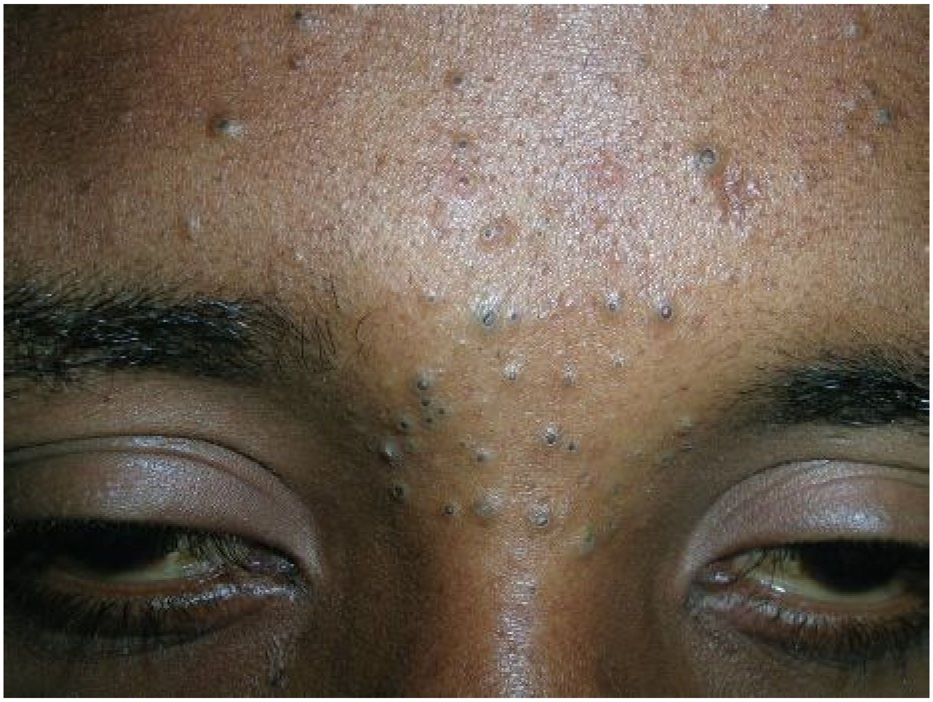

FIGURE 96-7 Comedonal acne in a 17-year-old girl. She has many large open comedones (blackheads). She is a very good candidate for acne surgery along with medical therapy. (*Used with permission from Richard P. Usatine, MD.*)

- Inflammatory acne has papules, pustules, nodules, and cysts in addition to comedones (**Figure 96-5**).

TYPICAL DISTRIBUTION

Face, back, chest, and neck.

LABORATORY STUDIES

None unless you suspect androgen excess and/or polycystic ovarian syndrome (PCOS).[3] SOR Ⓐ Obtain testosterone and DHEA-S levels if you suspect androgen excess and/or PCOS.

Consider follicle-stimulating hormone (FSH) and luteinizing hormone (LH) levels if you suspect PCOS.

DIFFERENTIAL DIAGNOSIS (INCLUDING SPECIAL TYPES OF ACNE)

- Acne conglobata is an uncommon and unusually severe form of acne characterized by multiple comedones, cysts, sinus tracks, and abscesses. The inflammatory lesions and scars can lead to significant disfigurement.[4] Sinus tracks can form with multiple openings that drain foul-smelling purulent material (**Figures 96-8** and **96-9**). The comedones and nodules are usually found on the chest, shoulders, back, buttocks, and face. In some cases, acne conglobata is part of a follicular occlusion triad including hidradenitis and dissecting cellulitis of the scalp.

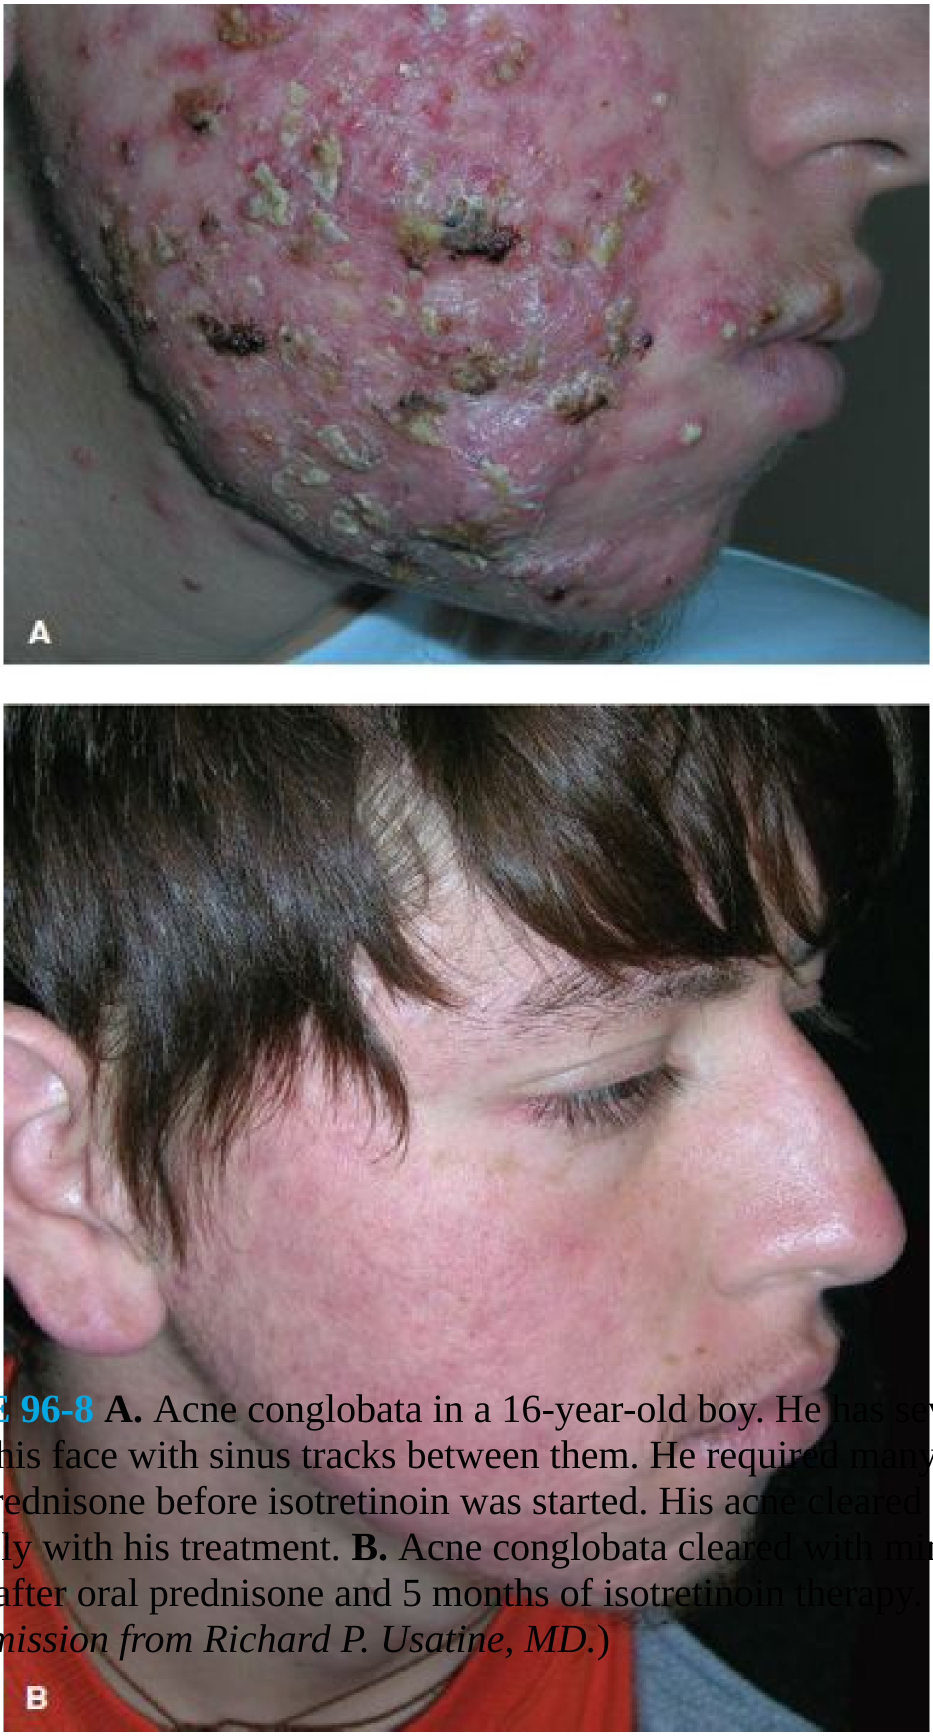

FIGURE 96-8 **A.** Acne conglobata in a 16-year-old boy. He has severe cysts on his face with sinus tracks between them. He required many weeks of oral prednisone before isotretinoin was started. His acne cleared completely with his treatment. **B.** Acne conglobata cleared with minimal scarring after oral prednisone and 5 months of isotretinoin therapy. (*Used with permission from Richard P. Usatine, MD.*)

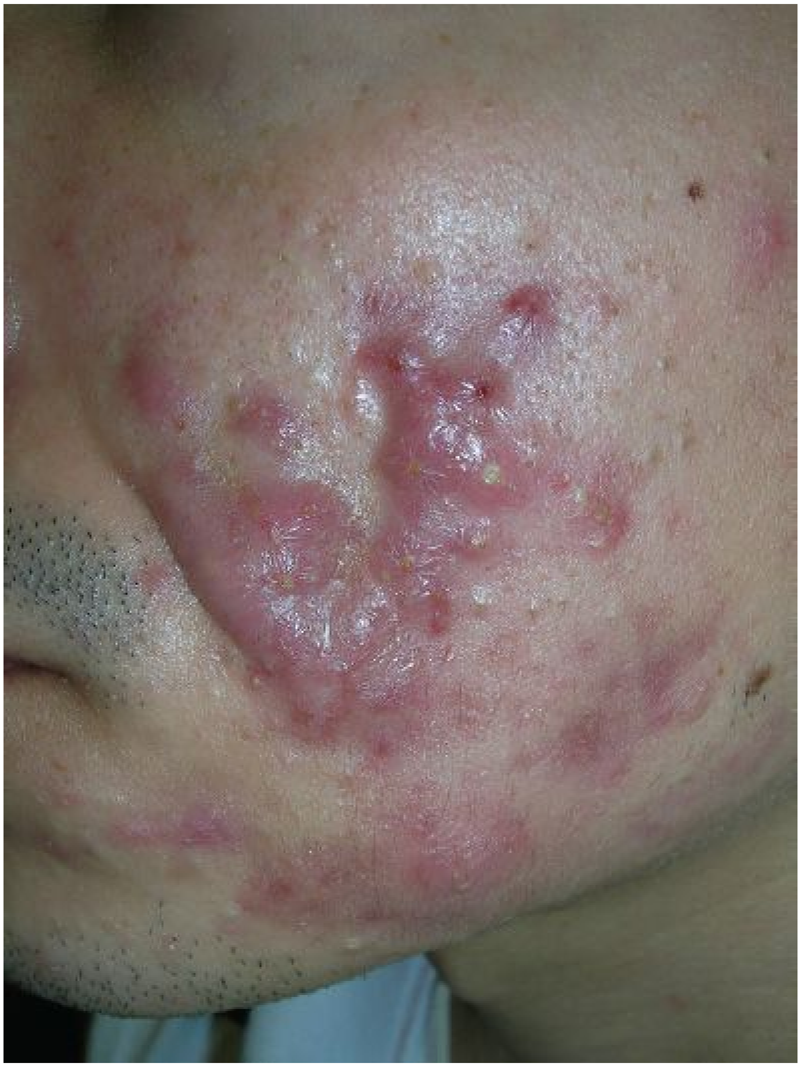

FIGURE 96-9 Acne conglobata on the face with sinus tracts and large cystic lesions in a teenage male. (*Used with permission from Richard P. Usatine, MD.*)

- Acne fulminans is characterized by sudden onset ulcerative crusting cystic acne, mostly on the chest and back (**Figures 96-10** and **96-11**).[5] Fever, malaise, nausea, arthralgia, myalgia, and weight loss are common. Leukocytosis and elevated erythrocyte sedimentation rate are usually found. There may also be focal osteolytic lesions. The term *acne fulminans* may also be used in cases of severe aggravation of acne without systemic features.[5]

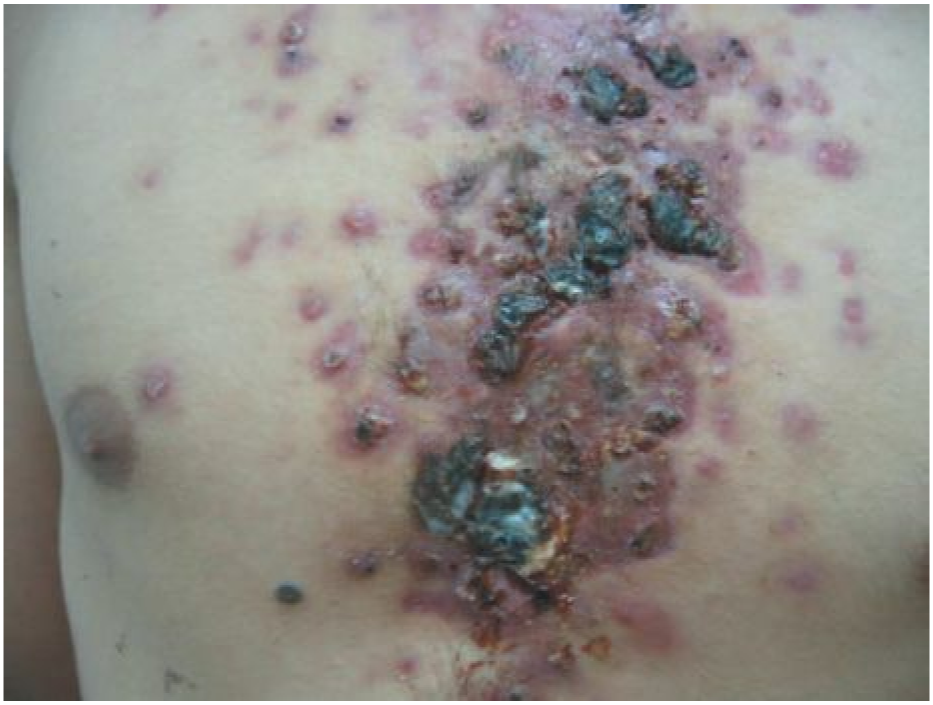

FIGURE 96-10 Acne fulminans in a 17-year-old boy. He was on isotretinoin when he developed worsening of his acne with polymyalgia and arthralgia. He presented with numerous nodules and cysts covered by hemorrhagic crusts on his chest and back. (*From Grunwald MH, Amichai B. Nodulo-cystic eruption with musculoskeletal pain. J Fam Pract. 2007;56:205-206, Reproduced with permission from Frontline Medical Communications*.)

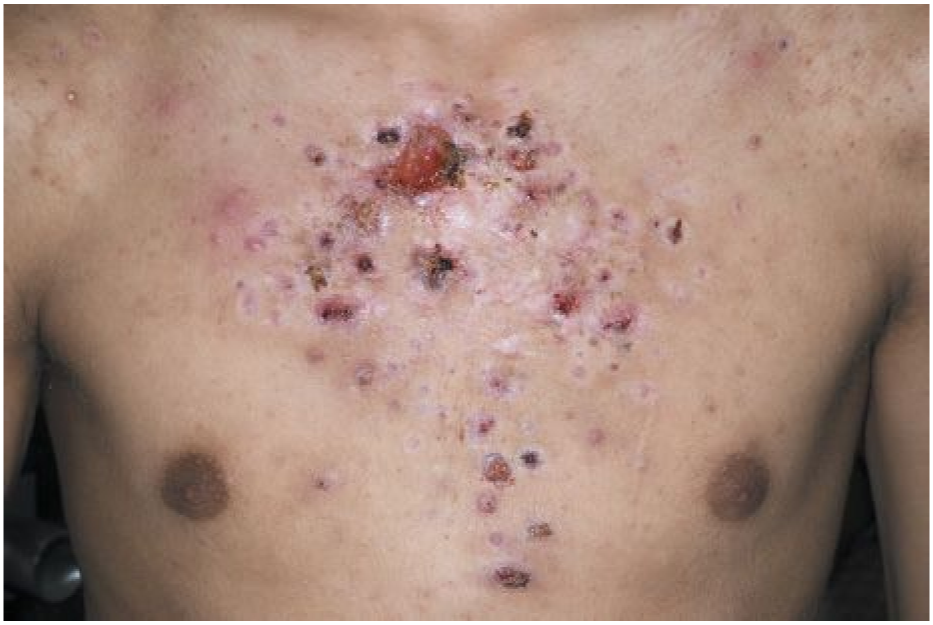

FIGURE 96-11 Acne fulminans with severe rapidly worsening truncal acne in a 15-year-old boy. He did not have fever or bone pain but had a white blood cell count of 17,000. He responded rapidly to prednisone and was started on isotretinoin. The ulcers and granulation tissue worsened initially on isotretinoin but prednisone helped to get this under control. (*Used with permission from Richard P. Usatine, MD.*)

- Pomade acne is described as acne that is caused or exacerbate by greasy hair products that get on the skin of the forehead. It is more commonly seen in African Americans (**Figure 96-12**).

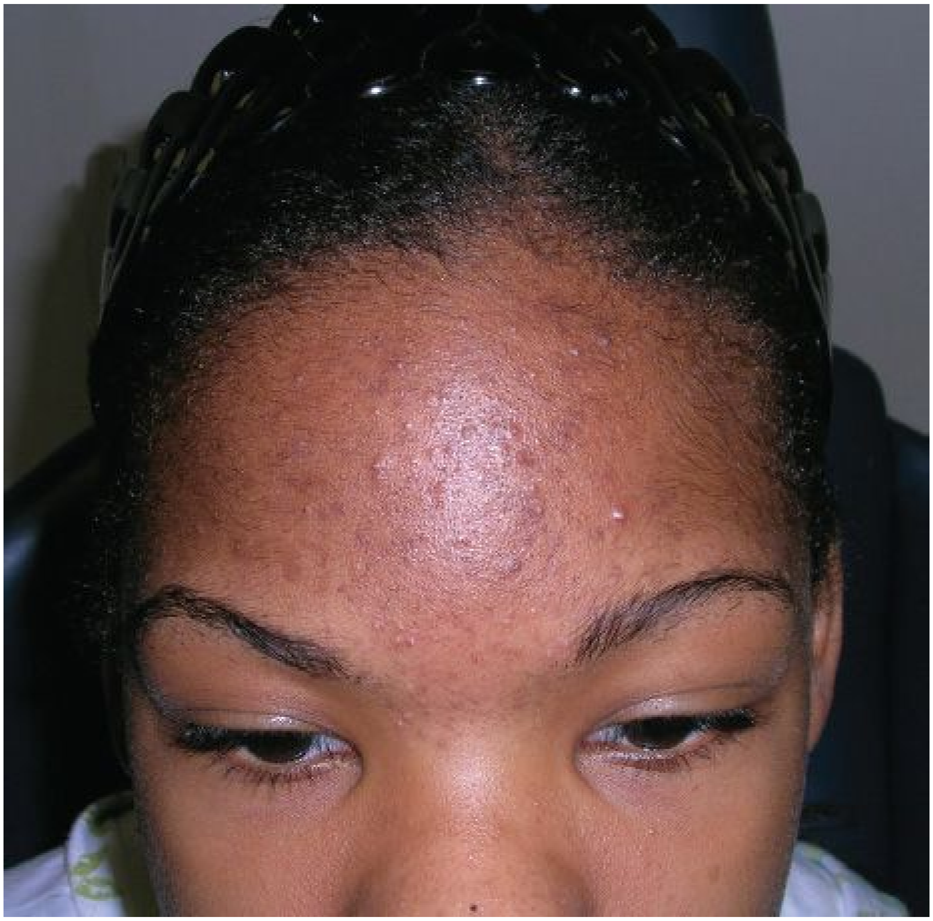

FIGURE 96-12 Pomade acne in a young African American teen that uses oily hair products to style her hair. Note how the acne is predominantly on the forehead. (*Used with permission from Richard P. Usatine, MD.*)

- Rosacea can resemble acne by having papules and pustules on the face. It is usually seen in older adults with prominent erythema and telangiectasias. Rosacea does not include comedones and may have ocular or nasal manifestations (Chapter 97, Rosacea).

- Folliculitis on the back may be confused with acne. Look for hairs centrally located in the inflammatory papules of folliculitis to help distinguish it from acne. Acne on the back usually accompanies acne on the face as well (Chapter 100, Folliculitis).
- Acne keloidalis nuchae consists of papules, pustules, nodules, and keloidal tissue found at the posterior hairline. It is most often seen in persons of color after shaving the hair at the nape of the neck (**Figure 96-13**).

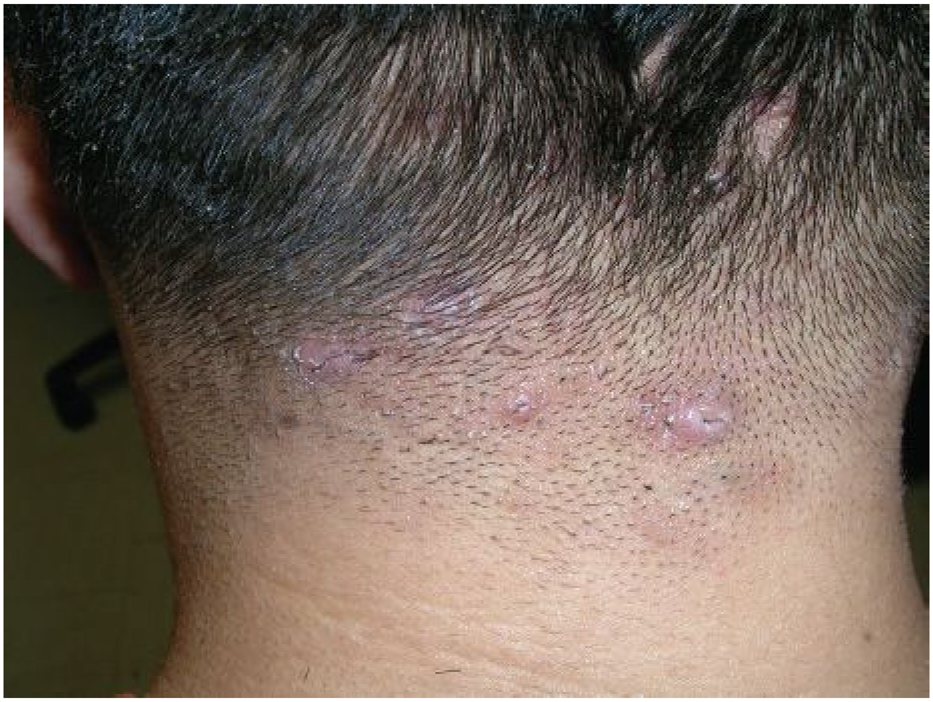

FIGURE 96-13 Acne keloidalis nuchae on the neck of a teen that shaves his hair in the back. The pathophysiology is more related to a folliculitis than actual acne. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

Treatment is based on type of acne and severity. Categories to choose from are topical retinoids, topical antimicrobials, systemic antimicrobials, hormonal therapy, oral isotretinoin, and injection therapy.

MEDICATIONS FOR ACNE THERAPY

In a review of 250 comparisons, the Agency for Health-care Research and Quality found 14 had evidence of level A.[6] These comparisons demonstrated the efficacy over vehicle or placebo control of topical clindamycin, topical erythromycin, benzoyl peroxide, topical tretinoin, oral tetracycline, and norgestimate/ethinyl estradiol.[4] Level A conclusions demonstrating equivalence include: Benzoyl peroxide at various strengths was equally efficacious in mild/moderate acne; adapalene and tretinoin were equally efficacious.[6] SOR Ⓐ

Topical:

- Benzoyl peroxide—Antimicrobial effect (gel, cream, lotion) (2.5%, 5%, 10%) 10 percent causes more irritation and is not more effective.[1] SOR Ⓐ
- Topical antibiotics—Clindamycin and erythromycin are the mainstays of treatment.
- Erythromycin—Solution, gel.[3] SOR Ⓐ
- Clindamycin—Solution, gel, lotion.[3] SOR Ⓐ
- Benzamycin gel—Erythromycin 3 percent, benzoyl peroxide 5 percent.[3] SOR Ⓐ
- BenzaClin gel—Clindamycin 1 percent, benzoyl peroxide 5 percent.[3] SOR Ⓐ
- Dapsone 5 percent gel.[7] SOR Ⓑ

Retinoids:

- Tretinoin (Retin-A) gel, cream, liquid, micronized.[1] SOR Ⓐ
- Adapalene gel—Less irritating than tretinoin.[1] SOR Ⓐ

- Tazarotene—Strongest topical retinoid with greatest risk of irritation.[8] SOR A

Topical retinoids will often result in skin irritation during the first 2 to 3 months of treatment, but new systematic reviews do not demonstrate that they worsen acne lesion counts during the initial period of use.[2]

- Azelaic acid—Useful to treat spotty hyperpigmentation and acne (**Figure 96-14**).[3] SOR B

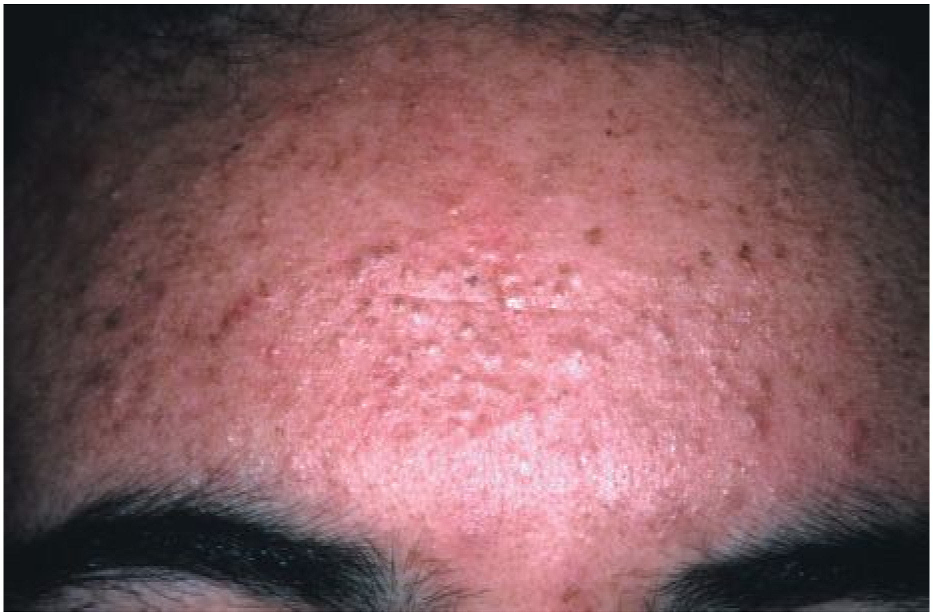

FIGURE 96-14 Obstructive or comedonal acne with spotty hyperpigmentation. Azelaic acid was helpful to treat the acne and the hyperpigmentation. (*Used with permission from Richard P. Usatine, MD.*)

Systemic

- Oral antibiotics.
  - Doxycycline 40 to 100 mg qd to bid—Inexpensive, well tolerated, can take with food and increases sun sensitivity.[3] SOR A
  - Minocycline 50 to 100 mg qd to bid—Expensive, not proven to be better than other systemic antibiotics including tetracycline.[3,9] SOR A

  - Erythromycin 250 to 500 mg bid—Inexpensive, frequent gastrointestinal (GI) disturbance but can be used in pregnancy.[3] SOR A
  - Trimethoprim/sulfamethoxazole DS bid—Effective but risk of Stevens-Johnson syndrome is real. Reserve for short courses in particularly severe and resistant cases.[3] SOR A
  - Oral azithromycin has been prescribed in pulse dosing for acne in a number of small poorly done studies and has not been found to be better than oral doxycyline.[10]
- Isotretinoin (Accutane) is the most powerful treatment for acne. It is especially useful for cystic and scarring acne that has not responded to other therapies.[3] SOR A Dosed at approximately 1 mg/kg per day for 5 months. Any female of childbearing potential must be abstinent from sexual intercourse or use two forms of contraception. Other risks that are controversial but important to discuss with patients and their parents are depression, suicide, and inflammatory bowel disease.
- The US Food and Drug Administration requires that prescribers of isotretinoin, patients who take isotretinoin, and pharmacists who dispense isotretinoin all must register with the iPLEDGE system (www.ipledgeprogram.com).
- Hormonal treatments are for females only:
  - Oral contraceptives—Choose ones with low androgenic effect.[3] SOR A FDA-approved oral contraceptives are Ortho Tri-Cyclen, Yaz, and Estrostep. Other oral contraceptives with similar formulations also help acne in women even though these have not received FDA approval for this indication. Note: Yaz and Yasmin have progestin drospirenone, which is derived from 17α-spirolactone. It shares an antiandrogenic effect with spironolactone.

COMPLEMENTARY/ALTERNATIVE THERAPY

Tea tree oil 5 percent gel.[11] SOR B

ACNE PROCEDURES

- Steroid injections for acne are useful for painful nodules and cysts. SOR C Patients often report that the lesion flattens and becomes painless by the next day. Follow these directions to avoid producing skin atrophy.
    - Dilute 0.1 mL of 10 mg/mL triamcinolone acetonide (Kenalog) with 0.4 mL of sterile saline in a 0.1 mL syringe to make a 2 mg/mL suspension. Shake the suspension well before injecting.
    - Inject 0.1 mL of this suspension into each nodule or cyst using a 30-gauge needle (**Figure 96-15**).

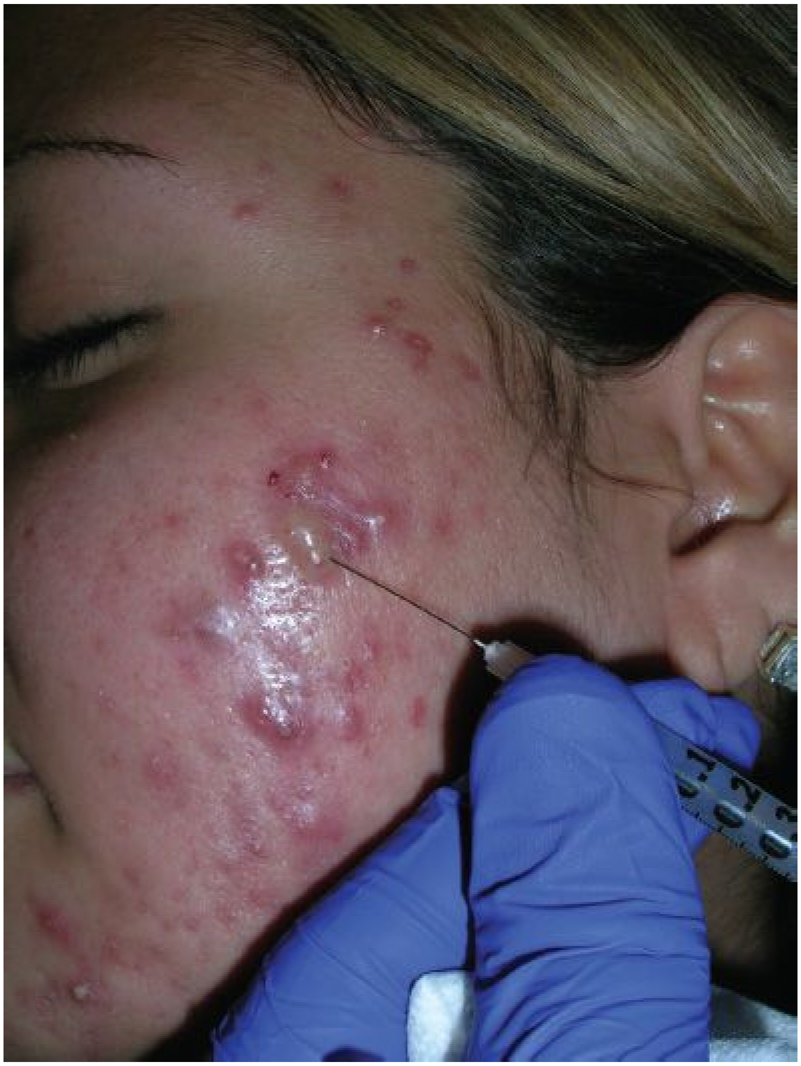

FIGURE 96-15 Injection of acne nodules with 2 mg/cc triamcinolone acetonide. (*Used with permission from Richard P. Usatine, MD.*)

- Acne surgery is a fancy name for extracting the material from open comedones. It helps to nick the comedone with a needle or #11 blade before expressing the material with a comedone extractor (**Figure 96-16**). The patient in **Figure 96-7** is a very good candidate for this procedure along with medical therapy.

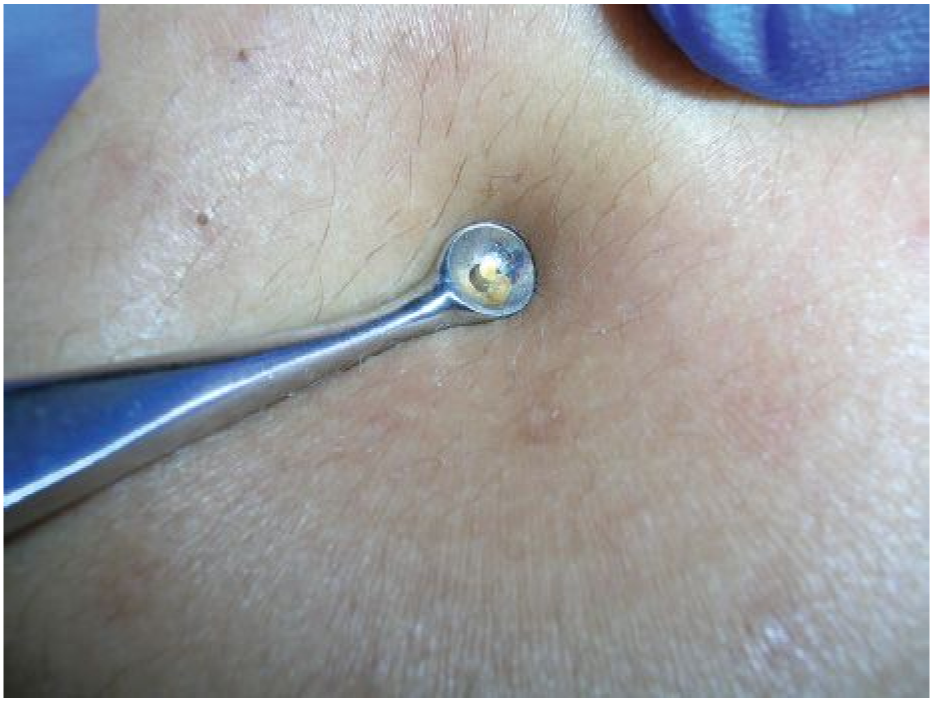

FIGURE 96-16 Acne surgery using a comedone extractor to remove the material from an open comedone after it was nicked with a #11 scalpel blade. (*Used with permission from Richard P. Usatine, MD.*)

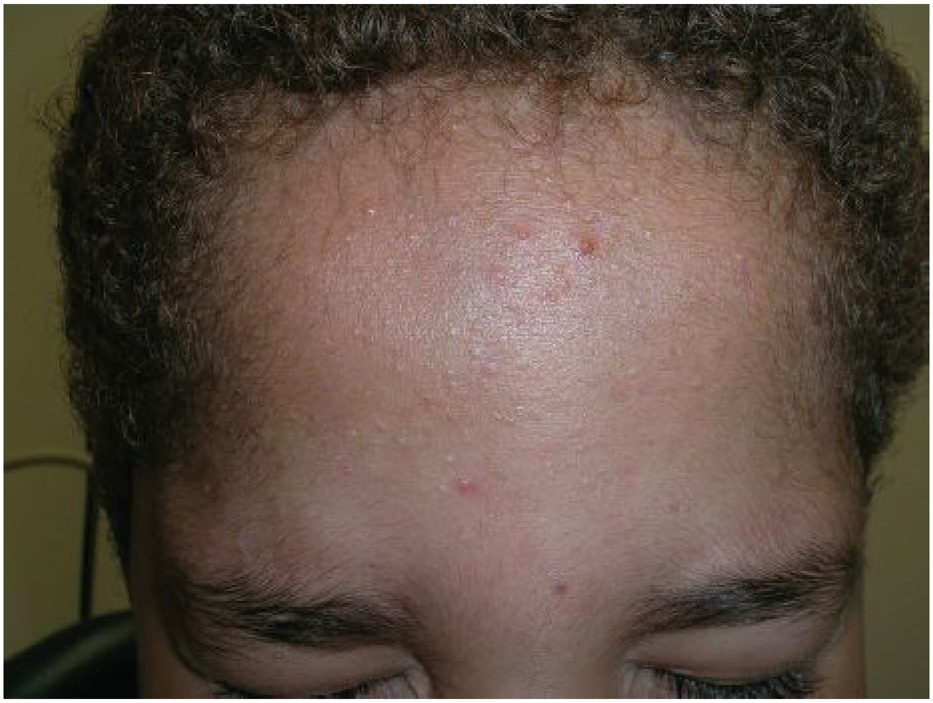

FIGURE 96-17 Comedonal acne beginning on the forehead on 9-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

ACNE THERAPY BY SEVERITY

Comedonal acne (Figures 96-6, 96-7, 96-17)

- Topical retinoids or azelaic acid are the most beneficial agents.
- No need for antibiotics—Do not need to kill *P. acnes*.
- Benzoyl peroxide may be beneficial.

Mild papulopustular

- Topical antibiotics and benzoyl peroxide.
- Topical retinoid or azelaic acid.
- May add oral antibiotics if topical agents are not working (**Figure 96-18**).

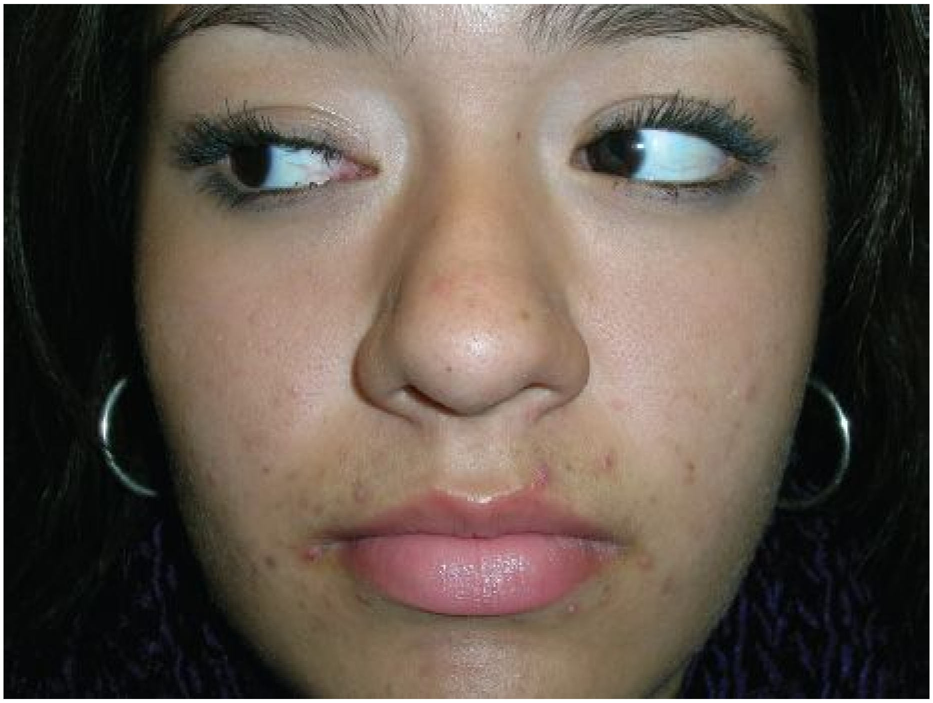

FIGURE 96-18 Mild inflammatory acne failing to fully improve with topical benzyl peroxide and erythromycin. (*Used with permission from Richard P. Usatine, MD.*)

Papulopustular or nodulocystic acne—moderate to severe—inflammatory

- Topical antibiotic, benzoyl peroxide, and oral antibiotic.
- Oral antibiotics are often essential at this stage especially if the trunk is involved.
- Topical retinoid or azelaic acid.
- Steroid injection therapy—For painful nodules and cysts.

Severe cystic or scarring acne

- Isotretinoin if there are no contraindications (**Figure 96-19**).

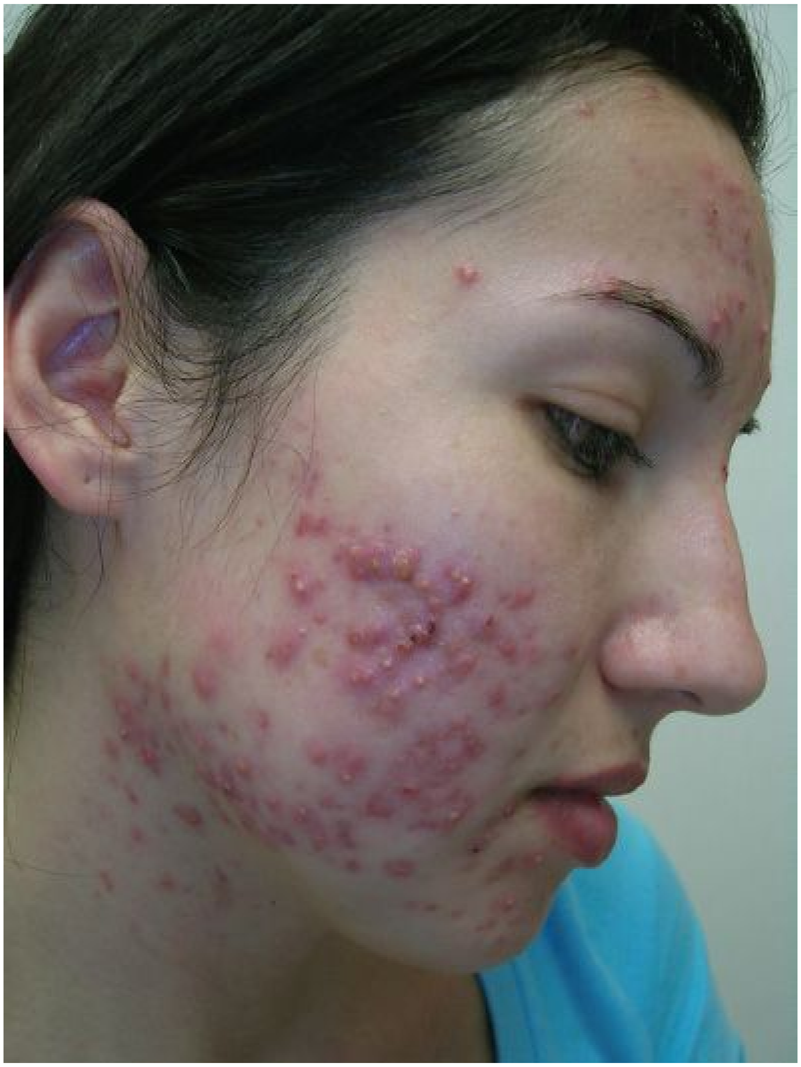

FIGURE 96-19 Severe nodulo-cystic acne in a 17-year-old teen prior to starting oral isotretinoin therapy. (*Used with permission from Richard P. Usatine, MD.*)

- Steroid injection therapy—For painful nodules and cysts.

Acne fulminans (Figures 96-10 and 96-11)

- Start with systemic steroids (prednisone 40 to 60 mg/day—Approximately 1 mg/kg per day).[12] SOR Ⓒ
- Systemic steroid treatment rapidly controls the skin lesions and systemic symptoms. The duration of steroid treatment in one Finnish series was 2 to 4 months to avoid relapses.[12] SOR Ⓒ

- Therapy with isotretinoin, antibiotics, or both was often combined with steroids, but the role of these agents is still uncertain.[12] SOR Ⓒ
- One British series used oral prednisolone 0.5 to 1 mg/kg daily for 4 to 6 weeks (thereafter slowly reduced to zero).[13] SOR Ⓒ
- Oral isotretinoin was added to the regimen at the fourth week, initially at 0.5 mg/kg daily and gradually increased to achieve complete clearance.[13] SOR Ⓒ
- Consider introducing isotretinoin at approximately 4 weeks into the oral prednisone if there are no contraindications. SOR Ⓒ

Acne conglobata (**Figures 96-8** and **96-9**) may be treated like acne fulminans but the course of oral prednisone does not need to be as long. SOR Ⓒ

COMBINATION THERAPIES

- Combination therapy with multiple topical agents can be more effective than single agents.[3] SOR Ⓑ
- Topical retinoids and topical antibiotics are more effective when used in combination than when either are used alone.[3] SOR Ⓑ
- Benzoyl peroxide and topical antibiotics used in combination are effective treatment for acne by helping to minimize antibiotic resistance.[3] SOR Ⓑ
- The adjunctive use of clindamycin/benzoyl peroxide gel with tazarotene cream promotes greater efficacy and may also enhance tolerability.[14]
- Combination therapy with topical retinoids and oral antibiotics can be helpful at the start of acne therapy. However, maintenance therapy with combination tazarotene and minocycline therapy showed a trend for greater efficacy but no statistical significance versus tazarotene alone.[15]

MEDICATION COST

The most affordable medications for acne include topical benzoyl peroxide, erythromycin, clindamycin, and oral tetracycline and doxycycline. The most expensive acne medications are the newest brand-name combination products of existing topical medication. These medications are convenient for those with insurance that covers them (Epiduo contains benzoyl peroxide and adapalene; Ziana contains clindamycin and tretinoin).

NEWER EXPENSIVE MODES OF THERAPY

Intense pulsed light and photodynamic therapy (PDT) use lasers, special lights, and topical chemicals to treat acne.[16–18] These therapies are very expensive and the data do not suggest that these should be first-line therapies at this time. Light and laser treatments have been shown to be of short-term benefit if patients can afford therapy and tolerate some discomfort. These therapies have not been shown to be better than simple topical treatments.[2]

One comparative trial demonstrated that PDT was less effective than topical adapalene in the short-term reduction of inflammatory lesions.[2]

FOLLOW-UP

Isotretinoin requires monthly follow-up visits but other therapies can be monitored every few months at first and then once to twice a year. Keep in mind that many treatments for acne take months to work, so quick follow-up visits may be disappointing.

PATIENT EDUCATION

Adherence with medication regimens is crucial to the success of the therapy. Adequate face washing twice a day is sufficient. Do not scrub the face with abrasive physical or chemical agents. If benzoyl peroxide is not being used as a leave-on product, it can be purchased to use for face washing.

97 ROSACEA

Richard P. Usatine, MD

PATIENT STORY

A 14-year-old girl presents with a red face and a history of easy facial flushing over the last two years (**Figure 97-1**). Her face has become persistently redder and she would like some treatment.

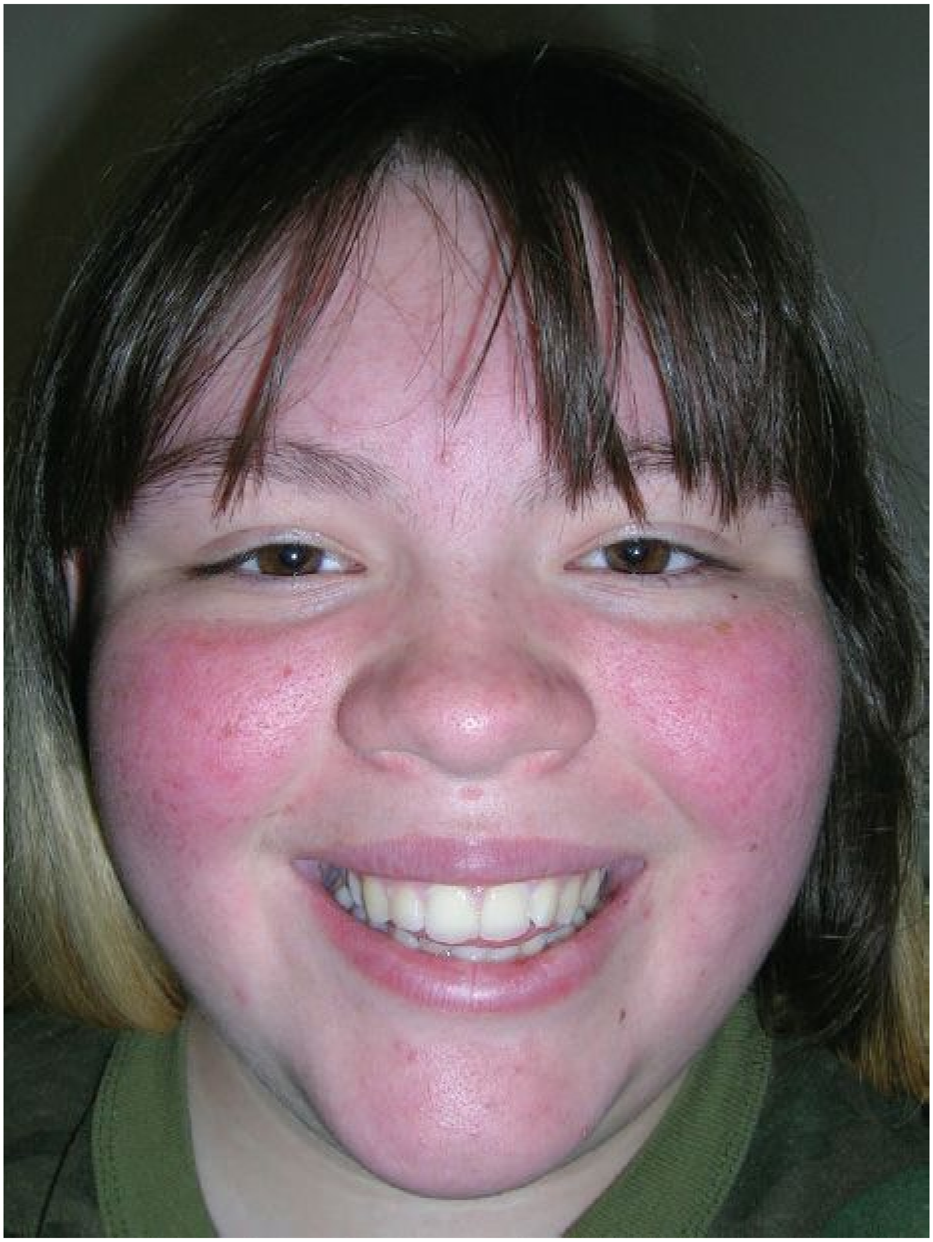

FIGURE 97-1 Rosacea in a 14-year-old girl showing erythema and papules. (*Used with permission from Richard P. Usatine, MD.*)

Her mom is in the room and has similar redness in her face. The family is from northern European heritage. The girl also has developed some “pimples.” Physical examination reveals some papules and erythema. No comedones are seen. She knows that the sun makes it worse but finds that many sunscreens are irritating to her skin. The patient is started on 0.75 percent metronidazole gel once daily. She agrees to wear a hat and stay out of the sun during the middle of the day. She will continue to look for a sunscreen she can tolerate. She knows that precipitating factors for her include hot and humid weather, alcohol, hot beverages, and spicy foods.

INTRODUCTION

Rosacea is an inflammatory condition of the face and eyes that mostly affects adults but can start in childhood. Most commonly the face becomes reddened over the cheeks and nose and this is often accompanied by telangiectasias and a papulopustular eruption (**Figures 97-2** and **97-3**).

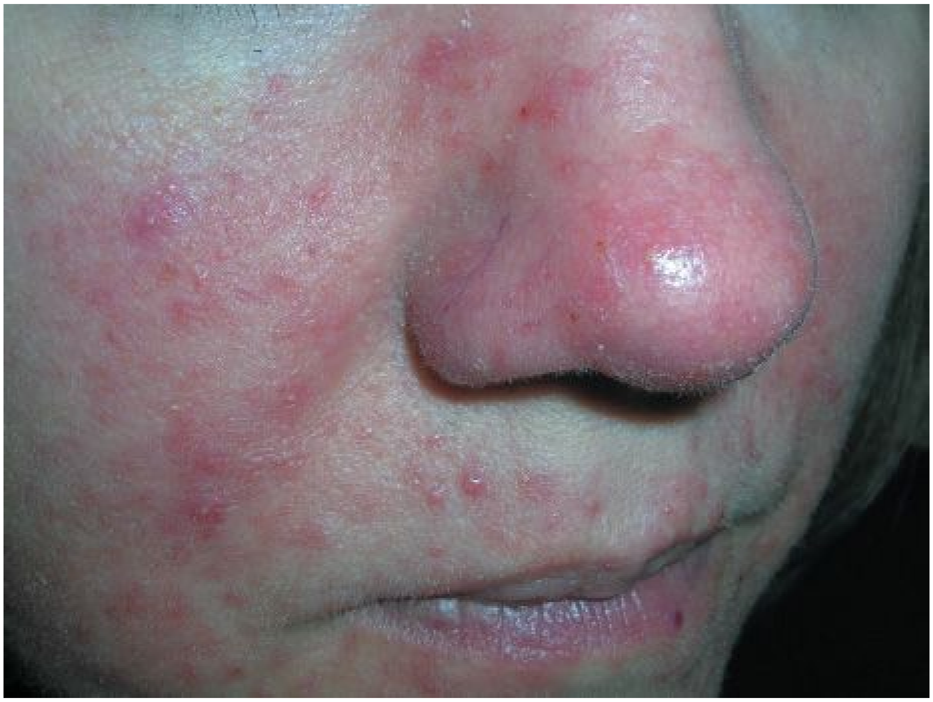

FIGURE 97-2 Close-up of papules and pustules in a young woman with rosacea. Note the absence of comedones. This is not acne. This is papulopustular rosacea. (*Used with permission from Richard P. Usatine, MD.*)

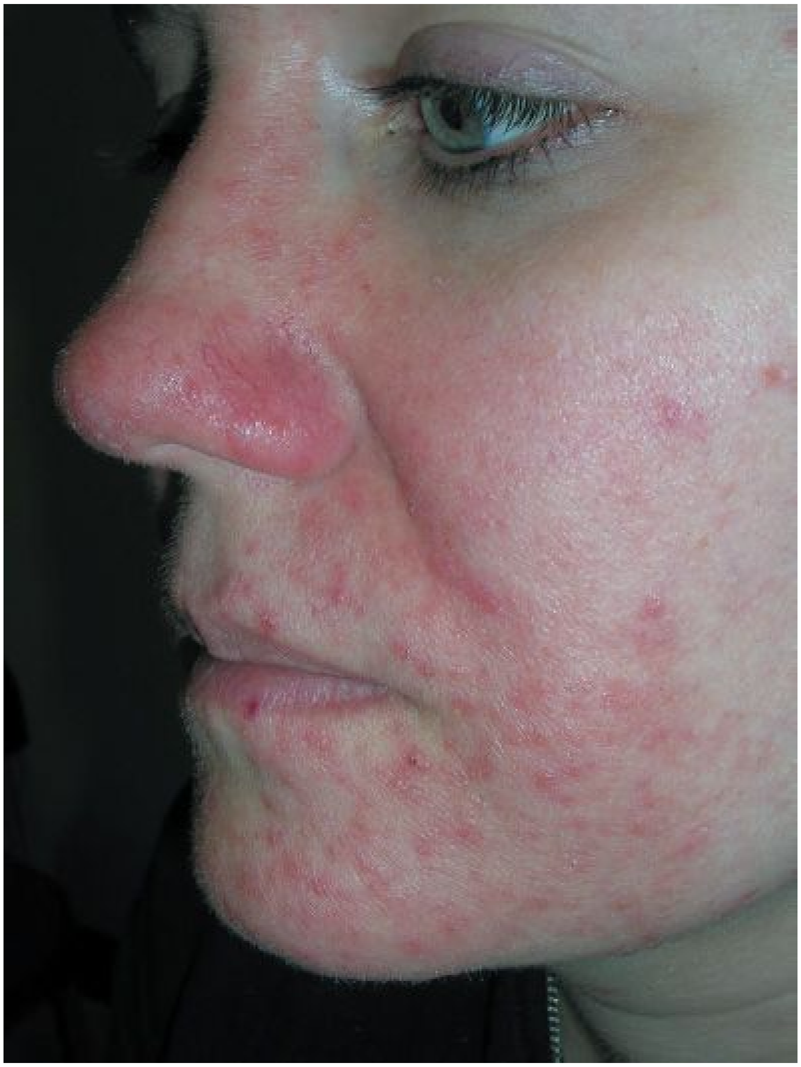

FIGURE 97-3 Close-up showing telangiectasias on the nose and papules around the mouth and chin. (*Used with permission from Richard P. Usatine, MD.*)

SYNONYMS

Rosacea is also called acne rosacea.

EPIDEMIOLOGY

- Common in fair-skinned people of Celtic and northern European heritage.
- Women and girls are more often affected than men and boys.
- Men are more prone to the extreme forms of hyperplasia, which causes rhinophymatous rosacea. However, even young women can have rhinophymatous rosacea. (**Figure 97-4**).

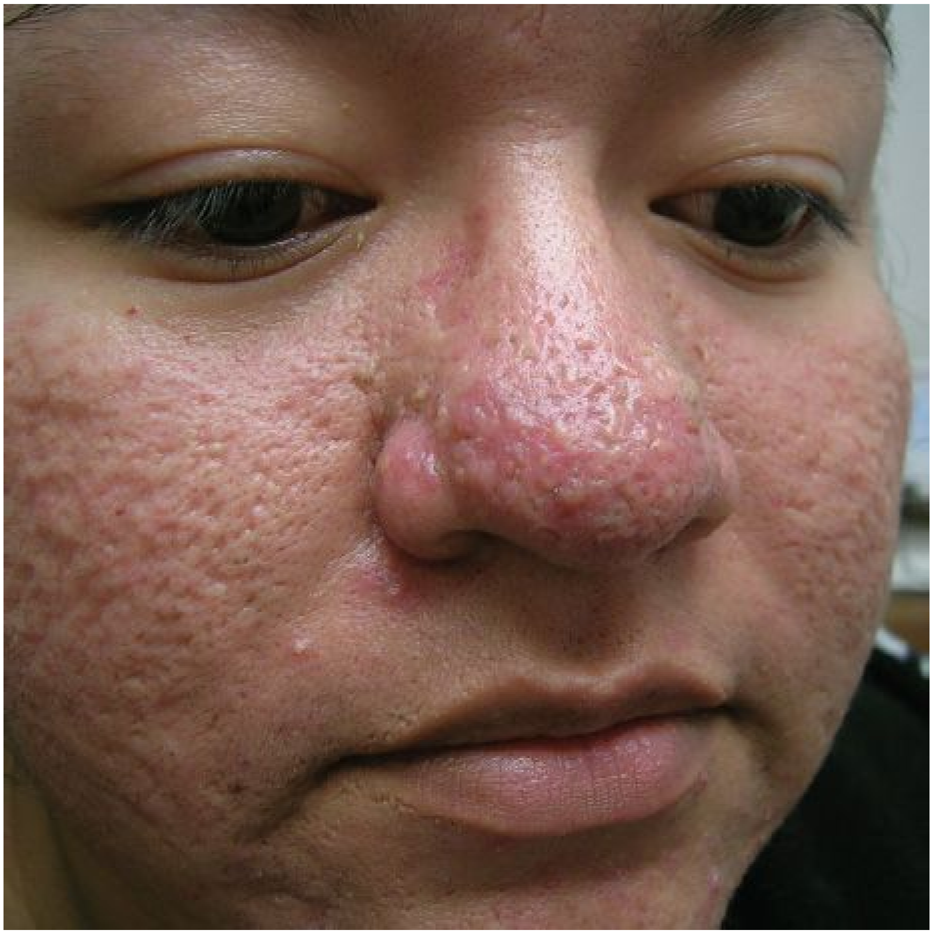

FIGURE 97-4 Rhinophymatous rosacea with hypertrophy of the skin of the nose of a young woman with acne scarring from adolescence. The patient denies heavy alcohol intake. This type of rosacea is very rare in children. (*Used with permission from Richard P. Usatine, MD.*)

ETIOLOGY AND PATHOPHYSIOLOGY

- Although the exact etiology is unknown, the pathophysiology involves nonspecific inflammation followed by dilation around follicles and hyperreactive capillaries. These dilated capillaries become telangiectasias (**Figures 97-5**).

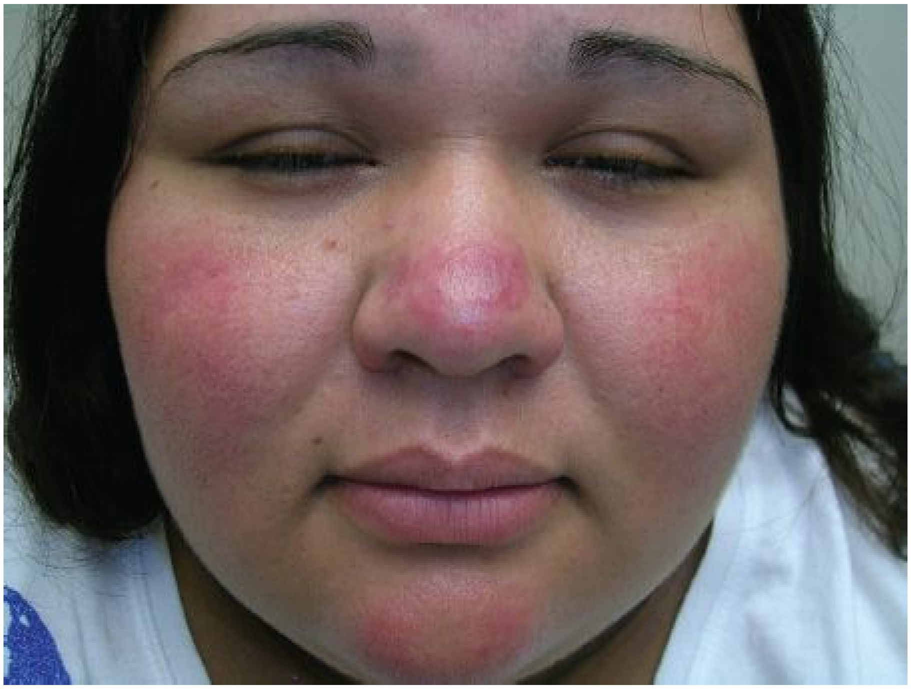

FIGURE 97-5 Erythematotelangiectatic subtype of rosacea in a Hispanic girl. (*Used with permission from Richard P. Usatine, MD.*)

- As rosacea progresses, diffuse hypertrophy of the connective tissue and sebaceous glands ensues (**Figure 97-4**).
- Alcohol may accentuate erythema, but does not cause the disease. Rosacea runs in families.
- Sun exposure may precipitate an acute rosacea flare, but flare-ups can happen without sun exposure.
- A significant increase in the hair follicle mite *Demodex folliculorum* is sometimes found in rosacea.[1] It is theorized that these mites play a role because they incite an inflammatory or allergic reaction by mechanical blockage of follicles.

RISK FACTORS

Genetics, *Demodex* infestation,[1] sun exposure.

DIAGNOSIS

CLINICAL FEATURES

Rosacea has four stages or subtypes:

1. *Erythematotelangiectatic rosacea* (**Figure 97-5**)—This stage is characterized by frequent mild to severe flushing with persistent central facial erythema.
2. *Papulopustular rosacea* (**Figure 97-6**)—This is a highly vascular stage that involves longer periods of flushing than the first stage, often lasting from days to weeks. Minute telangiectasias and papules start to form by this stage, and some patients begin having very mild ocular complaints such as ocular grittiness or conjunctivitis. These patients may have many unsightly pustules with severe facial erythema. They are more prone to develop a hordeolum (stye) (see Chapter 10, Hordeolum and Chalazion).

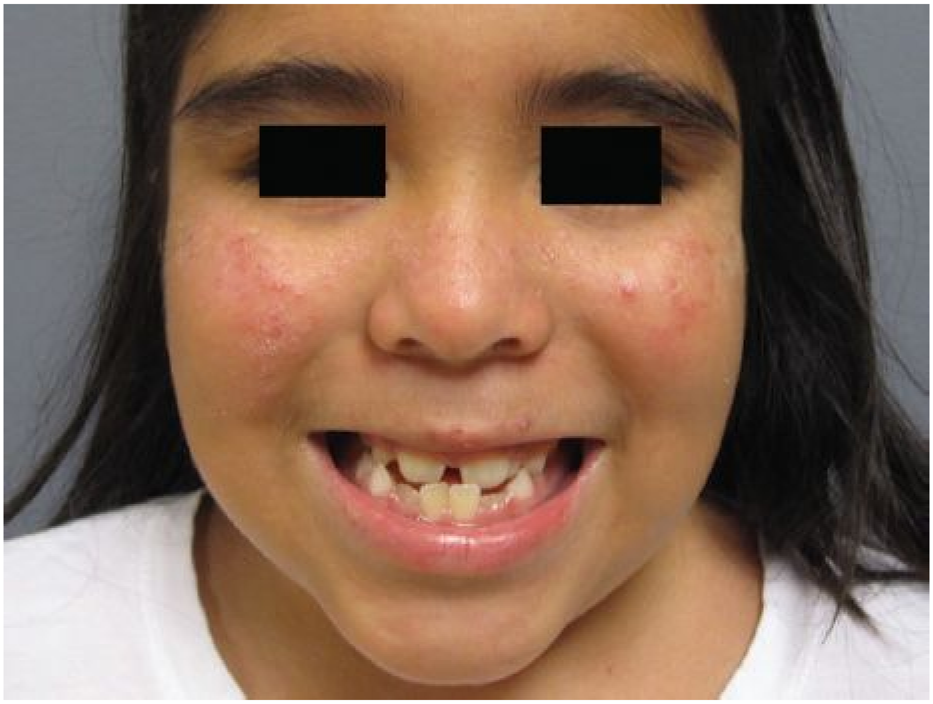

FIGURE 97-6 Papulopustular rosacea in a young girl. (*Used with permission from Jennifer Krejci-Manwaring, MD.*)

3. *Phymatous or Rhinophymatous rosacea* (**Figure 97-4**)—Characterized by hyperplasia of the sebaceous glands that form thickened confluent plaques on the nose known as rhinophyma. This hyperplasia can cause significant disfigurement to the forehead, eyelids, chin, and nose. The nasal disfiguration is seen more commonly in men than women. W. C. Fields is famous for his rhinophyma and intake of alcohol. Rhinophyma can occur without any alcohol use.
4. *Ocular rosacea* (**Figures 97-7** and **97-8**)—An advanced subtype of rosacea that is characterized by impressive, severe flushing with persistent telangiectasias, papules, and pustules. The patient may complain of watery eyes, a foreign-body sensation, burning, dryness, vision changes, and lid or periocular erythema. The eyelids are most commonly involved with telangiectasias, blepharitis, and recurrent hordeola and chalazia (**Figure 97-7**). Conjunctivitis may be chronic. Although corneal involvement is least common, it can have the most devastating consequences. Corneal findings may include punctate erosions, corneal infiltrates, and corneal neovascularization. In the

most severe cases, blood vessels may grow over the cornea and lead to blindness (**Figure 97-8**).

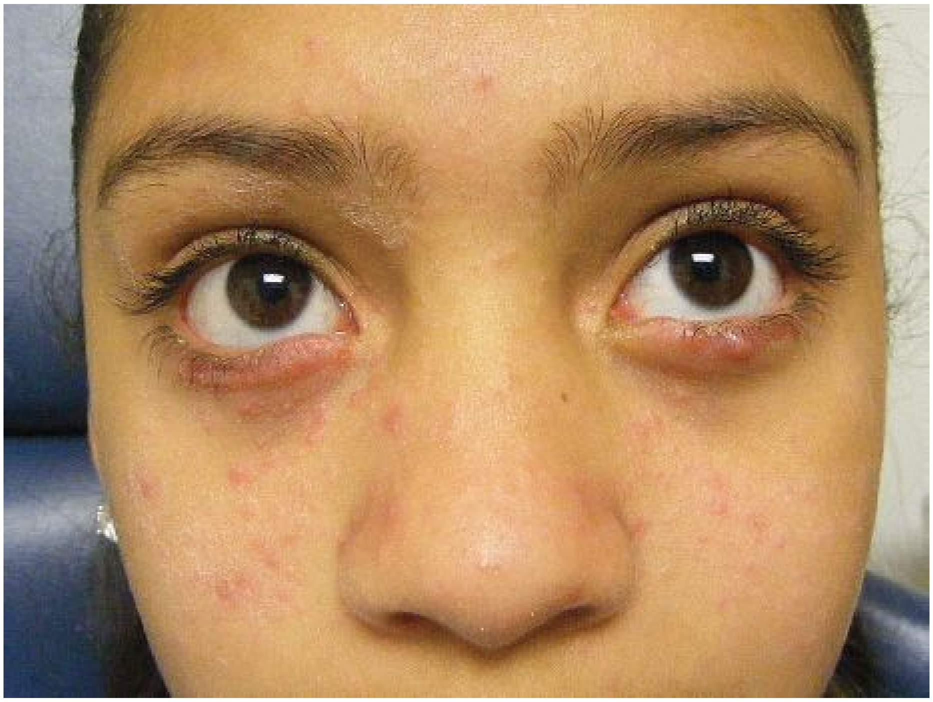

FIGURE 97-7 Ocular rosacea in an 11-year-old girl showing blepharitis, conjunctival hyperemia, and telangiectasias of the lid. (*Used with permission from Lewis Rose, MD.*)

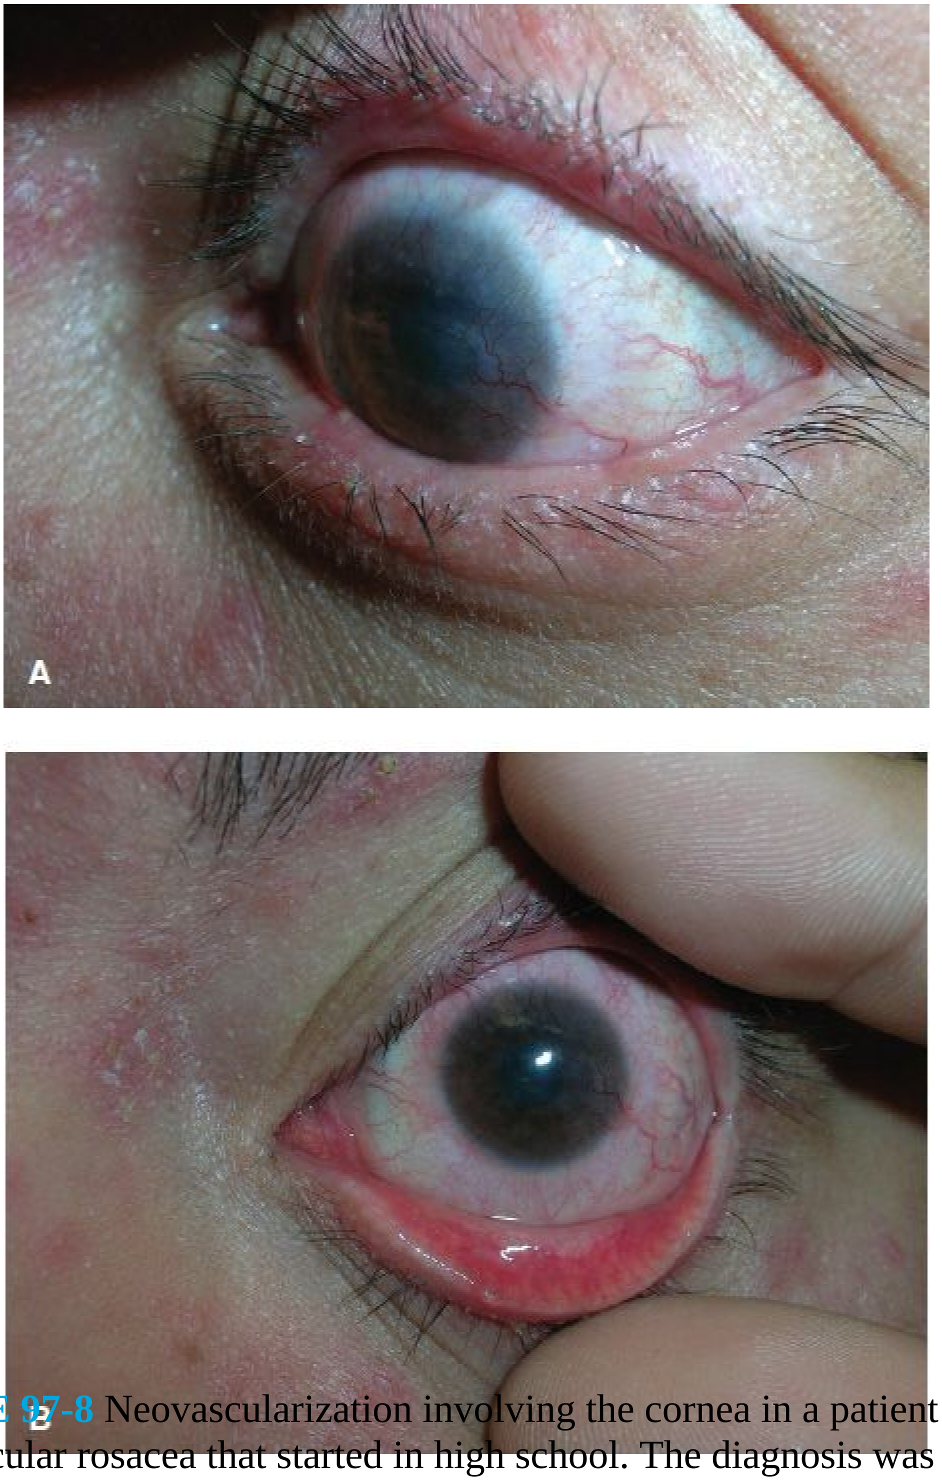

FIGURE 97-8 Neovascularization involving the cornea in a patient with severe ocular rosacea that started in high school. The diagnosis was missed for years and the corneal clouding diminishes her vision. **A.** Side view. **B.** Front view. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

Rosacea occurs on the face, especially on the cheeks and nose. However, the forehead, eyelids, and chin can also be involved.

LABORATORY STUDIES

Not needed when the clinical picture is clear. If you are considering lupus or sarcoid, an antinuclear antibody (ANA), chest x-ray, or punch biopsy may be needed (**Figure 97-9**).

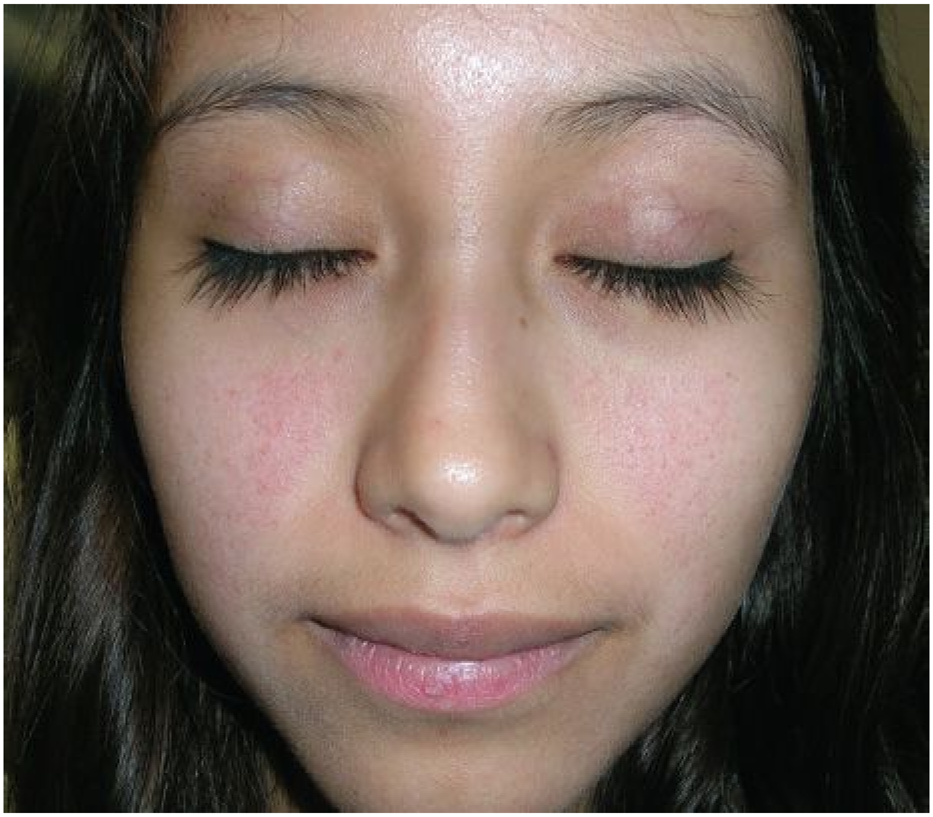

FIGURE 97-9 Biopsy proven rosacea in a 15-year-old girl. The red rash on her cheeks had been present for one year and had not responded to empirical therapy. The butterfly distribution of the rash and the lack of classic rosacea features led the physician to perform a punch biopsy to establish a definitive diagnosis and rule out lupus. (*Used with permission from Richard P. Usatine, MD.*)

DIFFERENTIAL DIAGNOSIS

- Acne—The age of onset for rosacea tends to be 30 to 50 years, much later than the onset for acne vulgaris. Comedones are prominent in most cases of acne and generally absent in rosacea (see Chapter 96, Acne Vulgaris).
- Sarcoidosis on the face is much less common than rosacea, but the inflamed plaques can be red and resemble the inflammation of rosacea (see Chapter 150, Sarcoidosis).
- Seborrheic dermatitis tends to produce scale, whereas rosacea does not. Although both cause central facial erythema, papules and telangiectasias are present in rosacea and are not part of seborrheic dermatitis (see Chapter 135, Seborrheic Dermatitis).
- Systemic lupus erythematosus (SLE) can be scarring, does not usually produce papules or pustules, and it spares the nasolabial folds and nose (see Chapter 173, Lupus: Systemic and Cutaneous). The patient in **Figure 97-9** has a butterfly distribution of her rosacea, but her biopsy clearly demonstrated the histology of rosacea.

The following three diagnoses were once considered variants of rosacea but a recent classification system identified these as separate entities:[2]

- Rosacea fulminans (known as pyoderma faciale) is characterized by the sudden appearance of papules, pustules, and nodules, along with fluctuating and draining sinuses that may be interconnecting. The condition appears primarily in women in their 20s, and intense redness and edema also may be prominent.[2]
- Steroid-induced acneiform eruption is not a variant of rosacea and can occur as an inflammatory response in any patient during or after chronic corticosteroid use. The same inflammatory response may also occur in patients with rosacea.
- Perioral dermatitis without rosacea symptoms should not be classified as a variant of rosacea. Perioral dermatitis is characterized by microvesicles, scaling, and peeling around the mouth (**Figure 97-10**). Perioraficial dermatitis is the same condition but may involve the skin around the nares and eyes (**Figure 97-11**).

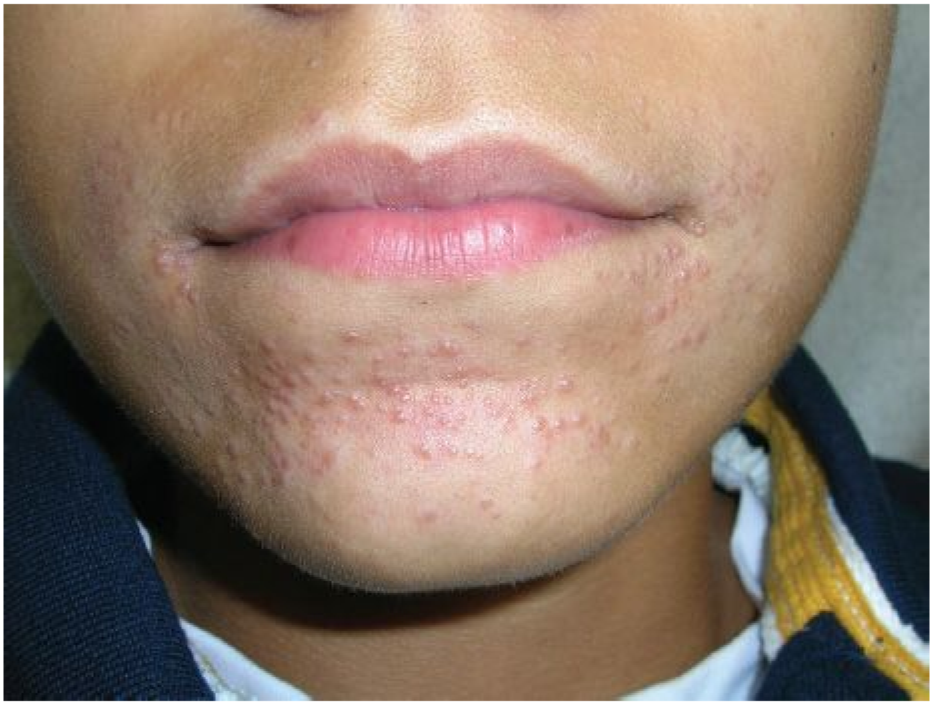

FIGURE 97-10 Perioral dermatitis in this 13-year-old boy with microvesicles, scaling, and peeling around the mouth. (*Used with permission from Richard P. Usatine, MD.*)

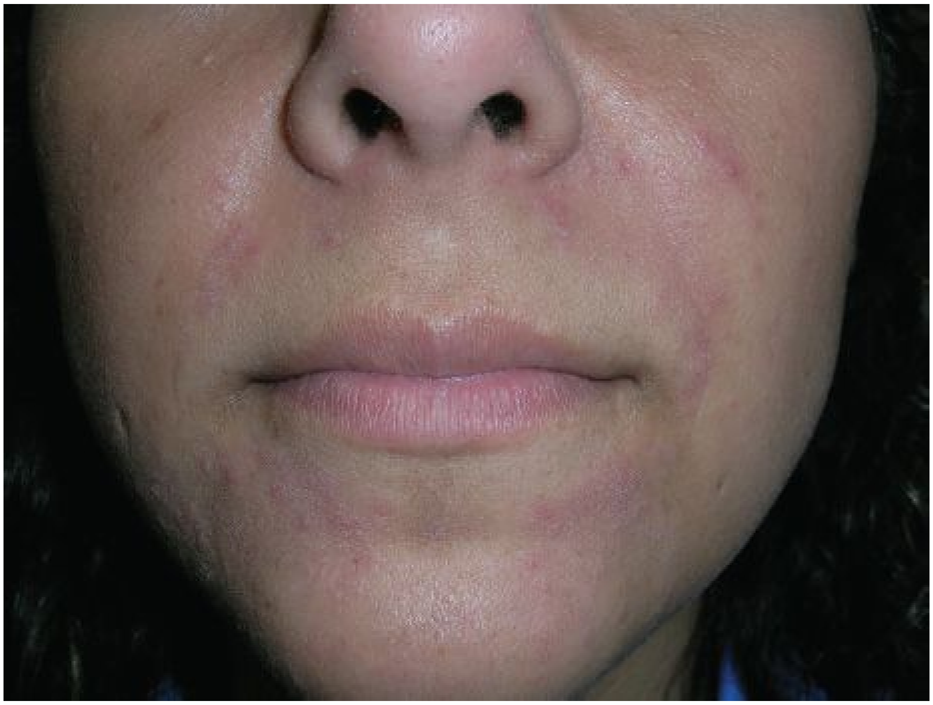

FIGURE 97-11 Perioraficial dermatitis in a teenage girl with papules, scale and erythema around the mouth and nares. Note that there are no comedones as seen with acne. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

- A Cochrane Database systematic review examined the efficacy of rosacea interventions.[3] Oral doxycycline appeared to be significantly more effective than placebo and there was no statistically significant difference in effectiveness between the 100-mg and 40-mg doses.[3] SOR Ⓐ They found some evidence to support the effectiveness of topical metronidazole (0.75% or 1%), azelaic acid (15% or 20%) for the treatment of moderate to severe rosacea.[3] SOR Ⓐ Cyclosporine ophthalmic emulsion was significantly more effective than artificial tears for treating ocular rosacea (for all outcomes).[3] SOR Ⓐ
- When there are a limited number of papules and pustules, start with topical metronidazole (0.75% or 1%) or topical azelaic acid (15% or 20%).[3]
  - There are no substantial differences between topical metronidazole of 0.75 percent and 1 percent, or between once daily and twice daily regimens.[4] Metronidazole cream, gel, and lotion have similar efficacies as well.[4]
- Azelaic acid in a 15 percent gel applied bid appeared to offer some modest benefits over 0.75 percent metronidazole gel in a manufacturer-sponsored study.[4] Azelaic acid was not as well tolerated, so both medications are reasonable options with the choice depending on patient preference and tolerance.[3] SOR Ⓑ One study found that once-daily azelaic acid 15 percent gel was as effective as twice-daily application, which can translate into a significant cost saving.[5]
- If the skin lesions are more extensive, oral antibiotics, such as doxycycline (40 mg or 100 mg daily) is recommended.[3] SOR Ⓐ When

attempting to avoid the photosensitivity side effects of doxycycline it is reasonable to prescribe oral tetracycline (250 mg to 500 mg daily) or oral metronidazole (250 mg to 500 mg daily). SOR Ⓒ

- Patients who are started on oral antibiotics alone and improve may be switched to topical agents such as metronidazole or azelaic acid for maintenance.
- The *Demodex* mite may be one causative agent in rosacea. One study found permethrin 5 percent cream to be as effective as metronidazole 0.75 percent gel and superior to placebo in the treatment of rosacea.[5] SOR Ⓑ
- Severe papulopustular disease refractory to antibiotics and topical treatments can be treated with oral isotretinoin at a low dose of 0.3 mg/kg per day.[6] SOR Ⓑ
- Simple electrosurgery or laser without anesthesia can be used to treat the telangiectasias associated with rosacea. SOR Ⓒ
- Rhinophyma can be excised with radiofrequency electrosurgery or laser. Isotretinoin is also used to treat rhinophyma.[6] SOR Ⓑ
- Traditional therapies for mild ocular rosacea include oral tetracyclines, lid hygiene, and warm compresses.[1] SOR Ⓒ Topical ophthalmic cyclosporine 0.05 percent (Restasis) is more effective than artificial tears for the treatment of rosacea-associated lid and corneal changes.[7] SOR Ⓑ Ocular rosacea that involves the cornea should be immediately referred to an ophthalmologist to prevent blindness (**Figure 97-8**).

FOLLOW-UP

Follow-up can be in 1 to 3 months as needed.

PATIENT EDUCATION

Sun protection, including use of a hat and daily application of sunscreen, should be emphasized. Choose a sunscreen that is nonirritating and protects against UVA and UVB rays. Advise patients to keep a diary to identify and avoid precipitating factors such as hot and humid weather, alcohol, hot beverages, spicy foods, and large hot meals.

98 HIDRADENITIS SUPPURATIVA

Richard P. Usatine, MD

PATIENT STORY

A 17-year-old teenager presents with new tender lesions in her axilla that started during her period 2 weeks ago (**Figure 98-1**). She has had two similar outbreaks in the axilla the year before. The clinician determined that the diagnosis was a mild case of hidradenitis suppurativa with folliculitis as an alternative diagnosis to be considered. The patient was started on doxycycline 100 mg twice daily and the condition cleared within 1 month. The patient was also a one pack per day smoker and she agreed to quit smoking for her health and to decrease her risk of further outbreaks of hidradenitis.

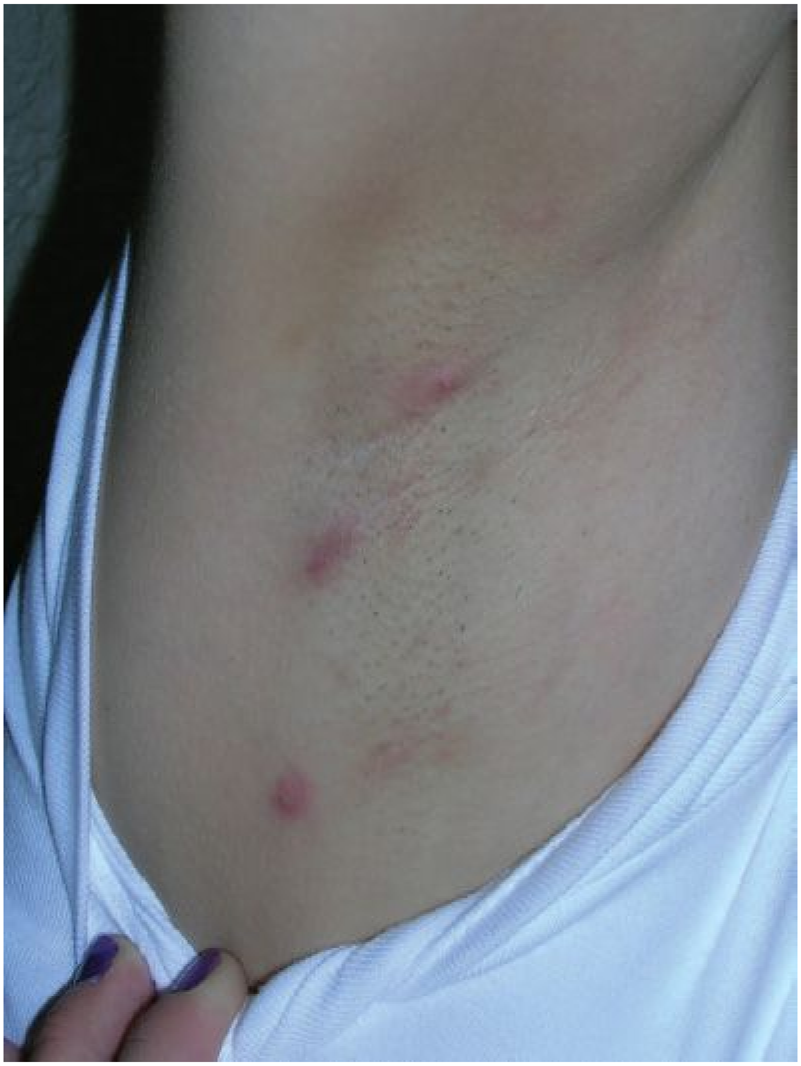

FIGURE 98-1 Mild hidradenitis suppurativa in the axilla. She has a history of recurrent lesions in her axilla. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Hidradenitis suppurativa (HS) is an inflammatory disease of the pilosebaceous unit in the apocrine gland-bearing skin. HS is most common in the axilla and inguinal area, but may be found in the inframammary area as well. It produces painful inflammatory nodules, cysts, and sinus tracks with mucopurulent discharge and progressive scarring.

SYNONYMS

It is called acne inversa because it involves intertriginous areas and not the regions affected by acne (similar to inverse psoriasis).

EPIDEMIOLOGY

- Occurs after puberty in approximately 1 percent of the population.[1]
- Incidence is higher in females, in the range of 4:1 to 5:1. Flare-ups may be associated with menses.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Disorder of the terminal follicular epithelium in the apocrine gland-bearing skin.[1]
- Starts with occlusion of hair follicles that lead to occlusion of surrounding apocrine glands.
- Chronic relapsing inflammation with mucopurulent discharge.
- Can lead to sinus tracts, draining fistulas and progressive scarring.

RISK FACTORS

Obesity, smoking, and tight-fitting clothing.

DIAGNOSIS

CLINICAL FEATURES

- Most common presentation is painful, tender, firm, nodular lesions in axillae (**Figures 98-1** and **98-2**).

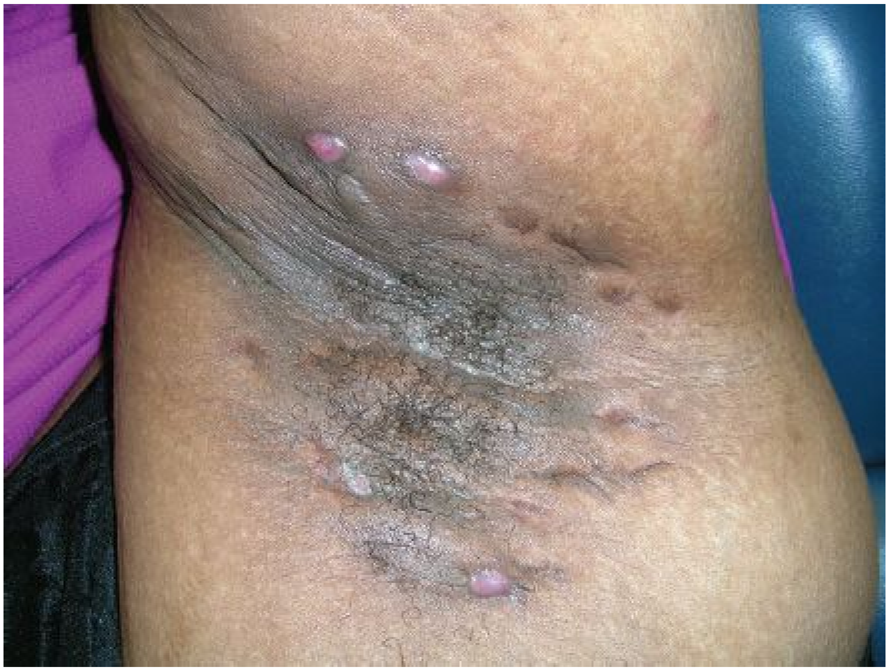

FIGURE 98-2 Hidradenitis in a young woman. The lesions are deeper and there have been some chronic changes with scarring and fibrosis from previous lesions. (*Used with permission from Richard P. Usatine, MD.*)

- Nodules may open and drain pus spontaneously and heal slowly, with or without drainage, over 10 to 30 days.[1]
- Nodules may recur several times yearly, or in severe cases new lesions form as old ones heal.
- Surrounding cellulitis may be present and require systemic antibiotic treatment.

- Chronic recurrences result in thickened sinus tracts, which may become draining fistulas (**Figures 98-3**).

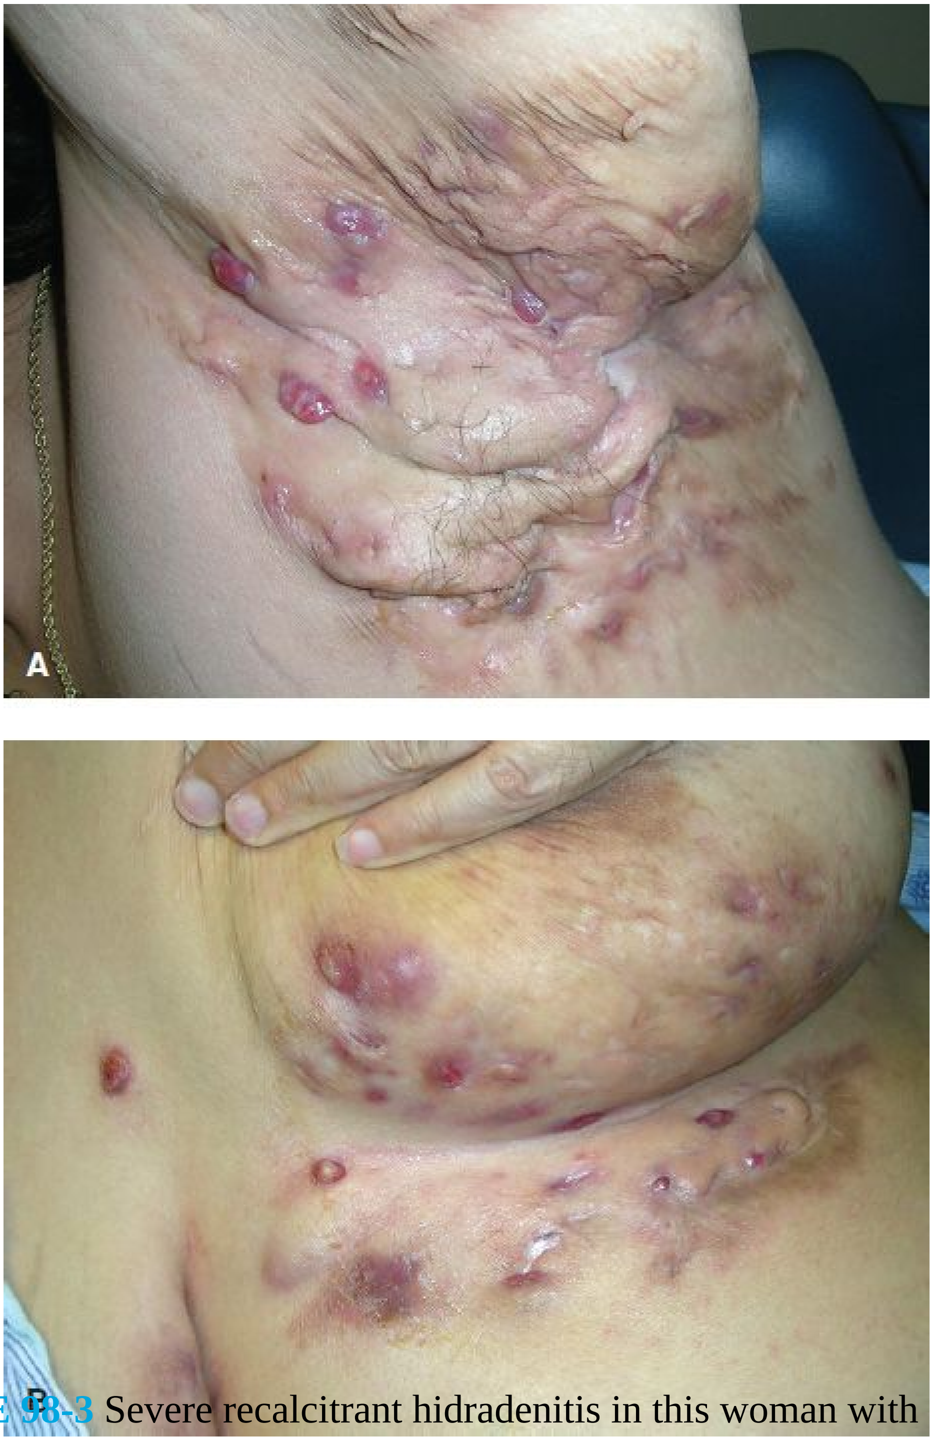

FIGURE 98-3 Severe recalcitrant hidradenitis in this woman with sinus tracts and scarring. **A.** Axillary involvement. **B.** Inframammary involvement. (*Used with permission from Richard P. Usatine, MD.*)

- HS can cause disabling pain, diminished range of motion, and social isolation.

TYPICAL DISTRIBUTION

- Axillary, inguinal, periareolar, intermammary (**Figure 98-4**), inframammary, pubic area (**Figure 98-5**), infraumbilical midline, gluteal folds, top of the anterior thighs, and the perianal region.[1]

(*Used with permission from Richard P. Usatine, MD.*)

LABORATORY STUDIES

Culture of purulence is likely to yield staphylococci and streptococci and is usually unnecessary to determine treatment. Culture may be useful if you suspect methicillin-resistant *Staphylococcus aureus*.

DIFFERENTIAL DIAGNOSIS

- Bacterial infections, including folliculitis, carbuncles, furuncles, abscess, and cellulitis, may resemble HS but are less likely to be recurrent in the intertriginous areas.
- Epidermal cysts in the intertriginous regions may resemble HS. Theses cysts contain malodorous keratin contents.
- Granuloma inguinale and lymphogranuloma venereum are sexually transmitted infections that can produce inguinal ulcers and adenopathy that could be mistaken for HS.

MANAGEMENT

- Lifestyle changes are recommended, including weight loss if obesity is present. SOR Ⓒ
- Smoking is a risk factor for HS and cessation is highly recommended for many reasons.[1] See SOR Ⓑ for HS and SOR Ⓐ for other health reasons.
- Frequent bathing and wearing loose-fitting clothing may help.

Medical treatment is similar to acne treatment:

- Oral antibiotics are used in acute and chronic treatment. Oral tetracyclines, clindamycin, rifampin, and dapsone have been touted as beneficial. If there is methicillin-resistant *S. aureus* present, trimethoprim/sulfamethoxazole or clindamycin should be used.

- Doxycycline 100 mg bid can be used acutely and to prevent new lesions in the mildest of cases. Many patients do not find these antibiotics to be of great help. SOR Ⓒ
- Topical clindamycin bid may be used in the mildest of cases. In one randomized controlled trial (RCT), systemic therapy with tetracyclines did not show better results than topical therapy with clindamycin.[1] SOR Ⓑ
    - Combination of systemic clindamycin (300 mg twice daily) and rifampin (600 mg daily) is recommended for patients with more severe HS.[2,3] In a series of 116 patients, parameters of severity improved, as did the quality-of-life score.[2] In another study, 28 of 34 patients (82%) experienced at least partial improvement, and 16 (47%) showed a total remission.[3] The maximum effect of treatment appeared within 10 weeks. Following total remission, 8 of 13 (61.5%) patients experienced a relapse after a mean period of 5 months. Nonresponders were predominantly patients with severe disease. The most frequent side effect is diarrhea.[2,3]
    - Oral dapsone may be considered when other therapies fail. However, in one study only 38 percent of patients experienced improvement.[4] SOR Ⓑ Rapid recurrence after stopping treatment suggests that antiinflammatory effects may predominate over antimicrobial effects. The total effect appears to be smaller than that reported with combination therapy using clindamycin and rifampicin. The use of oral dapsone requires frequent monitoring of blood counts because it frequently causes hemolysis. A G6PD level should be checked first to make sure the patient is not at high risk for severe hemolysis.
- Isotretinoin can reduce the severity of attacks in some patients but is not a reliable cure for HS.[5] SOR Ⓒ Also it is a potent teratogen and best avoided for females with this indication.
- Acitretin can be an effective treatment for refractory HS. In one study, all 12 patients achieved remission and experienced a significant decrease in pain. Long-lasting improvement was observed in 9 patients, with no recurrence of lesions after 6 months (n = 1), 1 year (n = 3), more than 2 years (n = 2), more than 3 years (n = 2), and more than 4 years (n = 1).[5] SOR Ⓑ However, acitretin is an oral retinoid that causes birth defects and may remain in the body for 3 years. Therefore, it should be reserved for

use in male adolescents only and strictly avoided in females of child-bearing potential.

- Antitumor necrosis factor (TNF) agents are being studied for severe, recalcitrant HS. In one series, infliximab therapy (weight based) was shown to be effective and well tolerated in 6 of 7 patients with HS who were resistant to previous therapy.[6] This was in agreement with preexisting literature showing that 52 of 60 patients (87%) were improved after infliximab therapy.[6] SOR Ⓑ Adalimumab helps in the short-term, but no long-term curative effect was uniformly seen.[7]
- Intense pulsed light (IPL) with laser may be worth considering for patients who can afford the cost and time for treatment. In one study of 18 patients who were randomized to treatment of one axilla, groin, or inframammary area with IPL 2 times per week for 4 weeks, there was a significant improvement in the mean examination score, which was maintained at 12 months. Patients reported high levels of satisfaction with the IPL treatment.[8] SOR Ⓑ

Surgical treatments include the following:

- Intralesional steroids with 5 to 10 mg/mL of triamcinolone may help to decrease inflammation and pain within 24 to 48 hours. SOR Ⓒ
- Incision and drainage of acute lesions are suggested for the large fluctuant abscesses that can occur in HS. Although this may give some relief of the pressure, the surgical treatment and repacking of the wound is painful, and there is no evidence that it speeds healing. SOR Ⓒ
- Lancing small nodules is more painful than helpful and is not recommended.
- Surgical excision of affected area with or without skin grafting is used for recalcitrant disabling disease and should be individualized based on the stage and location of the disease.[9] SOR Ⓑ One surgical group has been using a medial thigh lift for immediate defect closure after radical excision of localized inguinal hidradenitis.[10]

FOLLOW-UP

If there is cellulitis or a large abscess was drained, follow-up should be within days. Chronic relapsing disease can ultimately be managed with appointments every 3 to 6 months depending upon the treatment and its success.

PATIENT EDUCATION

Smoking cessation, weight loss if overweight, and avoidance of tight-fitting clothes.

SECTION 3 BACTERIAL

99 IMPETIGO

Richard P. Usatine, MD

PATIENT STORIES

A young boy presented to the office with a 3-day history of an untreated skin infection on his ear (**Figure 99-1**). His mother states that he has had white spots on his face for the past year but does not know how the ear infection started. The clinician noted honey crusts and purulent drainage from the lower pinna and pityriasis alba on the face. The child was not febrile and was behaving normally. Oral cephalexin was prescribed for the impetigo and 1 percent hydrocortisone ointment was given for the *p. alba*. Washing and hygiene issues were discussed to avoid spreading the infection within the household. During the 1-week follow-up appointment the impetigo was gone and the *p. alba* was improving.

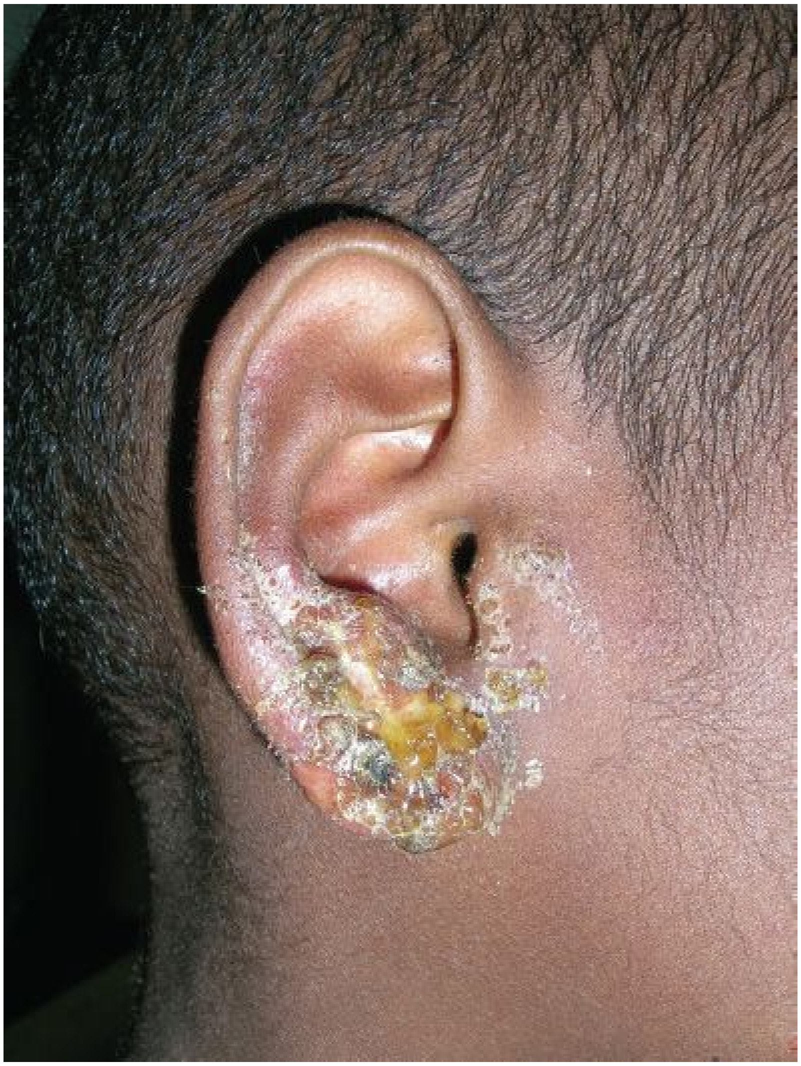

FIGURE 99-1 Typical honey-crusted plaque on the ear of young boy with impetigo. (*Used with permission from Richard P. Usatine, MD.*)

An 11-year-old-child presented with a 5-day history of a skin lesion that started after a hiking trip (**Figure 99-2**). This episode of bullous impetigo was found to be secondary to methicillin-resistant *Staphylococcus aureus* (MRSA). The lesion was rapidly progressive and was developing a surrounding cellulitis. She was admitted to a hospital and treated with intravenous clindamycin with good results.[1]

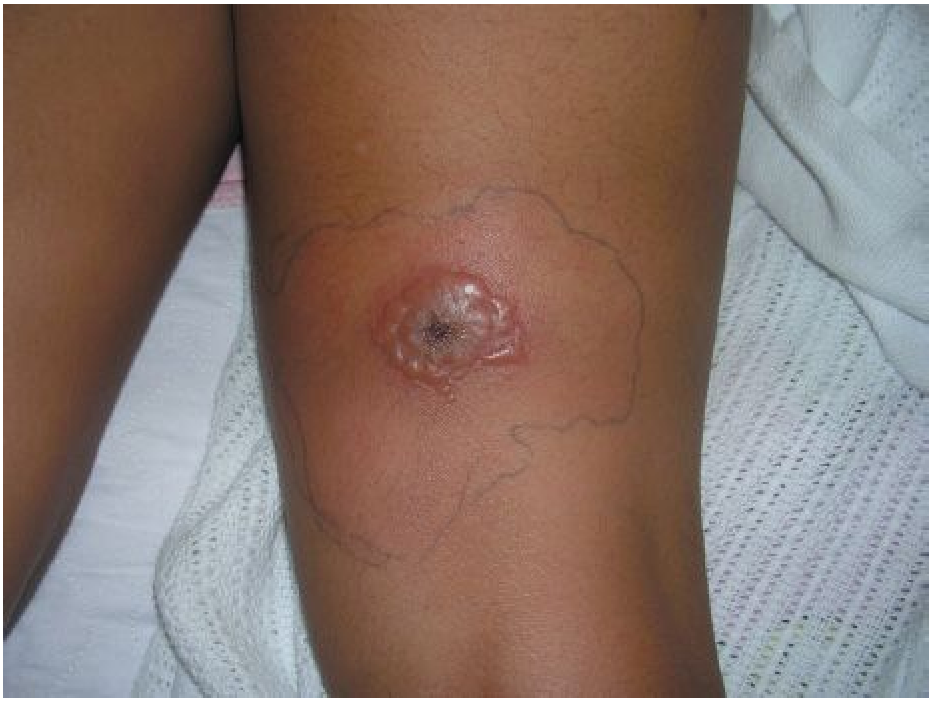

FIGURE 99-2 Bullous impetigo secondary to methicillin-resistant *Staphylococcus aureus* (MRSA) on the leg of an 11-year-old child. Note the surrounding cellulitis. (*With permission from Studdiford J, Stonehouse A. Bullous eruption on the posterior thigh 1. J Fam Pract. 2005;54:1041-1044. Reproduced with permission from Frontline Medical Communications.*)

INTRODUCTION

Impetigo is the most superficial of bacterial skin infections. It causes honey crusts, bullae, and erosions.

EPIDEMIOLOGY

- Most frequent in children ages 2 to 6 years, but it can be seen in patients of any age.

- Common among homeless people living on the streets.
    - Seen often in developing countries in persons living without easy access to clean water and soap.
- Contagious and can be spread within a household.

ETIOLOGY AND PATHOPHYSIOLOGY

- Impetigo is caused by *S. aureus* and/or group A β-hemolytic *Streptococcus* (GABHS).
- Bullous impetigo is almost always caused by *S. aureus* and is less common than the typical crusted impetigo.
- Impetigo may occur after minor skin injury, such as an insect bite, abrasion, or dermatitis.

DIAGNOSIS

CLINICAL FEATURES

- Vesicles, pustules, honey-colored (**Figure 99-1**), brown or dark crusts, erythematous erosions (**Figure 99-3**), ulcers in ecthyma (**Figure 99-4**), and bullae in bullous impetigo (**Figures 99-5** to **99-7**).

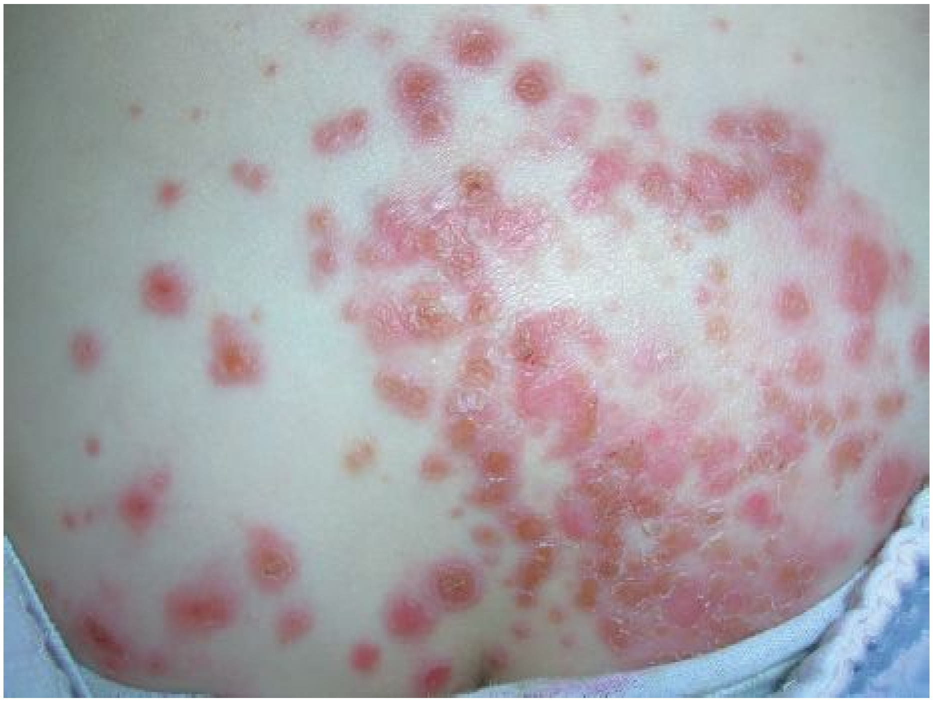

FIGURE 99-3 Widespread impetigo with honey-crusted erythematous lesions on the back of a 7-year-old child. (*Used with permission from Richard P. Usatine, MD.*)

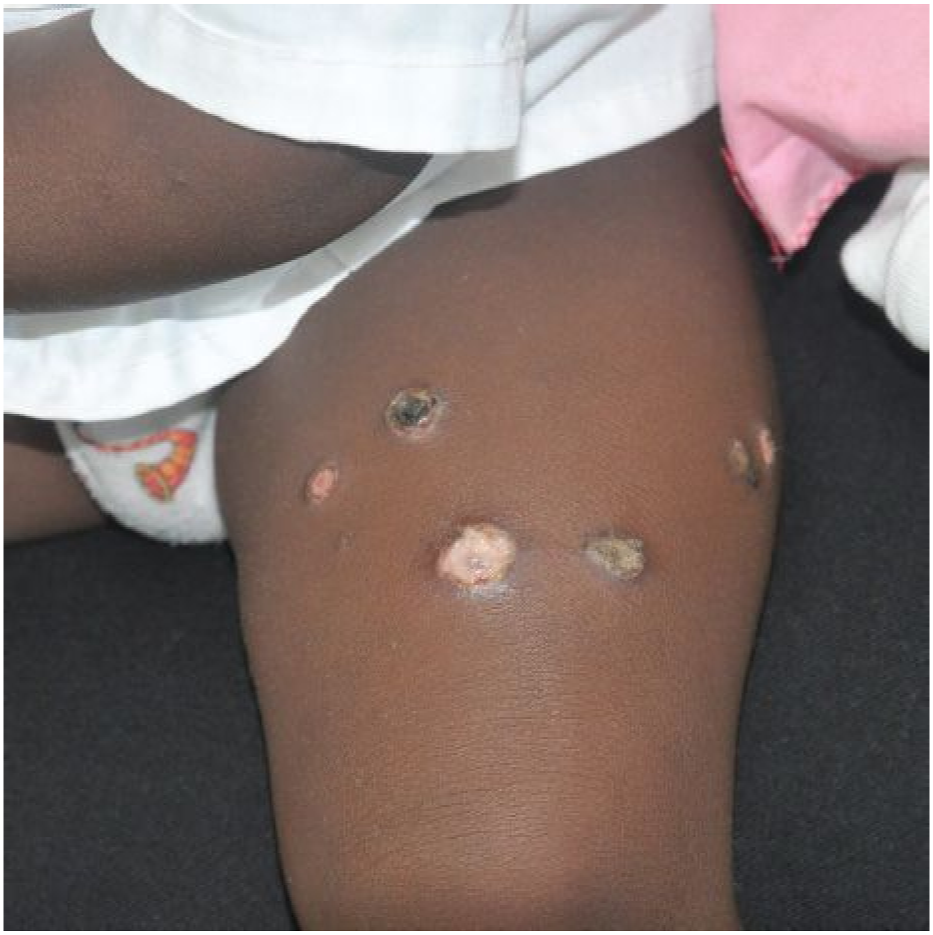

FIGURE 99-4 Impetigo on the leg of a girl in Haiti. Note the ecthyma (ulcerated impetigo) on the mid-thigh. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

- Face (**Figures 99-1**, **99-4** to **99-6**, and **99-8**) is most common, followed by hands, legs (**Figures 99-2** and **99-9**), trunk, and buttocks.

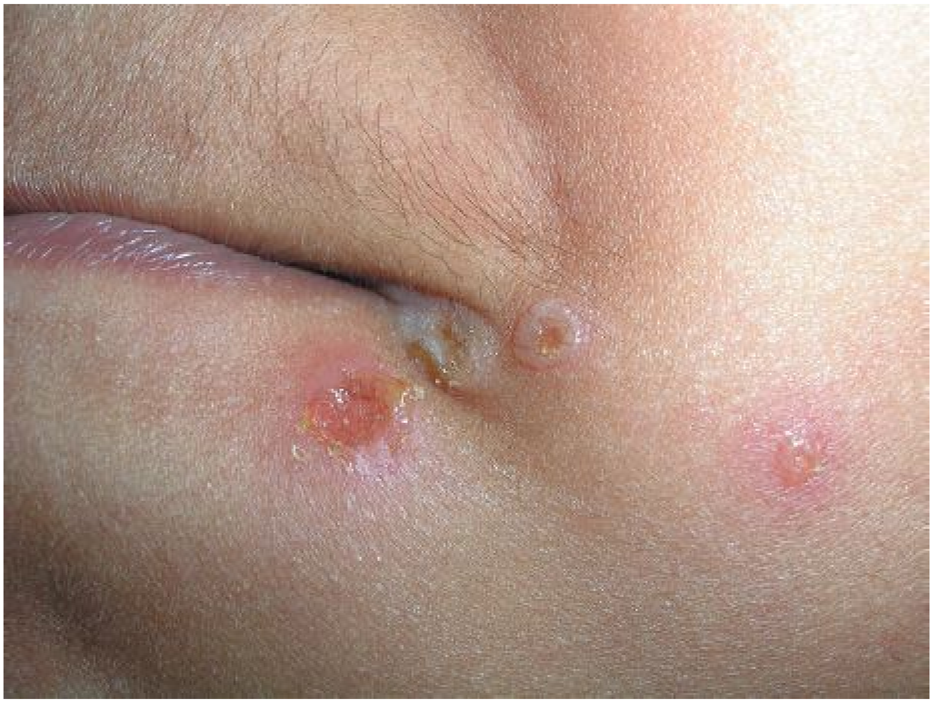

FIGURE 99-5 Bullous impetigo around the mouth of a young boy that progressed to desquamation of the skin on his hands and feet. (*Used with permission from Richard P. Usatine, MD.*)

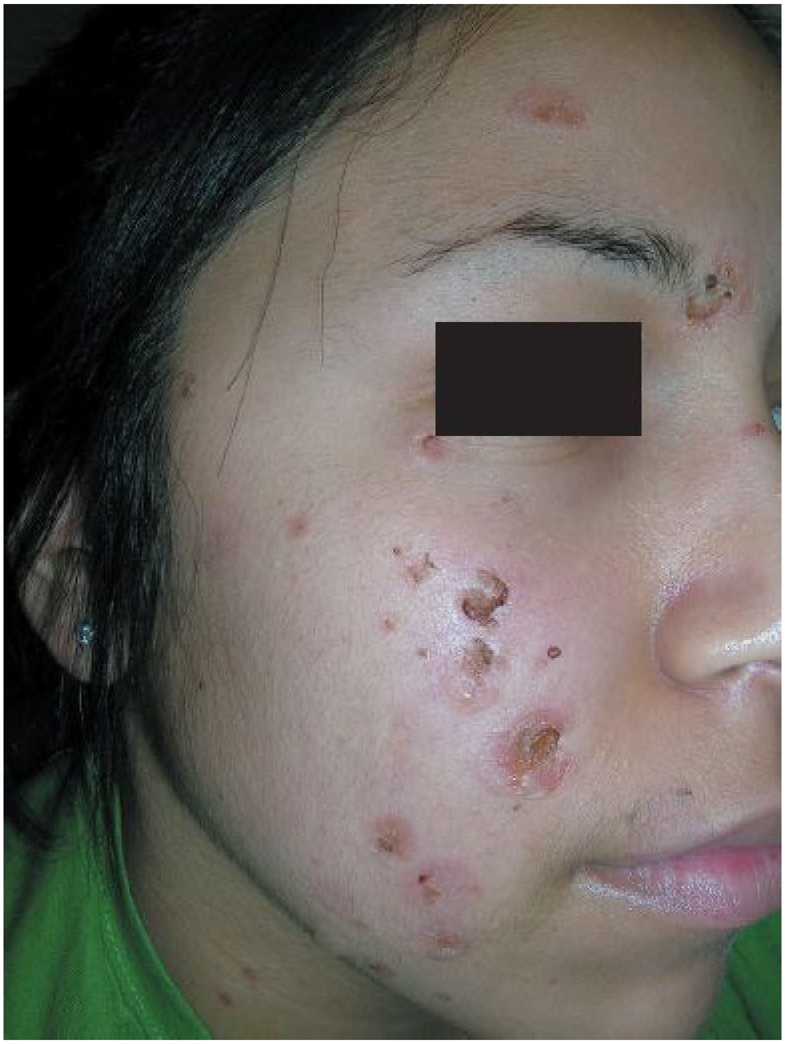

FIGURE 99-6 Bullous impetigo on the face of a 14-year-old girl. Methicillin-resistant *Staphylococcus aureus* was cultured from the impetigo. (*Used with permission from Richard P. Usatine, MD.*)

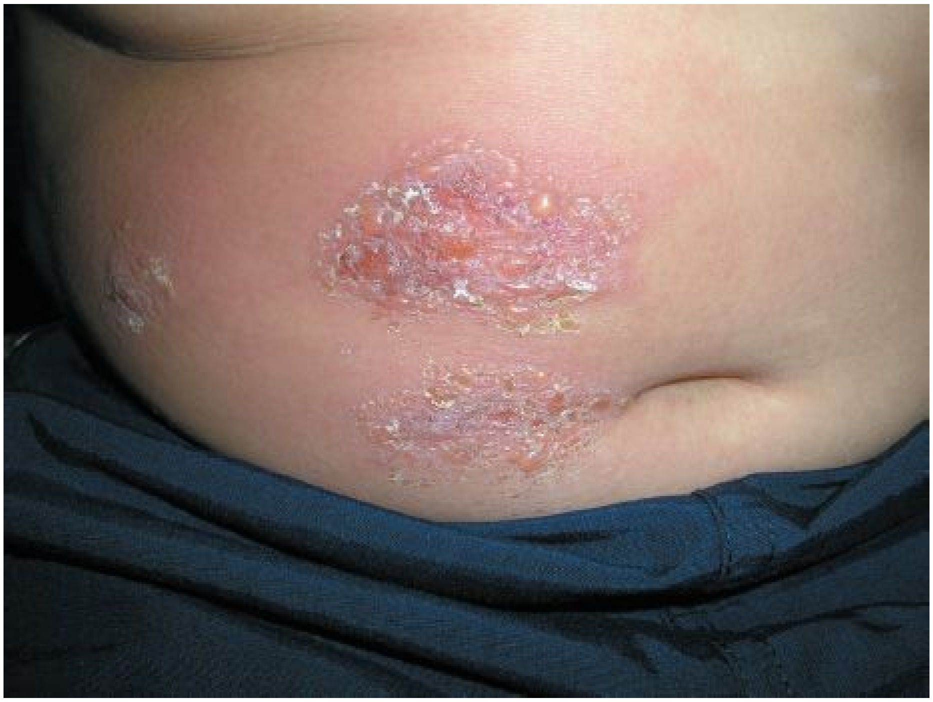

FIGURE 99-7 Bullous impetigo on the abdomen of an 8-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

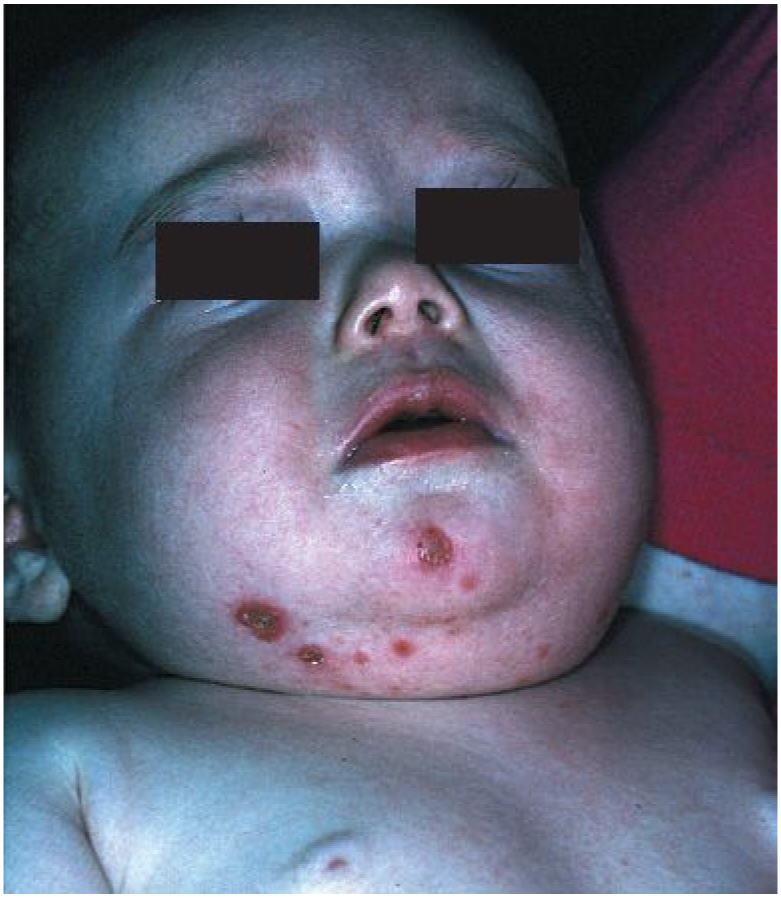

FIGURE 99-8 Impetigo on the face and neck of an infant. (*Used with permission from Richard P. Usatine, MD.*)

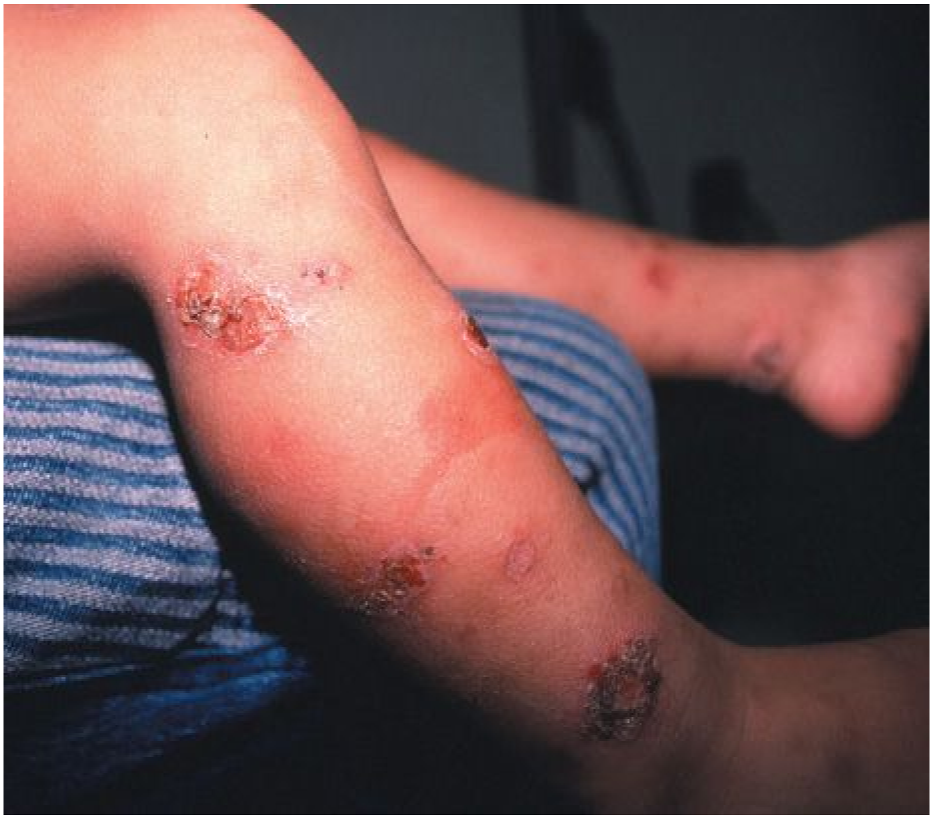

FIGURE 99-9 Impetigo secondary to flea bites on the legs of a young girl. (*Used with permission from Richard P. Usatine, MD. Previously published in the Western Journal of Medicine*.)

CULTURE

- Culture should be considered in severe cases because of the rising incidence of MRSA-causing impetigo.

DIFFERENTIAL DIAGNOSIS

Many of the conditions below can become impetigo after being secondarily infected (**Figures 99-10** and **99-11**) with bacteria. This process is called impetiginization.

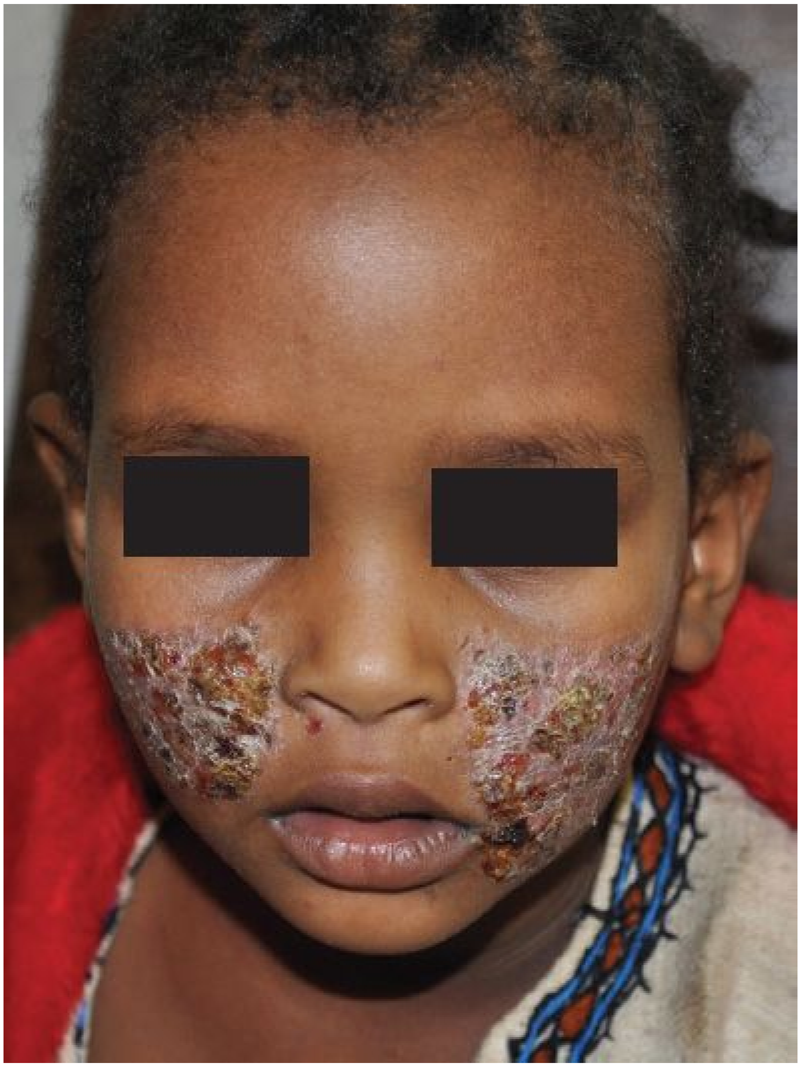

FIGURE 99-10 Atopic dermatitis complicated by secondary impetiginization. (*Used with permission from Richard P. Usatine, MD.*)

- Atopic dermatitis—A common inflammatory skin disorder characterized by itching and inflamed skin. It can become secondarily infected with bacteria (**Figure 99-10**; see Chapter 130, Atopic Dermatitis).
- Herpes simplex virus infection anywhere on the skin or mucous membranes can become secondarily infected (see Chapter 114, Herpes Simplex).
- Eczema herpeticum is eczema superinfected with herpes rather than bacteria (see Chapter 132, Eczema Herpeticum).

- Scabies—Pruritic contagious disease caused by a mite that burrows in skin (see Chapter 128, Scabies).
- Folliculitis—Inflammation and/or infection of hair follicles that may be bacterial (see Chapter 100, Folliculitis).
- Tinea corporis—A cutaneous fungal infection caused by dermatophytes, frequently with ring-like scale (see Chapter 123, Tinea Corporis).
- Varicella or Zoster forms vesicles and bullae that can resemble bullous impetigo. See **Figure 99-11** for a case of bullous impetigo that resembles zoster (see Chapters 108 and 109, Chickenpox and Zoster).

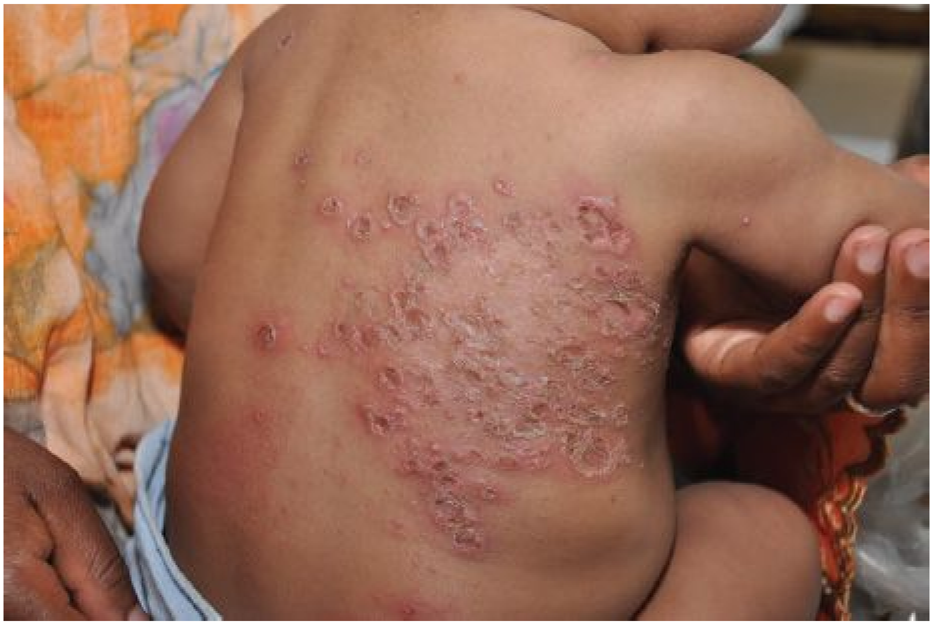

FIGURE 99-11 Bullous impetigo on the trunk of a 6-month-old Ethiopian child that resembles herpes zoster in its distribution and morphology. However, there are lesions on both sides of the back and the child is very young to have had varicella and now zoster. (*Used with permission from Richard P. Usatine, MD.*)

- Bullous disease of childhood—An autoimmune condition with multiple tense bullae that can form rosette-like rings (see Chapter 155, Chronic Bullous Disease of Childhood).
- Acute allergic contact dermatitis—Dermatitis from direct cutaneous exposure to allergens such as poison ivy. Acute lesions are erythematous

papules and vesicles in a linear pattern (see Chapter 131, Contact Dermatitis).

- Insect bites—Scratched, open lesions can become secondarily infected with bacteria (impetiginized) (**Figure 99-9**).
- Second-degree burn or sunburn—The blisters when opened leave the skin susceptible to secondary infection.
- Staphylococcal scalded skin syndrome—Life-threatening syndrome of acute exfoliation of the skin caused by an exotoxin from a staphylococcal infection. This condition is seen almost entirely in infants and young children (**Figure 99-12**; see Chapter 105, Staphylococcal Scalded Skin Syndrome).

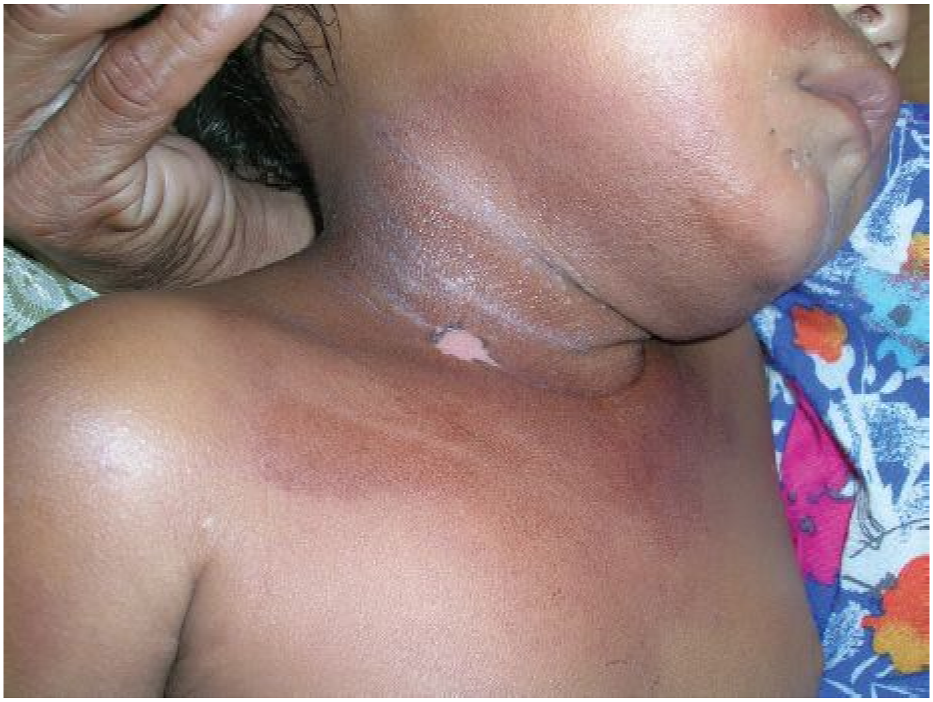

FIGURE 99-12 Staphylococcal scalded skin syndrome in a young child. A severe form of bullous impetigo with large areas of skin exfoliation. Note the prominent involvement of the neck as this condition tends to involve areas with skin folds. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

- There is good evidence that topical mupirocin is equally or more effective than oral treatment for people with limited impetigo. SOR Ⓐ Mupirocin also covers MRSA.[2]
- Extensive impetigo could be treated for 7 days with antibiotics that cover GABHS and *S. aureus*, such as cephalexin or dicloxacillin.[3] SOR Ⓐ
- Community-acquired MRSA can present as bullous impetigo in children (**Figures 99-2** and **99-6**) or adults.
- If you suspect MRSA, culture the lesions and start one of the following oral antibiotics: trimethoprim-sulfamethoxazole, clindamycin, or doxycycline (for patients 8 years and older).[4] SOR Ⓐ Trimethoprim-sulfamethoxazole achieved 100 percent clearance in the treatment of impetigo in children cultured with MRSA and GABHS in one small randomized controlled trial (RCT).[6]
- If there are recurrent MRSA infections, one might choose to prescribe intranasal mupirocin ointment and chlorhexidine bathing to decrease MRSA colonization.[5] SOR Ⓑ

PREVENTION

Practice good hygiene with soap and water. Avoid sharing towels and wash clothes.

FOLLOW-UP

Arrange follow-up based on severity of case and the age and immune status of the patient.

PATIENT EDUCATION

Discuss hygiene issues and how to avoid spread within the household or other living situations such as homeless shelters.

100 FOLLICULITIS

Richard P. Usatine, MD
Khalilah Hunter-Anderson, MD

PATIENT STORY

A young girl is seen for multiple papules and pustules on her lower abdomen (**Figure 100-1**). Further questioning demonstrates that she was in a friend's hot tub twice over the previous weekend. The outbreak started after she went into the hot tub the second time. This is a case of *Pseudomonas* folliculitis or "hot tub" folliculitis. The patient avoided this hot tub and the folliculitis disappeared spontaneously.

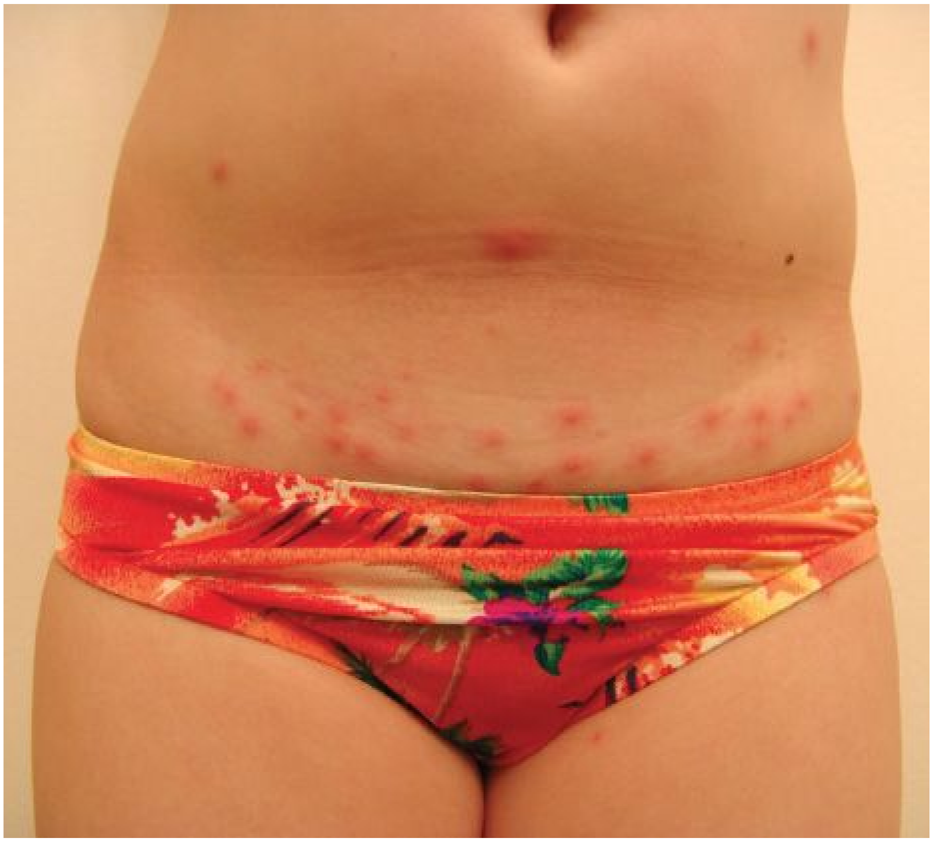

FIGURE 100-1 “Hot-tub” folliculitis from Pseudomonas aeruginosa in a hot tub. The folliculitis tends to be distributed under or around the bathing suit. (*Used with permission from Daniel Stulberg, MD*.)

INTRODUCTION

Folliculitis is an inflammation of hair follicles usually from an infectious etiology. Multiple species of bacteria have been implicated, as well as fungal organisms.

EPIDEMIOLOGY

- Folliculitis is a cutaneous disorder that affects all age groups and races, and both genders.
- It can be infectious or noninfectious. It is most commonly of bacterial origin (**Figure 100-2**).

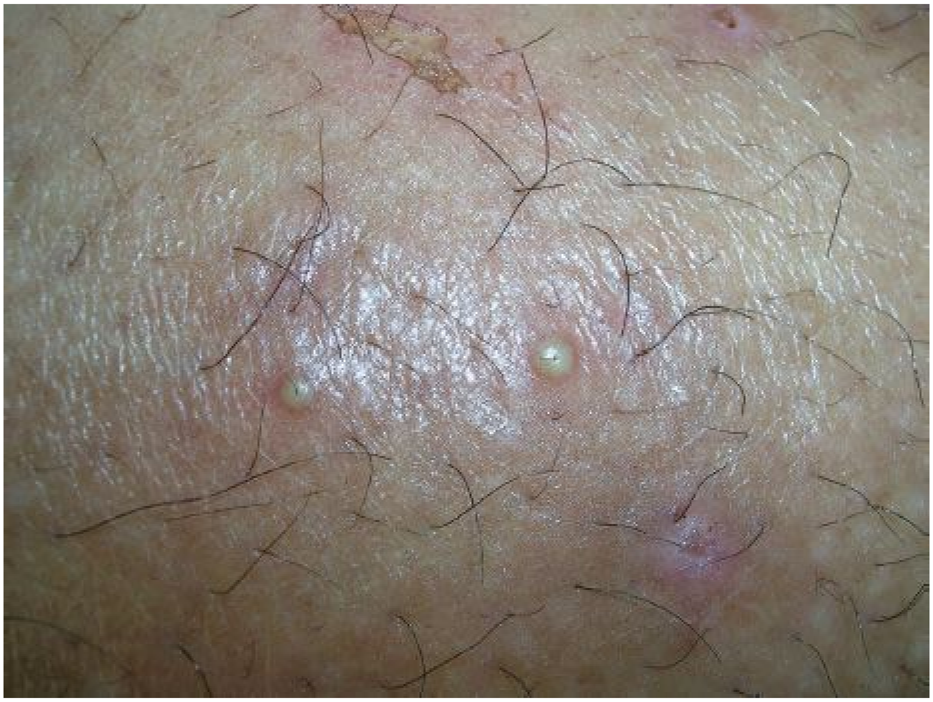

FIGURE 100-2 Close-up of bacterial folliculitis showing hairs coming through pustules. A culture grew out Staphylococcus aureus. (*Used with permission from Richard P. Usatine, MD.*)

- Pseudofolliculitis barbae is most frequently seen in men of color and made worse by shaving (**Figure 100-3**).[1]It is also known as "razor bumps" and can start in the teen years with the onset of shaving.

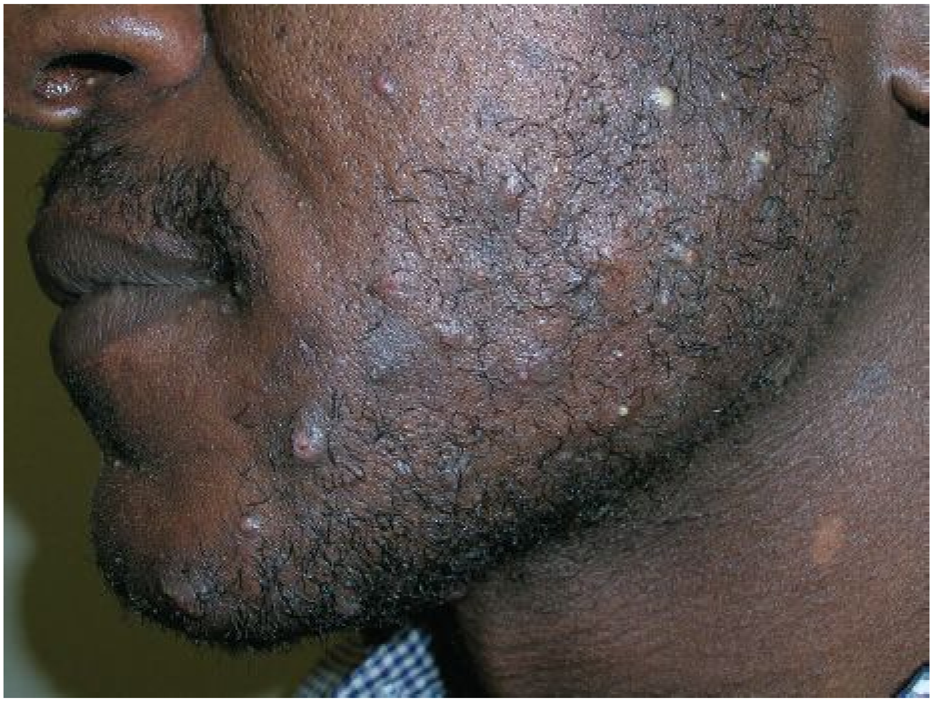

FIGURE 100-3 Pseudofolliculitis barbae in a young black man. Also known as "razor bumps" this started in his teen years with the onset of shaving. (*Used with permission from Richard P. Usatine, MD.*)

- Acne keloidalis nuchae or keloidal folliculitis is commonly seen in black patients, but can be seen in patients of any ethnic background (**Figures 100-4** and **100-5**).[2] Like pseudofolliculitis barbae, it is exacerbated by shaving.

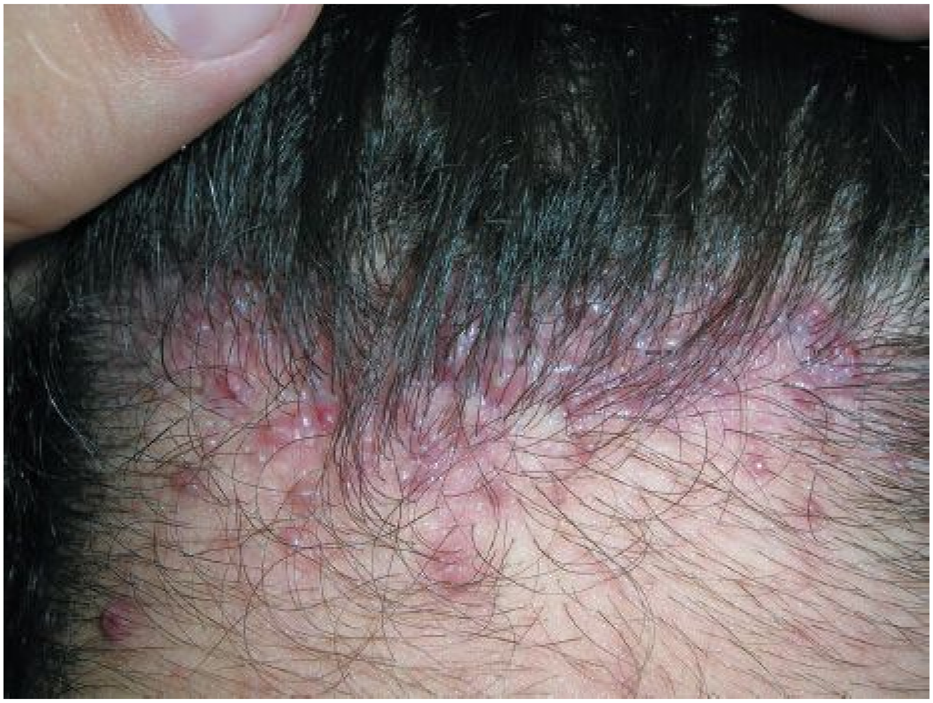

FIGURE 100-4 Acne keloidalis nuchae with inflamed papules and pustules on the neck of a young Hispanic man. (*Used with permission from Richard P. Usatine, MD*.)

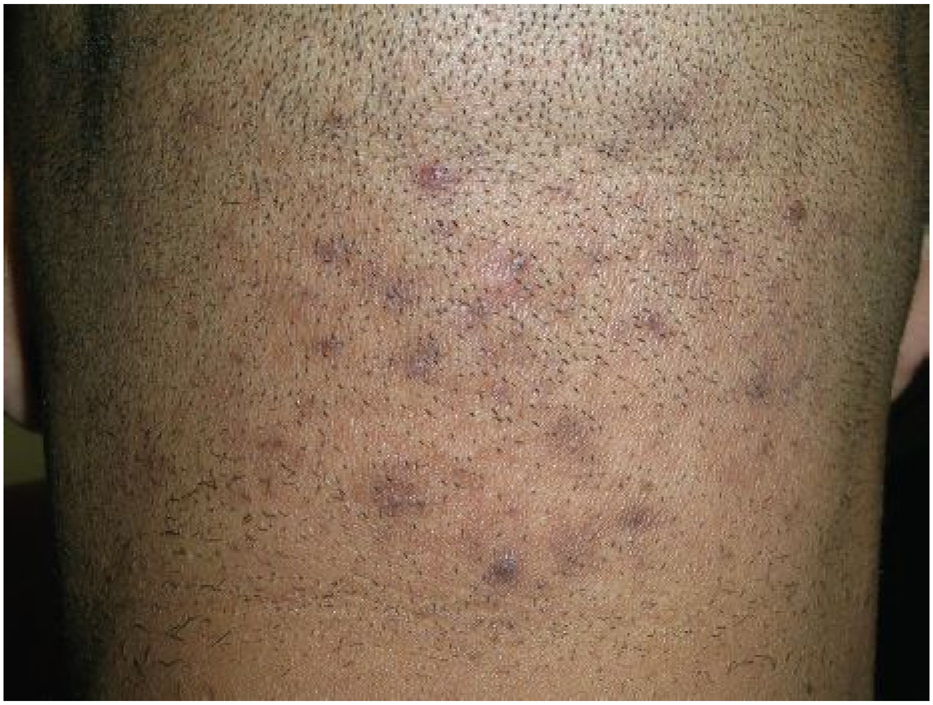

FIGURE 100-5 Acne keloidalis nuchae with inflamed papules and pustules on the posterior neck and scalp of a young African American man who shaves his head. (*Used with permission from Richard P. Usatine, MD*.)

- Methicillin-resistant *Staphylococcus aureus* (MRSA) can pose a challenge to the treatment of folliculitis (**Figure 100-6**).

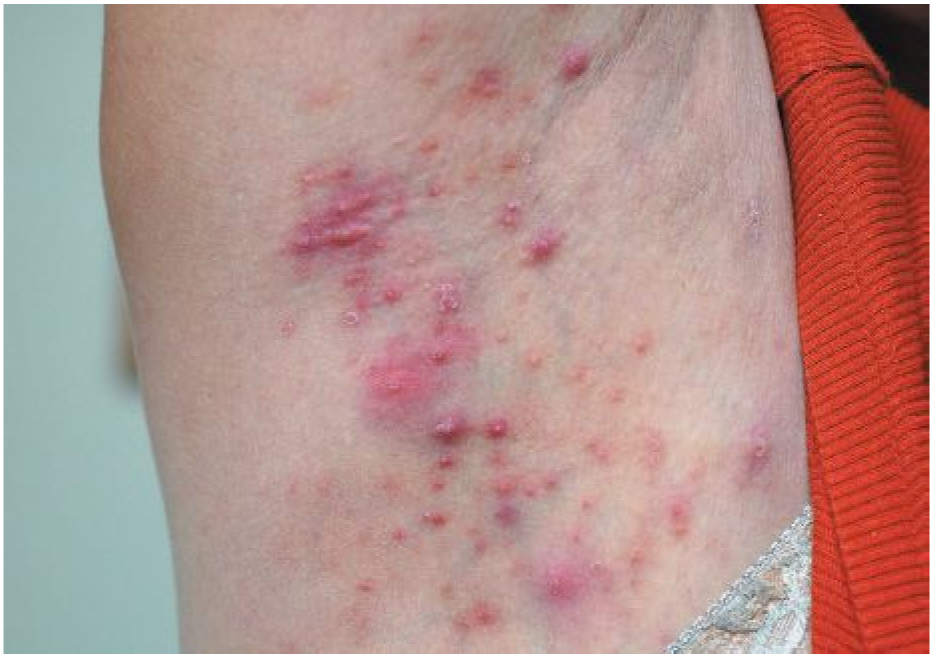

FIGURE 100-6 MRSA folliculitis in the axilla of a young woman. The lesions were present for 4 weeks in the axilla, left forearm, and right thigh. The MRSA was sensitive to tetracyclines and resolved with oral doxycycline. (*Used with permission from Plotner AN, Brodell RT. Bilateral axillary pustules. J Fam Pract. 2008;57(4):253-255*.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Folliculitis is an infection of the hair follicle and can be superficial, in which it is confined to the upper hair follicle, or deep, in which inflammation spans the entire depth of the follicle.

- Infection can be of bacterial, viral, or fungal origin. *S. aureus* is by far the most common bacterial causative agent.
- The noninfectious form of folliculitis is often seen in adolescents and young adults who wear tight-fitting clothes. Folliculitis can also be caused by chemical irritants or physical injury.
- Topical steroid use, ointments, lotions, or makeup can swell the opening to the pilosebaceous unit and cause folliculitis.
- Bacterial folliculitis or *Staphylococcus* folliculitis typically presents as infected pustules most prominent on the face, buttocks, trunk, or extremities. It can progress to a deeper infection with the development of furuncles or boils (**Figure 100-7**). Infection can occur as a result of mechanical injury or via local spread from nearby infected wounds. An area of desquamation is frequently seen surrounding infected pustules in *S. aureus* folliculitis.[12–3]

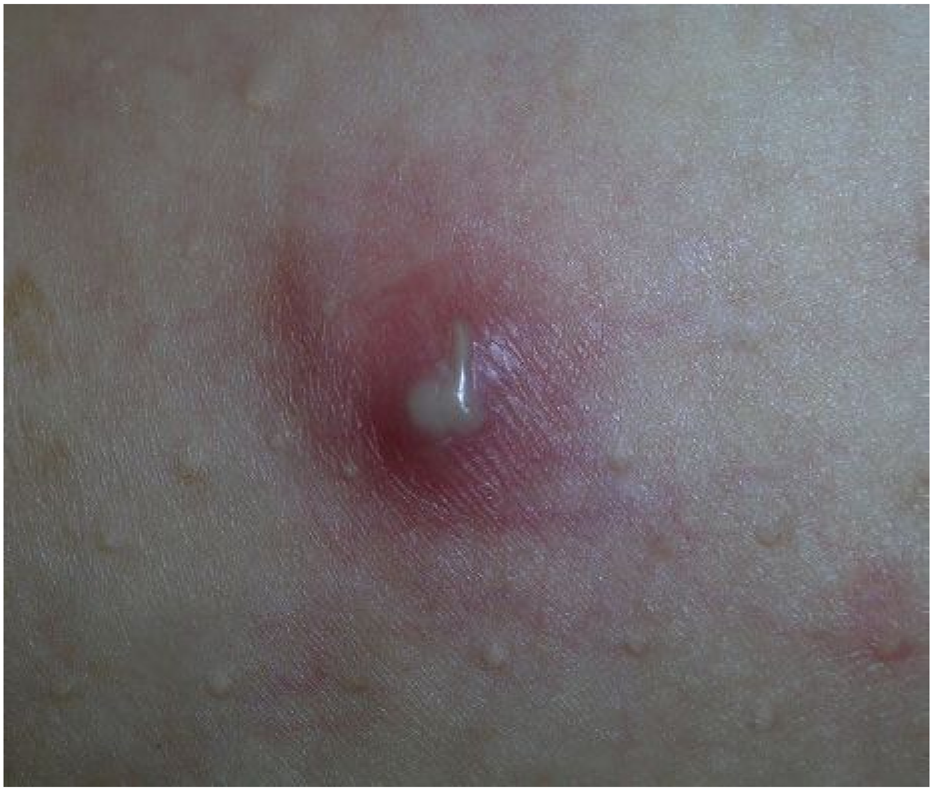

FIGURE 100-7 Isolated single furuncle. (*Used with permission from Richard P. Usatine, MD.*)

- Parasitic folliculitis usually occurs as a result of mite infestation (*Demodex*). These are usually seen on the face, nose, and back and typically cause an eosinophilic pustular-like folliculitis.[1]
- Folliculitis decalvans is a chronic form of folliculitis involving the scalp, leading to hair loss or alopecia (**Figure 100-8**). Staphylococci infection is the usual causative agent, but there also has been a suggested genetic component to this condition.[1] It is also called tufted folliculitis because some of the hair follicles will have many hairs growing from them simultaneously (**Figure 100-9**).

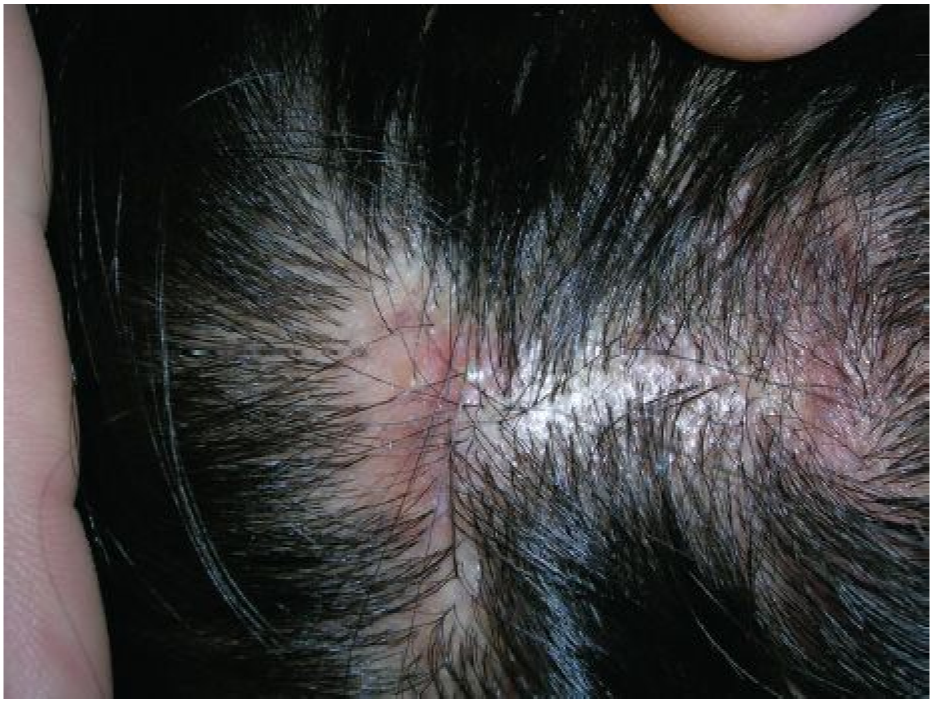

FIGURE 100-8 Early folliculitis decalvans showing scalp inflammation, pustules around hair follicles and scarring alopecia. (*Used with permission from Richard P. Usatine, MD*.)

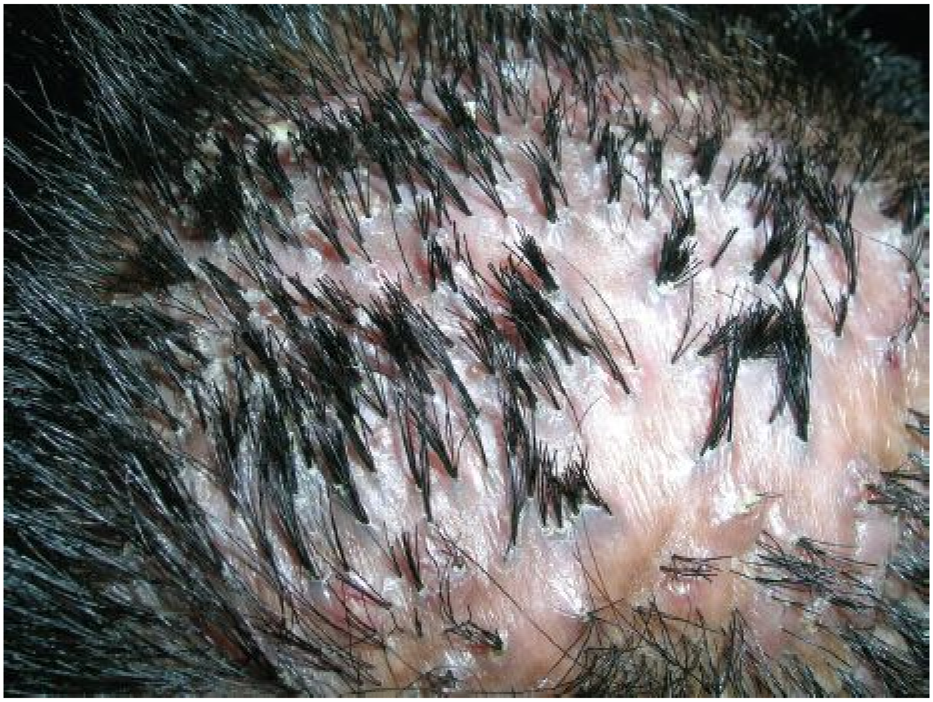

FIGURE 100-9 Tufted folliculitis with visible tufts of hair (multiple hairs from one follicle) growing from a number of abnormal follicles. This is one example of scarring alopecia. (*Used with permission from Richard P. Usatine, MD*.)

- Acne keloidalis nuchae is a chronic form of folliculitis found on the posterior neck that can be extensive and lead to keloidal tissue and alopecia (**Figures 100-4** and **100-5**).[12–3]
- Fungal folliculitis is epidermal fungal infections that are seen frequently. Tinea capitis infections are a form of dermatophytic folliculitis (see Chapter 122, Tinea Capitis). *Pityrosporum* folliculitis is caused by yeast infection (*Malassezia* species) and is seen in a similar distribution as bacterial folliculitis on the back, chest, and shoulders (**Figure 100-10**; see Chapter 126, Tinea Versicolor). Candidal infection is less common and is usually seen in individuals who are immunosuppressed, present in hairy areas that are moist, and unlike most cases of folliculitis, may present with systemic signs and symptoms.[123–4]

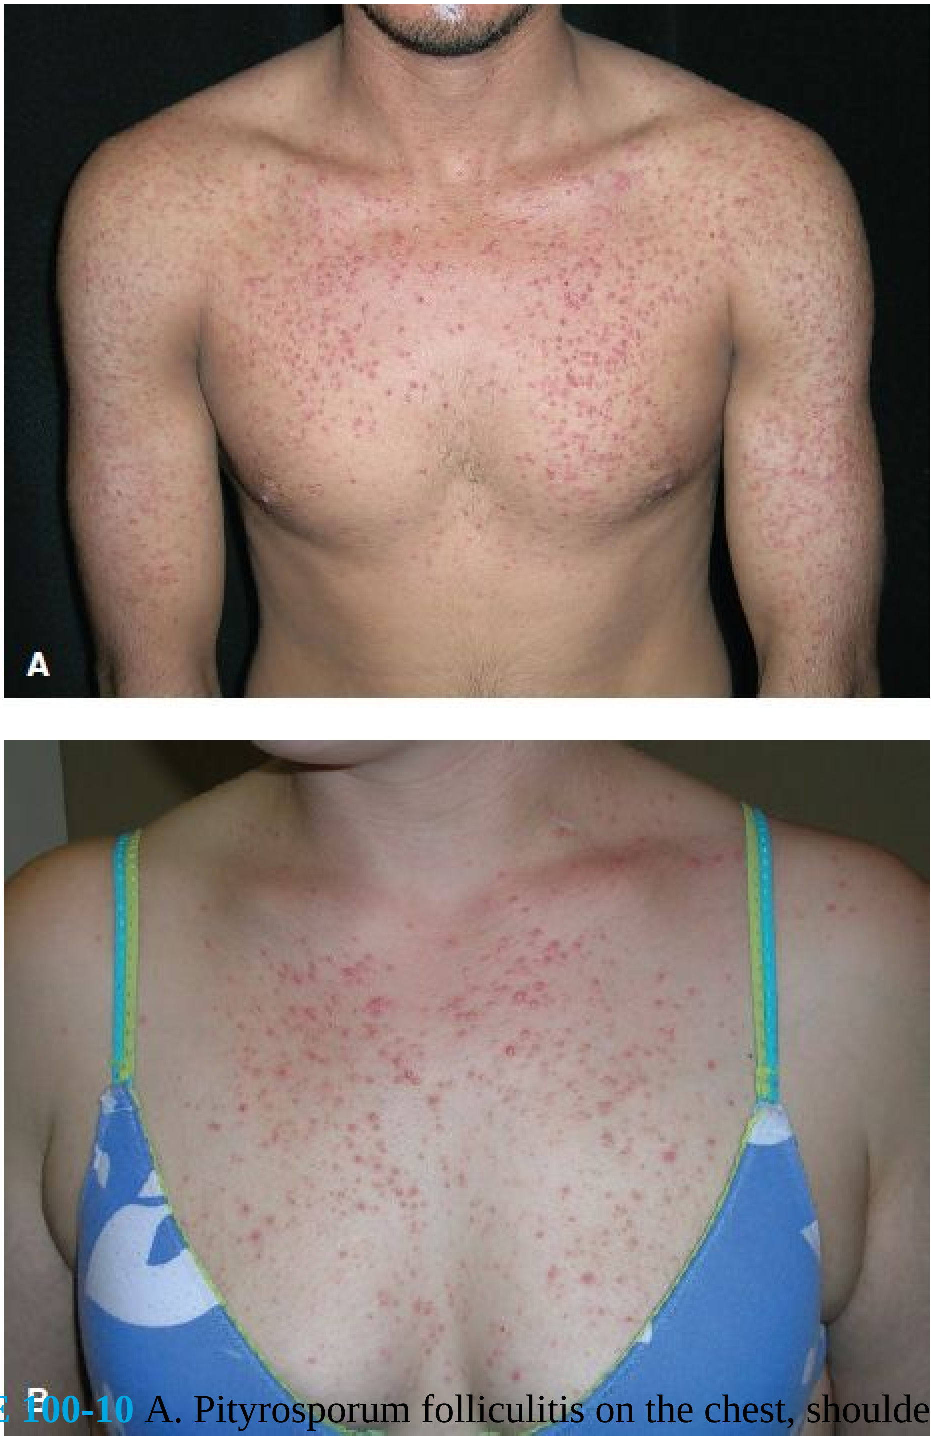

FIGURE 100-10 A. Pityrosporum folliculitis on the chest, shoulders, and arms of a young man; biopsy proven. B. Pityrosporum folliculitis on the chest of a young woman. KOH preparation showed Pityrosporum looking like ziti and meatballs. (*Used with permission from Richard P. Usatine, MD*.)

- *Pseudomonas* folliculitis or “hot tub” folliculitis is usually a self-limited infection that follows exposure to water or objects that are contaminated with *Pseudomonas aeruginosa* (**Figure 100-1**). This occurs when hot tubs are inadequately chlorinated or brominated. This also occurs when loofah sponges or other items used for bathing become a host for pseudomonal growth. Onset of symptoms is usually within 6 to 72 hours after exposure, with the complete resolution of symptoms in a couple of days, provided that the individual avoids further exposure.[4]
- Gram-negative folliculitis is an infection with Gram-negative bacteria that most typically occurs in individuals who have been on long-term antibiotic therapy, usually those taking oral antibiotics for acne. The most frequently encountered infective agents include *Klebsiella*, *Escherichia coli*, *Enterobacter*, and *Proteus*.[5]
- Pseudofolliculitis barbae (razor bumps) is most commonly seen in black males who shave. Papules develop when the sharp edge of the hair shaft reenters the skin (ingrown hairs), and is seen on the cheeks and neck as a result of curled ingrown hair.[2] It can also occur in females with hirsutism who shave or pluck their hairs.
- Viral folliculitis is primarily caused by herpes simplex virus and molluscum contagiosum.[4] Herpetic folliculitis is seen primarily in individuals with a history of herpes simplex infections type I or II. But most notably, it may be a sign of immunosuppression, as is the case with HIV infection.[6] The expression of herpes folliculitis in HIV infection ranges from simple to necrotizing folliculitis and ulcerative lesions. Molluscum is a pox virus and molluscum contagiosum has been well-documented in similar patient populations (i.e., HIV and AIDS) and in children (see Chapters 114, Herpes Simplex and 115, Molluscum Contagiosum).[6–7]
- Actinic superficial folliculitis is a sterile form of folliculitis seen predominantly in warm climates or during hot or summer months. Pustules occur primarily on the neck, over the shoulders, upper trunk, and upper arms, usually within 6 to 36 hours after sun exposure.[8]

DIAGNOSIS

Often the diagnosis of folliculitis is based on a good history and physical.

CLINICAL FEATURES

Folliculitis has its characteristic presentation as the development of papules or pustules that are thin-walled and surrounded by a margin of erythema or inflammation. Look for a hair at the center of the lesions (**Figure 100-2**). There is usually an absence of systemic signs and patients, symptoms range from mild discomfort and pruritus to severe pain with extensive involvement.

TYPICAL DISTRIBUTION

Any area of the skin may be affected and often location may be related to the pathogen or cause of folliculitis. The face, scalp, neck, trunk, axillae, extremities, and groin are some of the more common areas affected.

LABORATORY TESTS

Laboratory testing may be unnecessary in simple superficial folliculitis and where the history is clear and quick resolution occurs. Clinical diagnosis of herpes and fungal folliculitis may be difficult and diagnosis may be made based on strong clinical suspicion or as a result of failed antimicrobial therapy. KOH preps can be used to look for tinea versicolor or other fungal organisms. Herpes culture or a quick test for herpes can be used when herpes is suspected.[1] SOR A

DIFFERENTIAL DIAGNOSIS

- *Miliaria* is blockage of the sweat glands that can resemble the small papules of folliculitis (**Figure 100-11**). The eccrine sweat glands become blocked so that sweat leaks into the dermis and epidermis. Clinically, skin lesions may range from clear vesicles to pustules. These skin lesions primarily occur in times of increased heat and humidity, and are self-limited (see Chapter 92, Normal Skin Changes).[1]

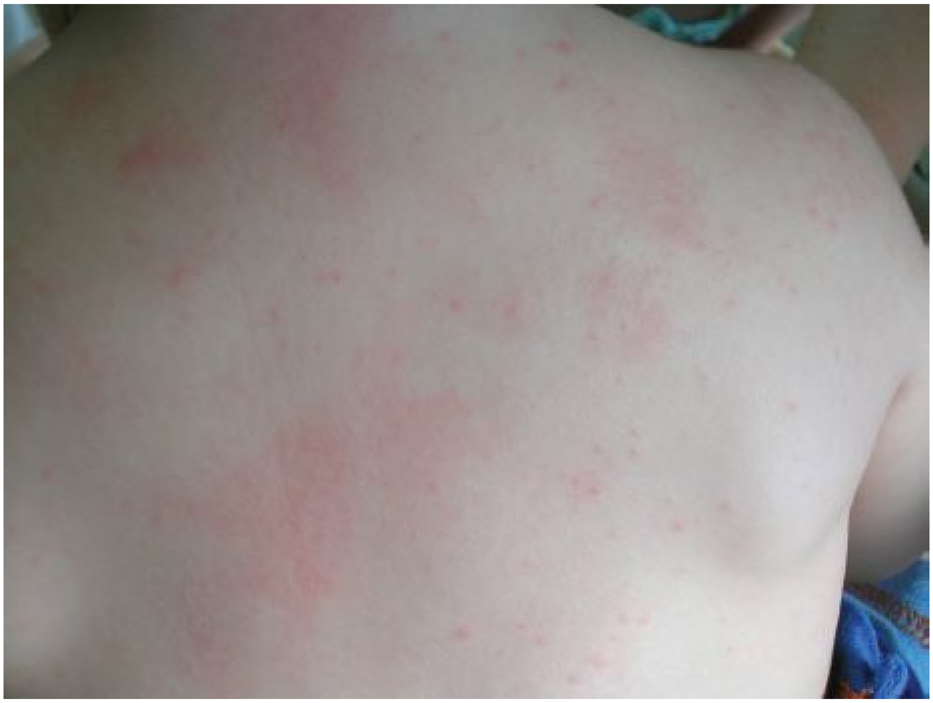

FIGURE 100-11 Miliaria in a 16-month-old child. This is an inflammation and blockage of the eccrine sweat glands and not the pilosebaceous units as seen in folliculitis. (*Used with permission from Richard P. Usatine, MD*.)

- Impetigo is a bacterial infection of the skin that affects the superficial layers of the epidermis as opposed to hair follicles. It is contagious, unlike folliculitis. It has a bullous and nonbullous form, and honey-crusted lesions frequently predominate as opposed to the usual pustules seen in folliculitis (see Chapter 99, Impetigo).[4]
- Keratosis pilaris consists of papules that occur as a result of a buildup of keratin in the openings of hair follicles, especially on the lateral upper arms and thighs. It is not an infection but can develop into folliculitis if lesions become infected (see Chapter 130, Atopic Dermatitis).[1]

- Acne vulgaris is characterized by the presence of comedones, papules, pustules, and nodules that are a result of follicular hyperproliferation and plugging with excessive sebum. Inflammation occurs when *Propionibacterium acnes* and other inflammatory substances get extruded from the blocked pilosebaceous unit.[?]Although acne on the face is rarely confused with folliculitis, acne on the trunk can resemble folliculitis. To distinguish between them look for facial involvement and comedones seen in acne (see Chapter 96, Acne Vulgaris).

MANAGEMENT

- Management of folliculitis varies by causative agent and underlying pathophysiology.
- Antivirals, antibiotics, and antifungals are used as topical and/or systemic agents. Approaches to nonpharmacologic therapy include patient education on the prevention of chemical and mechanical skin irritation. Glycemic control in diabetic patients may help treat folliculitis.[12–3] Good hygiene helps to control symptoms and prevent recurrence.
- With superficial bacterial folliculitis, treatment with topical preparations such as mupirocin (Bactroban) or fusidic acid may be sufficient.[1]SOR Ⓐ Additionally, topical clindamycin may be considered in the mildest cases in which MRSA is involved.[1]SOR Ⓐ
- Deep or extensive bacterial folliculitis warrants oral therapy with first-generation cephalosporins (cephalexin), penicillins (amoxicillin/clavulanate and dicloxacillin), macrolides, or fluoroquinolones.[1,4]SOR Ⓐ
- Pseudomonas or “hot tub” folliculitis usually resolves untreated within a week of onset (**Figure 100-1**). For severe cases, treatment with ciprofloxacin provides adequate antipseudomonal coverage.[1,4]SOR Ⓑ Application of a warm compress to affected areas also provides symptomatic relief.

- Pityrosporum folliculitis and/or tinea versicolor can be treated with systemic antifungals, topical azoles, and/or with shampoos containing azoles, selenium, or zinc (**Figure 100-12**) (see Chapter 126, Tinea Versicolor).[9]

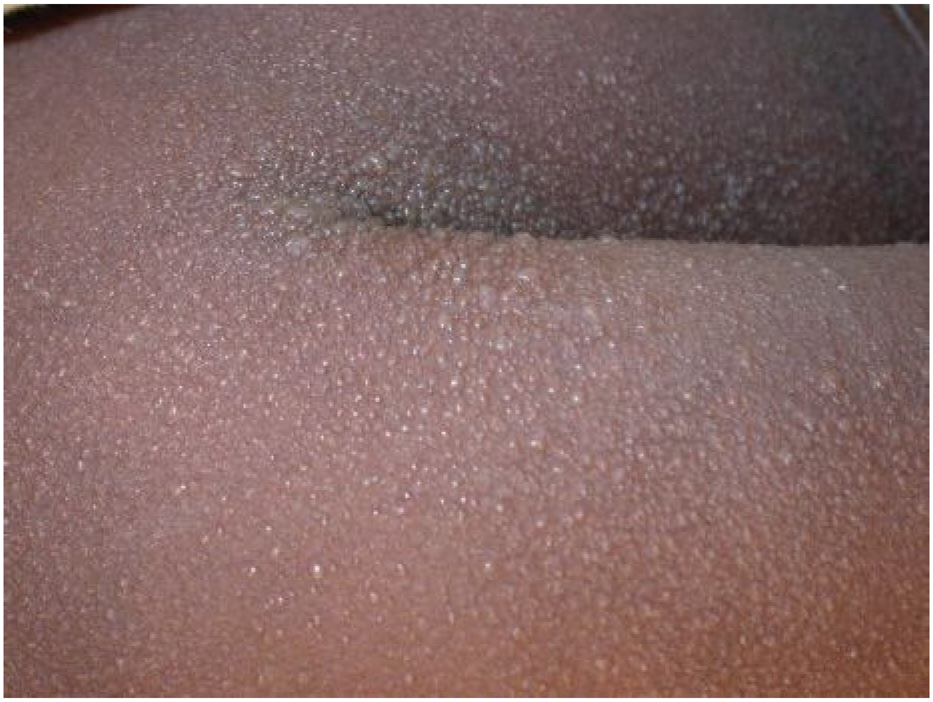

FIGURE 100-12 Miliaria crystallina in which the blockage of the eccrine sweat glands leads to small superficial crystalline vesicles. (*Used with permission from John Browning, MD*.)

- Candidal folliculitis in immunosuppressed persons may be treated with oral itraconazole or fluconazole (see Chapter 121, Candidiasis).[1] SOR Ⓑ
- *Demodex* folliculitis can be treated with ivermectin or topically with 5 percent permethrin cream.[4] SOR Ⓑ
- Herpes folliculitis can be treated with acyclovir, valacyclovir, and famciclovir. Regimens may frequently include acyclovir 200 mg five times a day for 5 days (see Chapter 114, Herpes Simplex).[1] SOR Ⓑ

FOLLOW-UP

Most cases of folliculitis are superficial and resolve easily with treatment. Dermatologic and surgical consultation may be required in cases of chronic folliculitis with scarring.

PATIENT EDUCATION

Prevention is most important, and centers on good personal hygiene and proper laundering of clothing. Patients should be encouraged to avoid tight-fitting clothing. Hot tubs should be properly cleaned and the chemicals should be maintained appropriately. Electric razors for shaving can help prevent pseudofolliculitis barbae and should be cleaned regularly with alcohol. Patients with acne keloidalis nuchae should avoid shaving the hair in the involved area.

101 PITTED KERATOLYSIS

Michael Babcock, MD
Richard P. Usatine, MD

PATIENT STORY

A 17-year-old boy comes to the office with a terrible foot odor problem. He is wearing cowboy boots and he says that his feet are always sweaty. He is embarrassed to remove his boots, but when his mother convinces him to do so the odor is unpleasant. The clinician sees the typical pits of pitted keratolysis and notes that the boy's socks are moist. His foot has many crateriform pits on the sole (**Figure 101-1**). He is prescribed topical erythromycin solution for the pitted keratolysis and topical aluminum chloride for the hyperhidrosis. It is suggested that he wear a lighter and more breathable shoe until this problem improves.

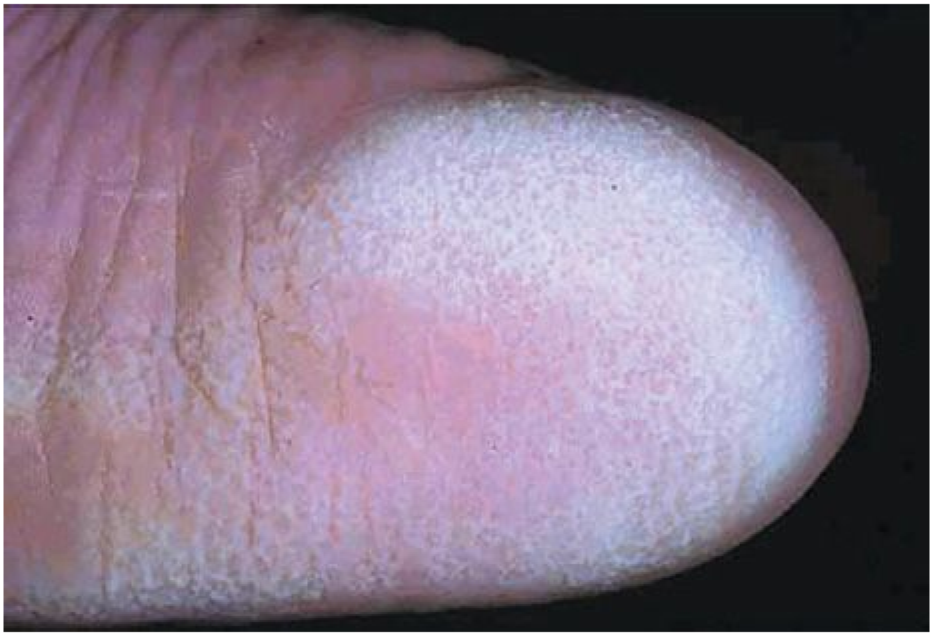

FIGURE 101-1 Many crateriform pits on the heel of the foot with pitted keratolysis and hyperhidrosis. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Pitted keratolysis is a superficial foot infection caused by Gram-positive bacteria. These bacteria degrade the keratin of the stratum corneum leaving visible pits on the soles of the feet.

EPIDEMIOLOGY

- Seen more commonly in males.
- Often a complication of hyperhidrosis.
- Seen more often in hot and humid climates.
- Prevalence can be as high as 42.5 percent among paddy field workers.[1]
- May be common in athletes with moist, sweaty feet.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- *Kytococcus sedentarius* (formerly *Micrococcus* spp.), *Corynebacterium* species, and *Dermatophilus congolensis* have all been shown to cause pitted keratolysis.[3]
- Proteases produced by the bacteria degrade keratins to give the clinical appearance.[4]
- The associated malodor is likely secondary to the production of sulfur byproducts.[3]

DIAGNOSIS

CLINICAL FEATURES

Pitted keratolysis usually presents as painless, malodorous, crateriform pits coalescing into larger superficial erosions of the stratum corneum (**Figures 101-1** to **101-4**). It may be associated with itching and a burning sensation in some patients (**Figure 101-3**).

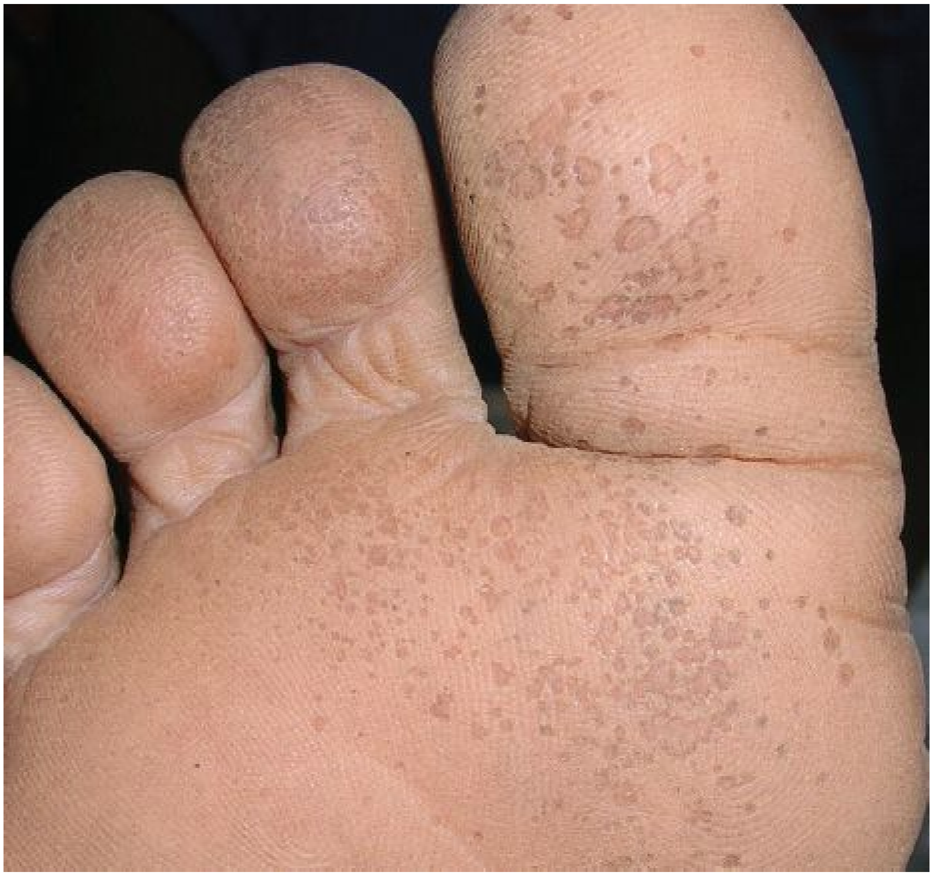

FIGURE 101-2 Pitted keratolysis on the pressure-bearing areas of the toes and the ball of the foot. (*Used with permission from Richard P. Usatine, MD*.)

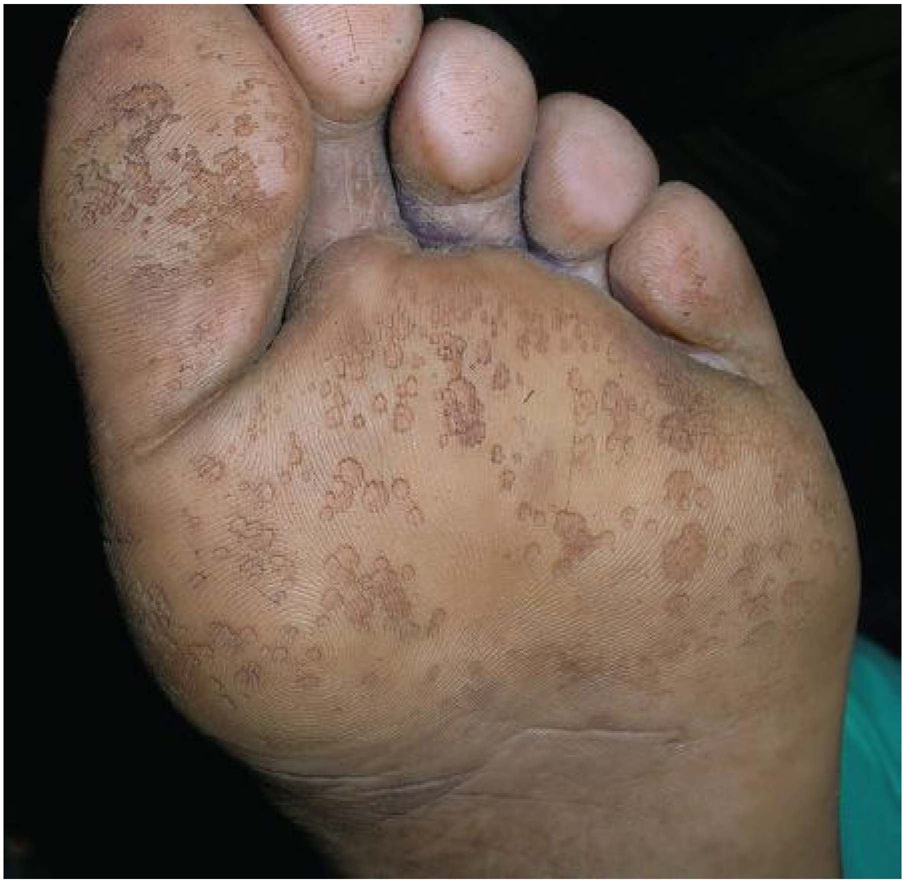

FIGURE 101-3 Pitted keratolysis with hyperpigmented crateriform pits on the pressure-bearing areas of the foot. The patient complained of itching and burning on the feet. (*Used with permission from Richard P. Usatine, MD*.)

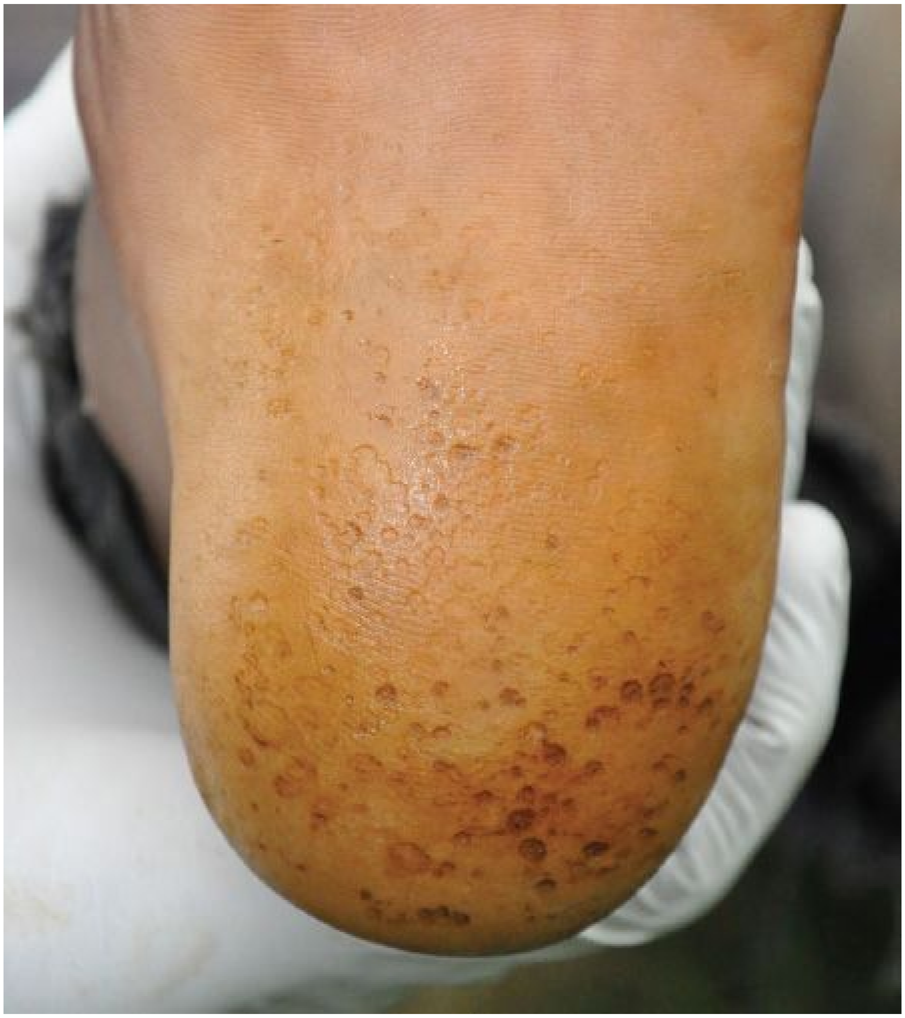

FIGURE 101-4 Pitted keratolysis with many crateriform pits on the heel. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

Pitted keratolysis usually involves the callused pressure-bearing areas of the foot, such as the heel, ball of the foot, and plantar great toe. It can also be found in friction areas between the toes.[5]

LABORATORY STUDIES

Typically a clinical diagnosis, but biopsy will reveal keratin pits lined by bacteria.

DIFFERENTIAL DIAGNOSIS

Characteristic clinical features make the diagnosis easy, but it is possible to have other diseases causing plantar pits:

- Plantar warts are typically not as numerous. They have a firm callus ring around a soft core with small black dots from thrombosed capillaries (see Chapter 119, Plantar Warts).
- Arsenic toxicity can result in pits on the palms and soles, but it can also have hyperpigmentation, many skin cancers, Mees lines (white lines on the fingernails), or other nail disorders.

MANAGEMENT

- Treatment is based on bacterial elimination and reducing the moist environment in which the bacteria thrive. Various topical antibiotics are effective for pitted keratolysis.
- Topical erythromycin or clindamycin solution or gel can be applied twice daily until the condition resolves. SOR Ⓒ Generic 2 percent erythromycin solution with an applicator top is a very inexpensive and effective preparation. It may take 3 to 4 weeks to clear the odor and skin lesions.
- Topical mupirocin is more expensive but also effective. SOR Ⓒ
- Oral erythromycin is effective and may be considered if topical therapy fails. SOR Ⓒ
- Treating underlying hyperhidrosis is also important to prevent recurrence (**Figure 101-5**). This can be done with topical aluminum chloride of varying concentrations. SOR Ⓒ Drysol is 20 percent aluminum chloride solution and can be prescribed with an applicator top.

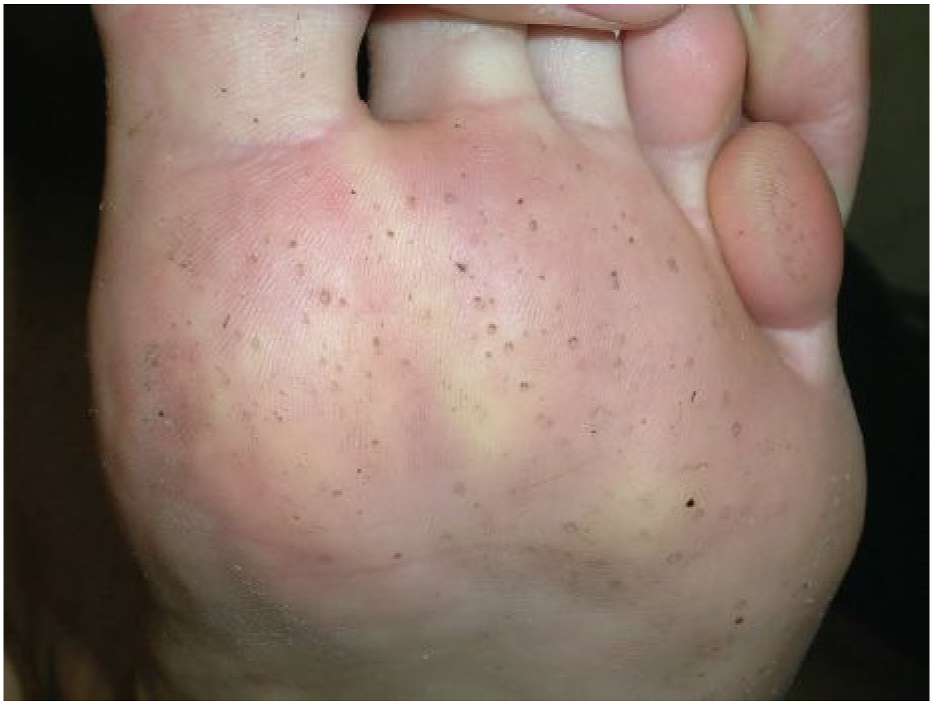

FIGURE 101-5 Pitted keratolysis with small crateriform pits on the ball of the foot. This teen also had hyperhidrosis, which was simultaneously treated with aluminum chloride. Treatment of the hyperhidrosis prevented recurrence of the pitted keratolysis. (*Used with permission from Richard P. Usatine, MD.*)

- Botulinum toxin injection is an expensive and effective treatment for hyperhidrosis.[6] SOR Ⓒ It should be reserved for treatment failures because of the cost, the discomfort of the multiple injections, and the need to repeat the treatment every 3 to 4 months.

FOLLOW-UP

Follow-up is needed for treatment failures, recurrences, and the treatment of underlying hyperhidrosis if present. Follow-up can be performed annually for prescription aluminum chloride or approximately every 4 months for botulinum toxin injections.

PATIENT EDUCATION

Patients should be taught about the etiology of this disorder to help avoid recurrence. Helpful preventive strategies include avoiding occlusive footwear and using moisture-wicking socks or changing sweaty socks frequently.

102 ERYTHRASMA

Anna Allred, MD
Richard P. Usatine, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 12-year-old Hispanic girl, accompanied by her mother, presents with a 1-year history of a red irritated rash in both axillae (**Figure 102-1**). She has been seen by multiple physicians and has tried many antifungal creams with no results. Even hydrocortisone did not help. She had stopped wearing deodorant for fear that she was allergic to all deodorants. Although the rash barely fluoresced at all, the physical examination and history were most consistent with erythrasma. The patient was given a prescription for oral erythromycin and the erythrasma cleared to the great delight of the patient and her mother.

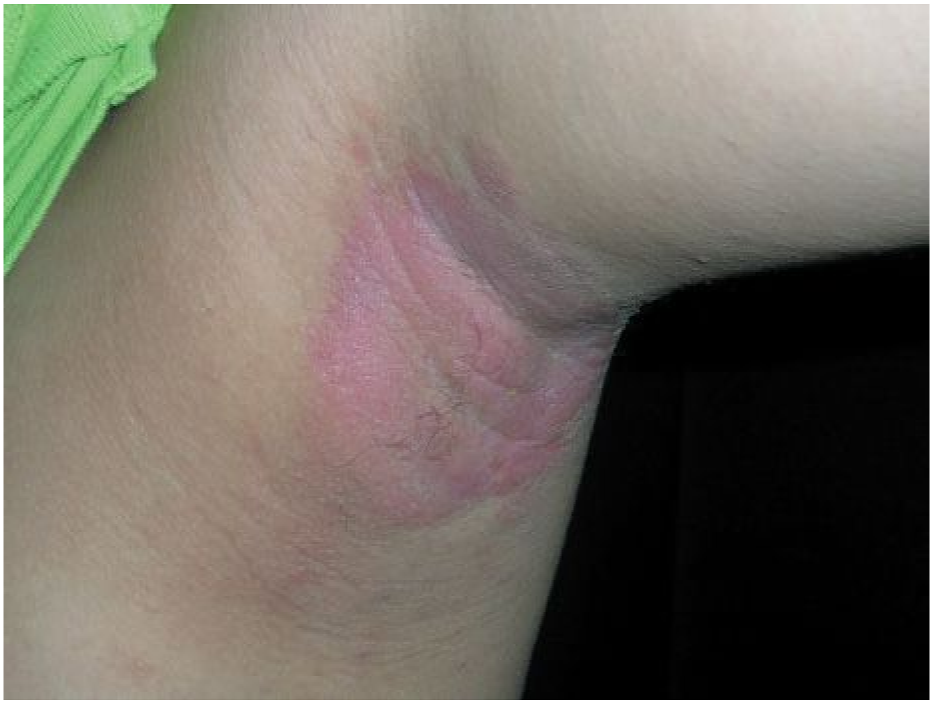

FIGURE 102-1 Erythrasma in the axilla of a 12-year-old Hispanic girl. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Erythrasma is a chronic superficial bacterial skin infection that usually occurs in a skin fold.

EPIDEMIOLOGY

- The incidence of erythrasma is approximately 4 percent.[1]
- Both sexes are equally affected.
- The inguinal location is more common in males.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Corynebacterium minutissimum*, a lipophilic Gram-positive non–spore-forming rod-shaped organism, is the causative agent.
- Under favorable conditions, such as heat and humidity, this organism invades and proliferates the upper 1/3 of the stratum corneum.
- The organism produces porphyrins that result in the coral red fluorescence seen under a Wood lamp (**Figure 102-2**).

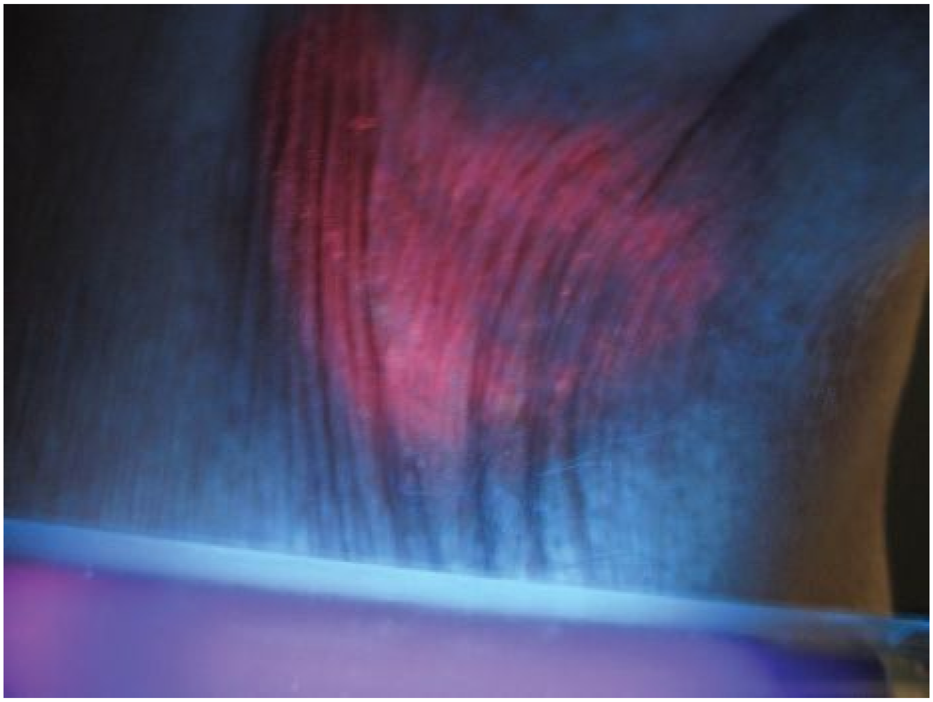

FIGURE 102-2 Coral red fluorescence seen with a Wood lamp held in the axilla of a patient with erythrasma. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

RISK FACTORS[1]

- Warm climate.

- Diabetes mellitus.
- Immunocompromised states.
- Obesity.
- Hyperhidrosis.
- Poor hygiene.
- Advanced age.

DIAGNOSIS

CLINICAL FEATURES

- Erythrasma is a sharply delineated, dry, red-brown patch with slightly scaling patches. Some lesions appear redder, whereas others have a browner color (**Figures 102-3** and **102-4**).

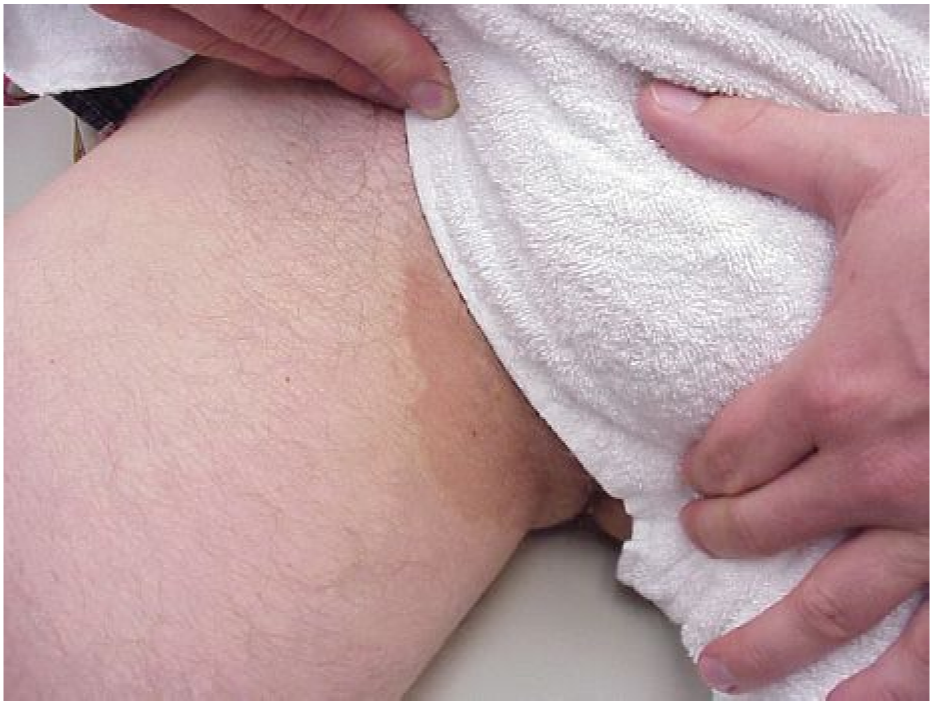

FIGURE 102-3 Light brown erythrasma in the groin of a young man. does not have the degree of scaling usually seen with tinea cruris. (*Used with permission from Dan Stulberg, MD*.)

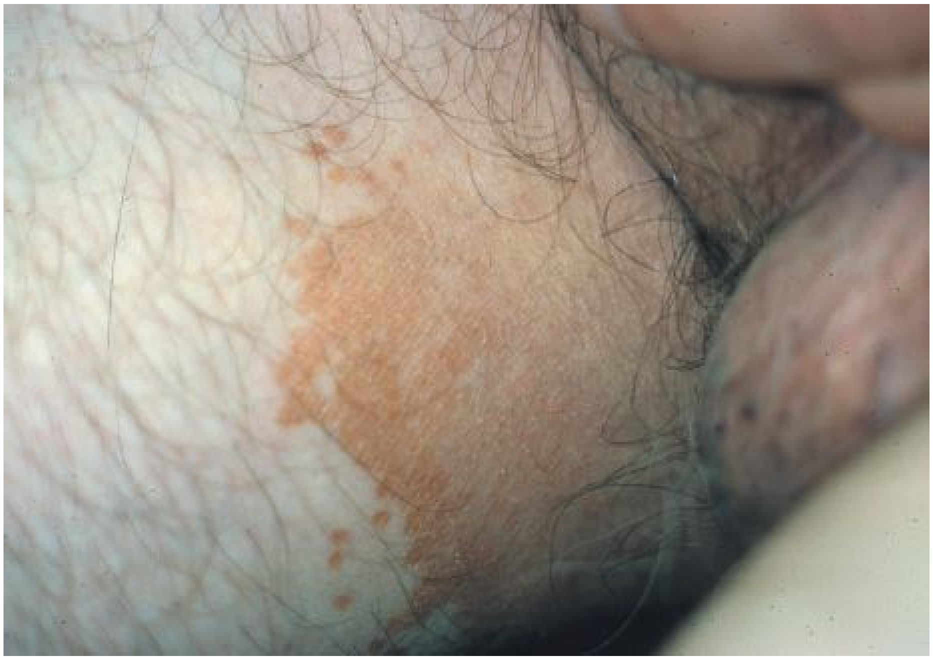

FIGURE 102-4 Brown erythrasma in the groin of a young man with diabetes. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

- The lesions are typically asymptomatic; however, patients sometimes complain of itching and burning when lesions occur in the groin (**Figure 102-3**).

TYPICAL DISTRIBUTION

Erythrasma is characteristically found in the intertriginous areas, especially the axilla and the groin. Patches of erythrasma may also be found in the interspaces of the toes, intergluteal cleft, perianal skin, and inframammary area.

LABORATORY STUDIES

- Illumination of the plaque with a Wood lamp reveals coral-red fluorescence. It should be noted that washing the area before examination may eliminate the fluorescence.
- The diagnosis may be confirmed by applying Gram stain or methylene blue stain to scrapings from the skin to reveal Gram-positive rods and dark blue granules, respectively. However, if the presentation is typical and the plaque reveals fluorescence then microscopic examination and cultures are not needed.
- Microscopic examination is useful if erythrasma is suspected but the plaque does not fluoresce.

DIFFERENTIAL DIAGNOSIS

- Psoriasis—Inverse psoriasis occurs in the same areas as erythrasma and also causes pink to red plaques with well-demarcated borders. The best way to distinguish psoriasis from erythrasma is to look for other clues of psoriasis in the patient, including nail pitting or onycholysis and hyperkeratotic plaques on the elbows, knees, or scalp. Also, inverse psoriasis may be seen in the intergluteal cleft as well as below the breasts or pannus in overweight individuals (see Chapter 136, Psoriasis). The Wood lamp may help differentiate between these diagnoses.
- Dermatophytosis—Cutaneous fungal infections also closely resemble erythrasma when they occur in the axillary and inguinal areas. Tinea infections also have well-demarcated borders that can be raised with central clearing. This distinctive ringworm look is more obvious with tinea than erythrasma but a scraping for microscopic examination should be able to distinguish between the two conditions. Examination of the feet will frequently show tinea pedis and onychomycosis when there are tinea infections elsewhere on the body (see Chapters 123, Tinea Corporis and 124, Tinea Cruris).
- Candidiasis—Look for satellite lesions to help distinguish candidiasis from erythrasma. Candidiasis will not fluoresce and a microscopic

examination of a *Candida* infection should show branching pseudohyphae (see Chapter 121, Candidiasis).

- Intertrigo—This is a term for inflammation in intertriginous areas (skin folds). It is caused or exacerbated by heat, moisture, maceration, friction, and lack of air circulation. It is frequently made worse by infection with *Candida*, bacteria, or dermatophytes, and therefore overlaps with the erythrasma, *Candida*, and dermatophytosis. Obesity and diabetes especially predispose to this condition. All efforts should be made to find coexisting infections and treat them.
- Contact dermatitis to deodorants can mimic erythrasma. The history and Wood lamp should help to differentiate the two conditions (see Chapter 131, Contact Dermatitis).

MANAGEMENT

NONPHARMACOLOGIC

- It has been advocated that the areas should be vigorously washed with soap and water prior to application of topical antibiotics.[5] SOR C
- Consider loose-fitting cotton undergarments during treatment and to help prevent recurrence.[5] SOR C

MEDICATIONS

- Although the bacteria responds to a variety of antibacterial agents (e.g., penicillins, first-generation cephalosporins), the treatment of choice is oral erythromycin 250 mg four times a day for 14 days. Erythromycin shows cure rates as high as 100 percent.[2–4] SOR B
- However, some advocate that oral erythromycin is only required for the treatment of extensive or resistant cases.[5] SOR C

- Topical therapy (antibacterial, antifungal, benzoic acid 6%) has been recommended in addition to oral therapy in patients with hidden reservoirs of infection (i.e., interdigital involvement). SOR Ⓒ
- Topical clindamycin may be applied once daily during the course of oral erythromycin therapy and for 2 weeks after physical clearance of the lesions for treatment and prophylaxis.[3,6] SOR Ⓒ
- Topical erythromycin 2 percent solution applied twice daily.[4,5,7] SOR Ⓒ
- In a Turkish study, topical fusidic acid was more effective than erythromycin or single-dose clarithromycin based on Wood light reflection scores.[8]
- Optimal blood glucose control is recommended in the management of a diabetic patient with erythrasma.[2] SOR Ⓒ

PROGNOSIS

- Usually a benign condition; however, in immunocompromised individuals, *Corynebacterium* can cause abscess formation, bacteremia, endocarditis, pyelonephritis, cellulitis, and meningitis.[1]
- The condition tends to recur if the predisposing condition is not addressed.

FOLLOW-UP

Have the patient follow up in 2 to 4 weeks as needed to determine if erythrasma has resolved.

PATIENT EDUCATION

Reassure the patient that erythrasma is curable with antibiotic treatment.

103 CELLULITIS

Richard P. Usatine, MD

PATIENT STORY

A 4-year-old child presents with a fever and a red and swollen foot (**Figure 103-1**). The patient injured her foot 3 days before with a door. On physical examination, the foot was warm, tender, red, and swollen, and the child's temperature was 39.4°C (103°F). This is classic cellulitis and the child was admitted for IV antibiotics.

INTRODUCTION

Cellulitis is an acute infection of the skin that involves the dermis and subcutaneous tissues.

EPIDEMIOLOGY

- In one review of serious skin infections in children admitted to a hospital in New Zealand, the most common types of infection were cellulitis (38%) and subcutaneous abscesses (36%).[1] The most frequent sites of infection were the head, face and neck, (32%) and lower limbs (32%). The most frequently isolated organisms were *Staphylococcus aureus* (48%) and *Streptococcus pyogenes* (20%).[1]
- Facial cellulitis occurs more often in children ages 6 months to 3 years.

- Perianal cellulitis occurs more commonly in young children (see Chapter 95, Diaper Rash and Perianal Dermatitis).

ETIOLOGY AND PATHOPHYSIOLOGY

- Often begins with a break in the skin caused by trauma, a bite, or an underlying dermatosis (e.g., atopic dermatitis) (**Figures 103-1** to **103-4**).

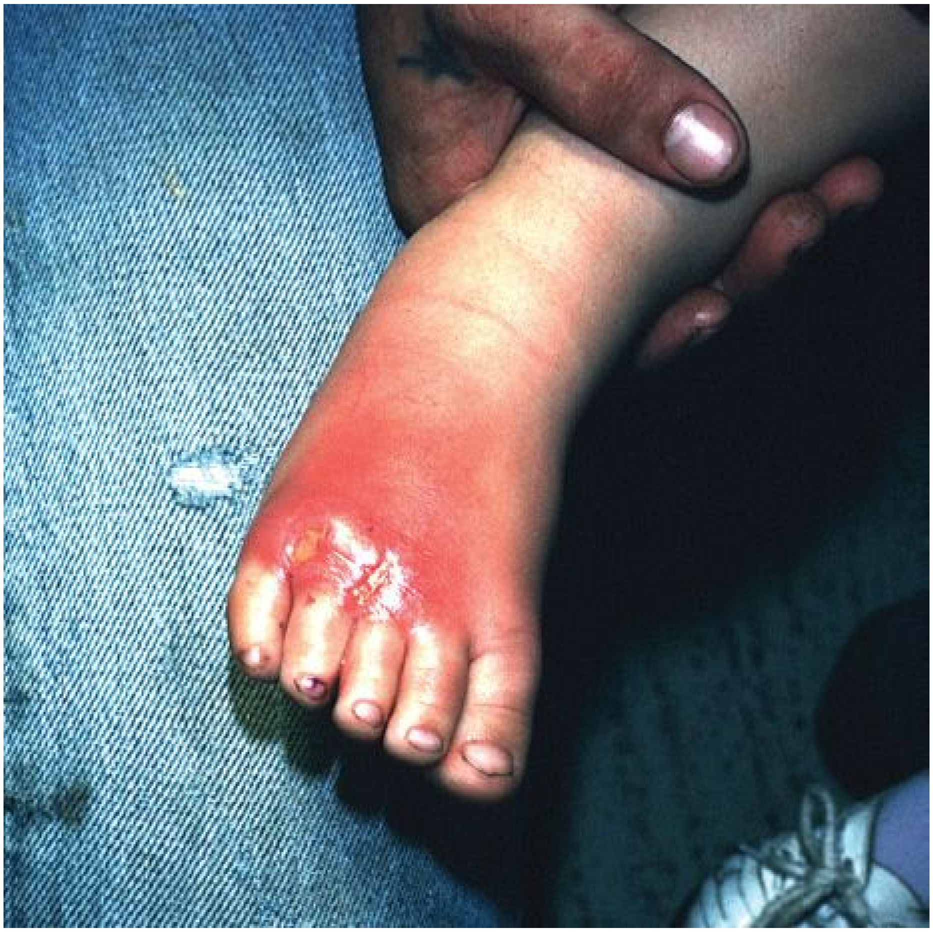

FIGURE 103-1 Cellulitis of the foot after an injury with a door in a 4-year-old girl. (*Used with permission from Richard P. Usatine, MD.*)

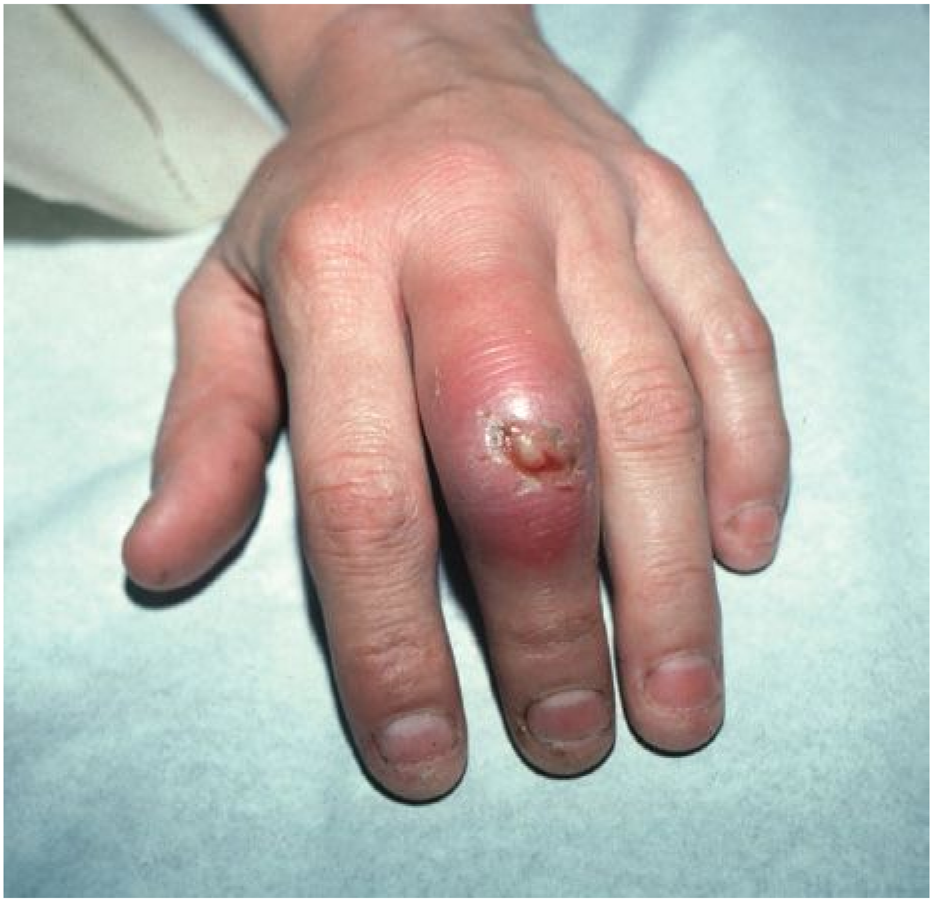

FIGURE 103-2 Cellulitis at the site of a clenched-fist injury when a young man hit another person on the tooth during a fight. This can result in a septic joint as well as a septic tenosynovitis. (*Used with permission from Richard P. Usatine, MD.*)

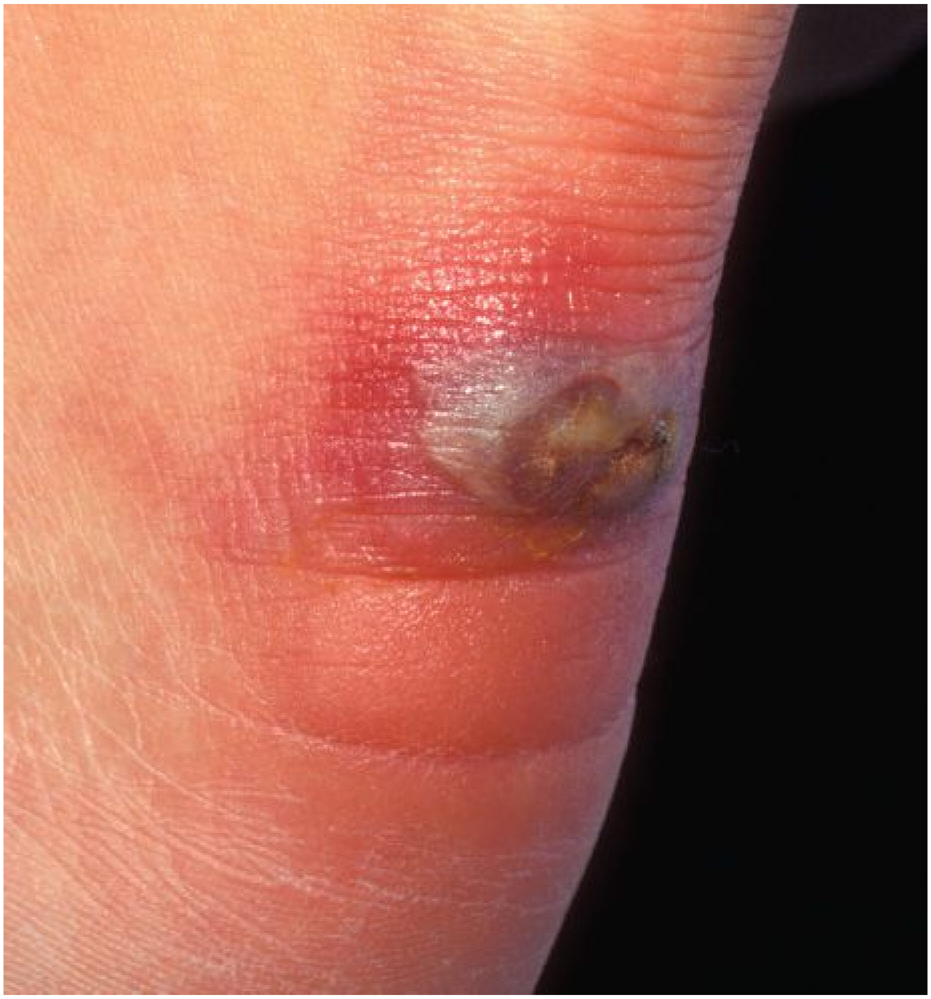

FIGURE 103-3 Group A β-hemolytic *Streptococcus* (GAS) cellulitis of the achilles heel that started as local trauma in a boy. (*Used with permission from Camille Sabella, MD.*)

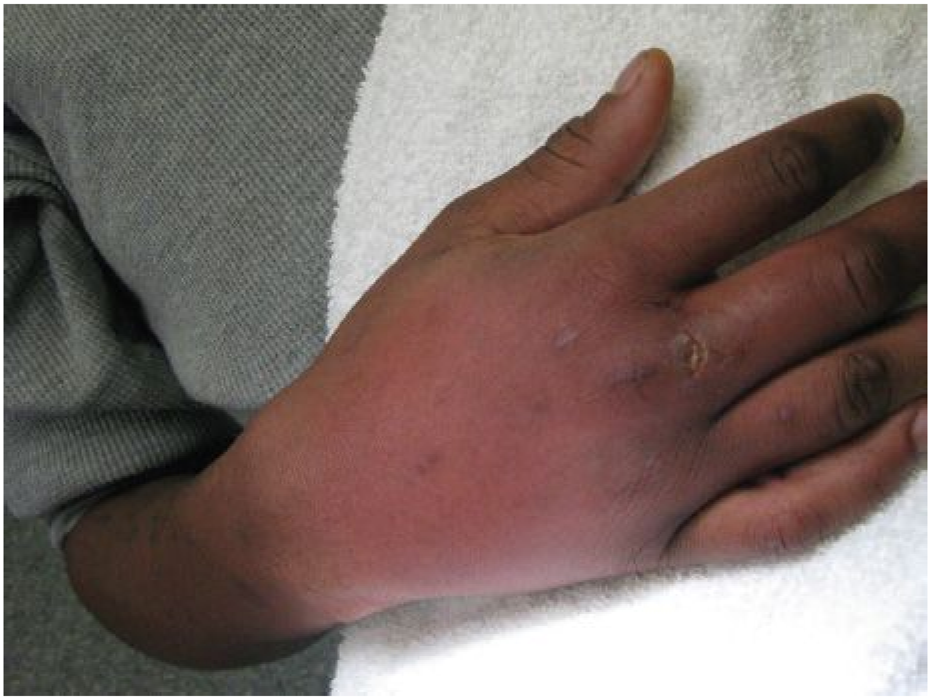

FIGURE 103-4 Cellulitis resulting from a cat bite injury in a child. The most likely organism is *Pasteurella multocida*. (*Used with permission from Emily Scott, MD.*)

- Is most often caused by group A β-hemolytic *Streptococcus* (GAS) (**Figure 103-3**) or *Staphylococcus aureus*. The most common etiology of cellulitis with intact skin, when it has been determined through needle aspiration and/or punch biopsy, is *S. aureus*, outnumbering GAS by a ratio of nearly 2:1.[2]
- There are increasing concerns about the role of community-acquired methicillin-resistant *S. aureus* (MRSA) in all soft-tissue infections including cellulitis.[3–6]
- After a cat or dog bite, cellulitis is often caused by *Pasteurella multocida* (**Figure 103-4**).
- After saltwater exposure, cellulitis can be secondary to *Vibrio vulnificus* in warm climates. A *Vibrio vulnificus* infection can be especially deadly.
- Erysipelas is a specific type of superficial cellulitis with prominent lymphatic involvement and leading to a sharply defined and elevated border **Figures 103-5** and **103-6**).

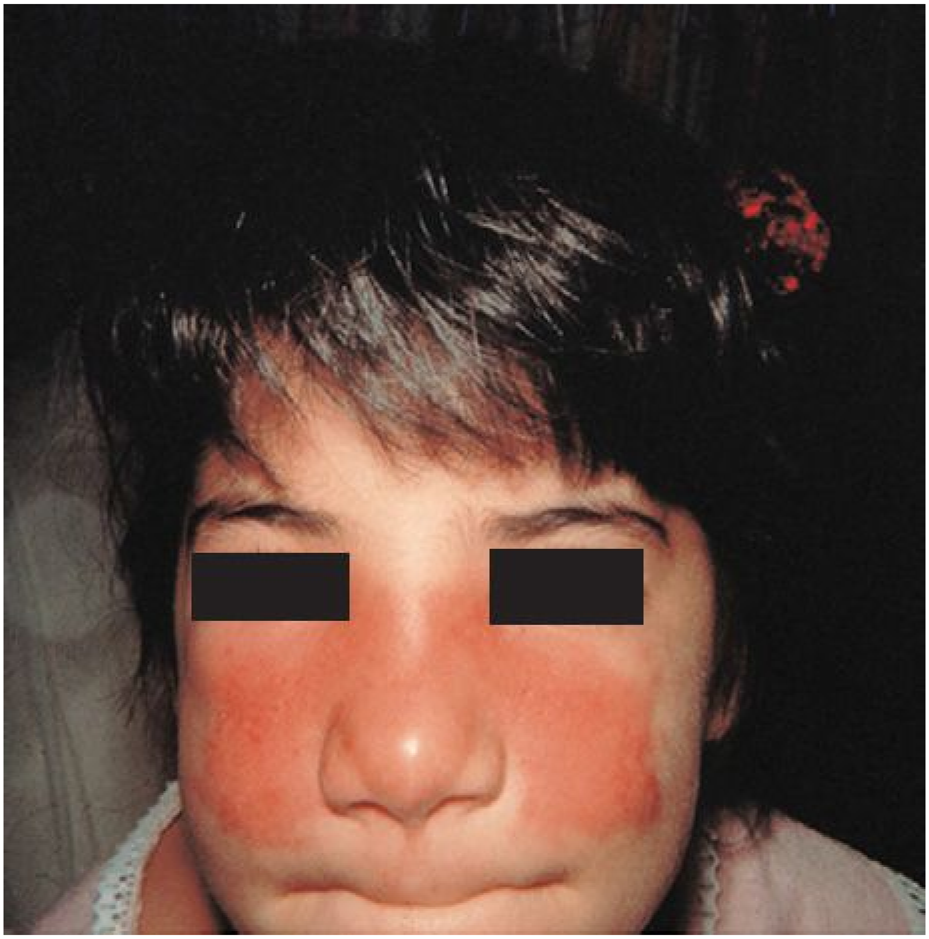

FIGURE 103-5 Butterfly rash of erysipelas. The sharp demarcation between the salmon-red erythema and the normal surrounding skin is evident. (*Reproduced with permission from Shah BR, Lucchesi M: Atlas of Pediatric Emergency Medicine, © 2006, McGraw-Hill, New York.*)

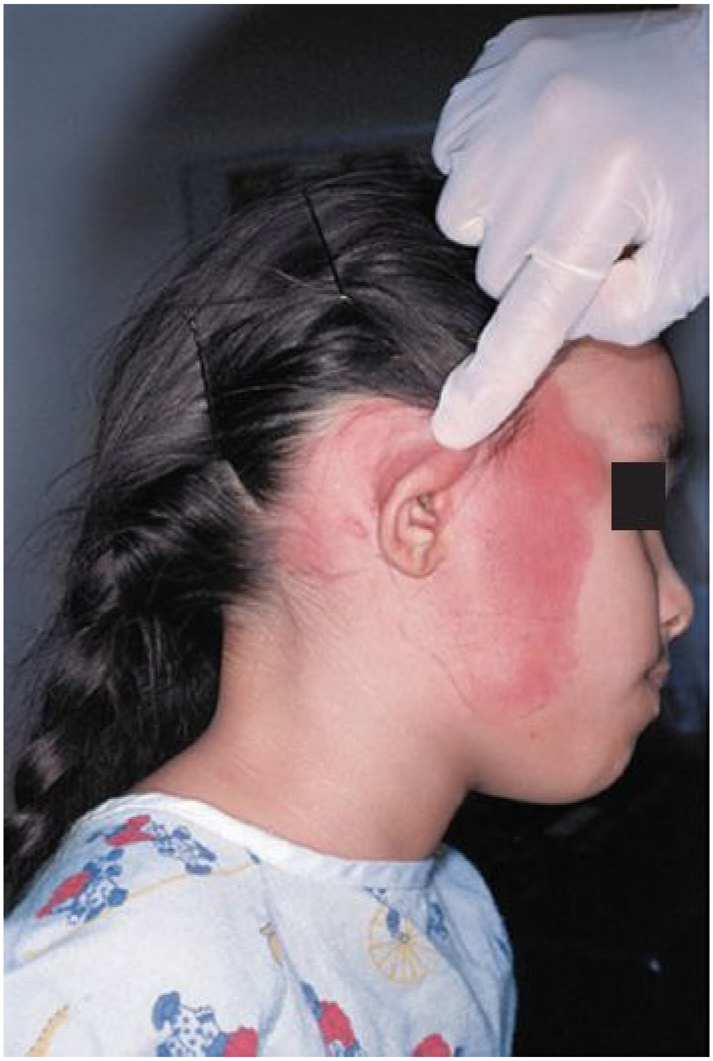

FIGURE 103-6 Erysipelas surrounding the ear of this girl. Note the well-demarcated borders were traced by a pen to monitor treatment progress. (*Reproduced with permission from Shah BR, Lucchesi M: Atlas of Pediatric Emergency Medicine, © 2006, McGraw-Hill, New York.*)

- Risk factors for hospitalization for staphylococcal skin infections in children in California were age less than 3 years, being Black, and lacking private insurance.[7]

DIAGNOSIS

CLINICAL FEATURES

Rubor (red), calor (warm), tumor (swollen), and dolor (painful).

TYPICAL DISTRIBUTION

Can occur on any part of the body, but is most often seen on the extremities and face (**Figures 103-1** to **103-6**). Periorbital cellulitis can be life-threatening (**Figure 103-7**). Infants can develop cellulitis around the umbilicus (omphalitis), which can spread rapidly through the umbilical vessels (**Figure 103-8**).

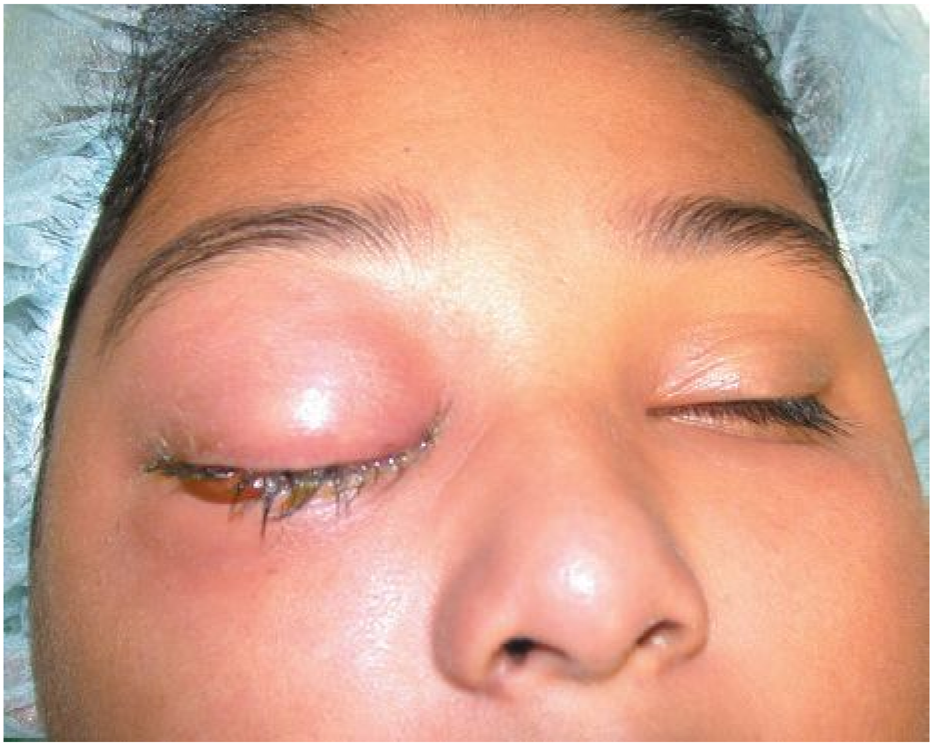

FIGURE 103-7 Life-threatening staphylococcal periorbital cellulitis requiring operative intervention. (*Used with permission from Frank Miller, MD.*)

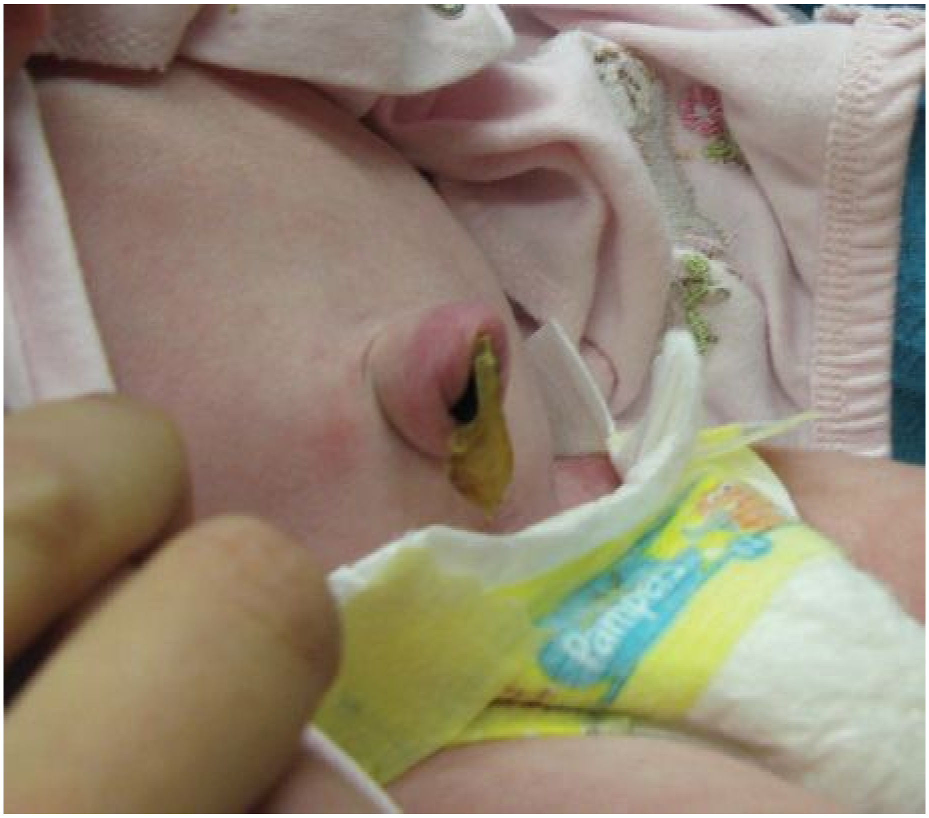

FIGURE 103-8 Omphalitis (cellulitis of the umbilicus) in a newborn. (*Used with permission from Emily Scott, MD.*)

LABORATORY TESTS

- Aspiration—If there is fluctuance within the area of erythema, a needle aspiration or incision and drainage should be performed (**Figure 103-9**). If pus is aspirated, perform a culture to guide antibiotic use.

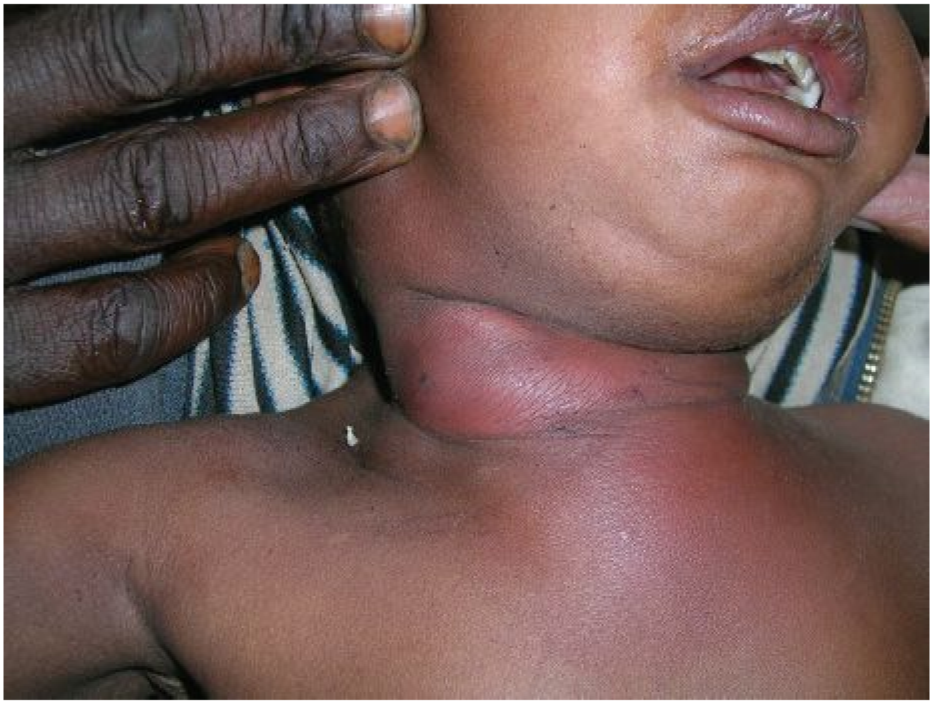

FIGURE 103-9 Cellulitis and abscess of the neck and chest in a 2-yearold girl in Ethiopia. Incision and drainage of the fluctuance over the neck revealed pus. A drain was placed to allow the pus to continue to drain from the incision site. She was treated with IV ceftriaxone and she survived. (*Used with permission from Richard P. Usatine, MD.*)

- Blood cultures—Results are positive in only 5 percent of cases and the results of culture of needle aspirations of the inflamed skin are variable and not recommended.[5]

DIFFERENTIAL DIAGNOSIS

- Abscess can have overlying erythema and appear like cellulitis. If fluctuance can be palpated this is often a sign of an underlying abscess. Sometimes the only way to tell the difference is to aspirate the area with a needle. Of course the two conditions can coexist when an abscess is surrounded by cellulitis (**Figure 103-9**; see Chapter 104, Abscess).

- Staphylococcal scalded skin syndrome (SSSS) is a toxin-mediated illness mediated by exfoliative toxins A and B of *Staphylococcus aureus*. The red skin can appear similar to a cellulitis at first but the exfoliation of skin should be a tip of that this is a toxin mediated illness (**Figure 103-10**; see Chapter 106, Staphylococcal Scalded Skin Syndrome).

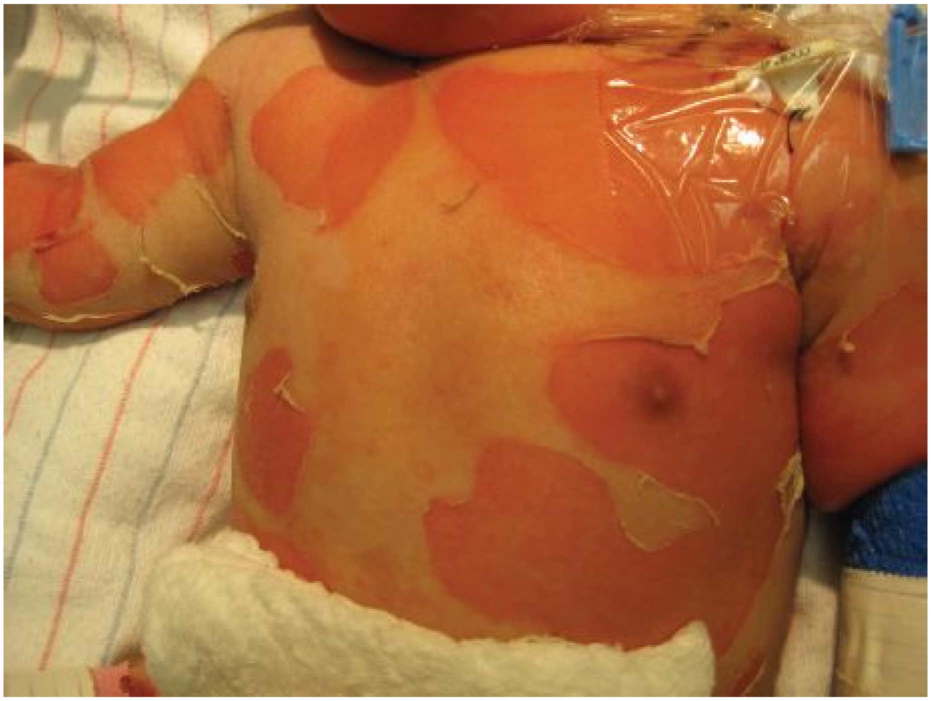

FIGURE 103-10 Erythema and desquamation of the skin in this infant with staphylococcal scalded skin syndrome. (*Used with permission from John C Browning, MD.*)

- Necrotizing fasciitis—Deep infection of the subcutaneous tissues and fascia with diffuse swelling, severe pain, and bullae in a toxic-appearing patient. It is important to recognize the difference between standard cellulitis and necrotizing fasciitis. Imaging procedures can detect gas in the soft tissues. Rapid progression from mild erythema to violaceous or necrotic lesions and/or bullae in a number of hours is a red flag for necrotizing fasciitis. The toxicity of the patient and the other physical findings should encourage rapid surgical consultation (see Chapter 106, Necrotizing Fasciitis).

MANAGEMENT

- The first decision is whether or not the patient needs hospitalization and IV antibiotics. It is often best to hospitalize any immunocompromised patients (e.g., HIV, transplant recipient, chronic renal or liver disease, on prednisone, diabetes out of control) with cellulitis because they may decompensate quickly. SOR Ⓒ
- Evidence comparing different durations of treatment and oral versus intravenous antibiotics is lacking.[8]
- Standard oral therapy for cellulitis not requiring hospitalization (in the pre-MRSA era) involves covering GAS and *S. aureus* with cephalexin or dicloxacillin.[5] SOR Ⓐ The typical duration is 7 to 10 days. SOR Ⓒ
- Penicillin-allergic patients may be treated with clindamycin rather than erythromycin because of macrolide resistance and increasing MRSA prevalence.[5] SOR Ⓐ
- Parenteral treatment is usually done with penicillinase-resistant penicillins or first-generation cephalosporins such as cefazolin, or, for patients with life-threatening penicillin allergies, clindamycin, or vancomycin.[5] SOR Ⓐ
- Although MRSA is increasing in its prevalence in skin and soft-tissue infections,[4] the difficulty in obtaining microbiologic cultures for cellulitis still makes it difficult to know how much MRSA is a problem in cellulitis with intact skin. If there is a coexisting abscess or crusting lesion, it is best to obtain a culture to guide therapy and start empiric therapy with trimethoprim-sulfamethoxazole and clindamycin.[3] SOR Ⓑ
- Do not miss necrotizing fasciitis. Patients with severe pain, bullae, crepitus, skin necrosis, or significant toxicity merit imaging and immediate surgical consultation (see Chapter 106, Necrotizing Fasciitis).
- Treat underlying conditions (e.g., atopic dermatitis, tinea pedis) that predispose the patient to the infection. SOR Ⓒ

PATIENT EDUCATION

Recommend that the patient rest and elevate the involved extremity. If outpatient therapy is followed, then provide precautions (e.g., vomiting and unable to hold medicine down) for which the patient should seek more immediate follow-up.

FOLLOW-UP

If prescribing oral outpatient therapy, consider follow-up in 1 to 2 days to assess response to the antibiotic and to determine the adequacy of outpatient therapy.

104 ABSCESS

Richard P. Usatine, MD

PATIENT STORY

A 2-year-old girl in Ethiopia is brought to see the visiting American doctor for a painful swollen hand. The hand was massively swollen and the child did not want to use it. On examination she had a temperature of 99° F and there was visible pus under the skin (**Figure 104-1**). An incision and drainage was performed and much pus and blood squirted from the abscess. The abscess was packed lightly to stop any bleeding and to prevent it from closing prematurely. Oral antibiotics were given to cover the surrounding cellulitis and any deeper infections. A culture to look for methicillin-resistant *Staphylococcus aureus* (MRSA) was not available in rural Ethiopia, but close follow-up was set for the next day and the patient was doing much better. The medical team performed twice daily home visits and administered the oral trimethoprim-sulfamethoxazole while changing the dressings. Within one week, the child was playing happily, the erythema and swelling were resolving, and she was beginning to use her hand again.

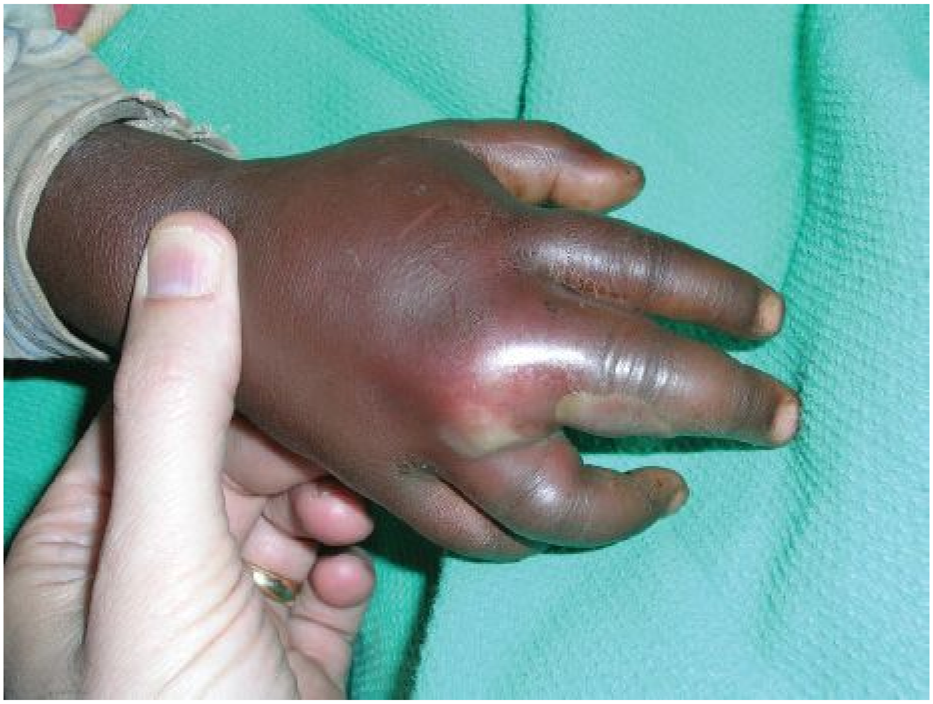

FIGURE 104-1 A large abscess of the hand in a 2-year-old girl in Ethiopia. Incision and drainage was performed and antibiotics were given to cover the surrounding cellulitis and any deeper infections. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

An abscess is a collection of pus in the infected tissues. The abscess represents a walled-off infection in which there is a pocket of purulence. In abscesses of the skin the offending organism is almost always *S. aureus*.

EPIDEMIOLOGY

- MRSA was the most common identifiable cause of skin and soft-tissue infections among patients presenting to emergency departments in 11 US cities. *S. aureus* was isolated from 76 percent of these infections and 59 percent were community-acquired MRSA (CA-MRSA).[1]

- Risk factors for MRSA infection and other abscesses—Intravenous drug abuse, homelessness, dental disease, contact sports, incarceration, and high prevalence in the community.
- In one review of serious skin infections in children admitted to a hospital in New Zealand, the most common types of infection were cellulitis (38%) and subcutaneous abscesses (36%).[2] The most frequent sites of infection were the head, face and neck (32%), and lower limbs (32%). The most frequently isolated organisms were *Staphylococcus aureus* (48%) and *Streptococcus pyogenes* (20%).[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Most cutaneous abscesses are caused by *S. aureus*.
- Risk factors for developing an abscess with MRSA include patients who work or are exposed to a health-care system, intravenous drug use, previous MRSA infection and colonization, recent hospitalization, being homeless, African American, and having used antibiotics within the last 6 months.[3]
- Risk factors for hospitalization for staphylococcal skin infections in children in California were age less than 3 years, being Black, and lacking private insurance.[4]
- CA-MRSA has become prevalent in the US. One study that evaluated management of skin abscesses drained in the emergency department showed that there was no significant association between amount of surrounding cellulitis or abscess size with the likelihood of MRSA-positive cultures.[3]

DIAGNOSIS

CLINICAL FEATURES

Collection of pus in or below the skin. Patients often feel pain and have tenderness at the involved site. There is swelling, erythema, warmth, and fluctuance in most cases (**Figures 104-1** to **104-3**). Determine if the patient is febrile and if there is surrounding cellulitis.

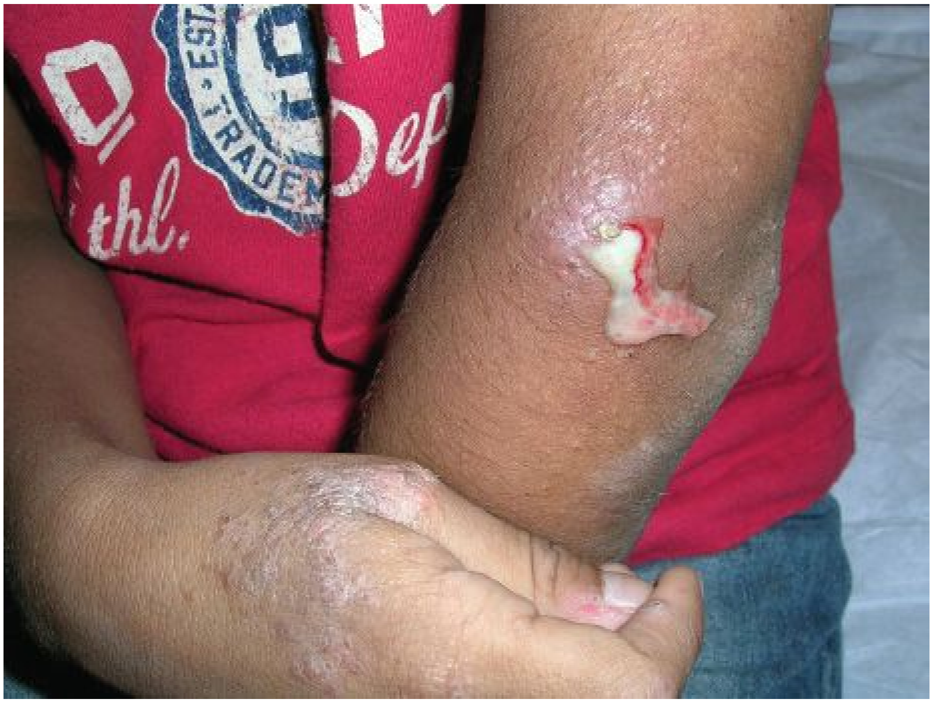

FIGURE 104-2 An atopic boy with bilateral abscesses on the elbows. This abscess drained spontaneously once gentle pressure was applied to the area of fluctuance. The culture revealed *S. aureus* sensitive to methicillin and all the skin infections cleared with oral antibiotics. The atopic dermatitis was treated successfully with 0.1 percent triamcinolone ointment. (*Used with permission from Richard P. Usatine, MD.*)

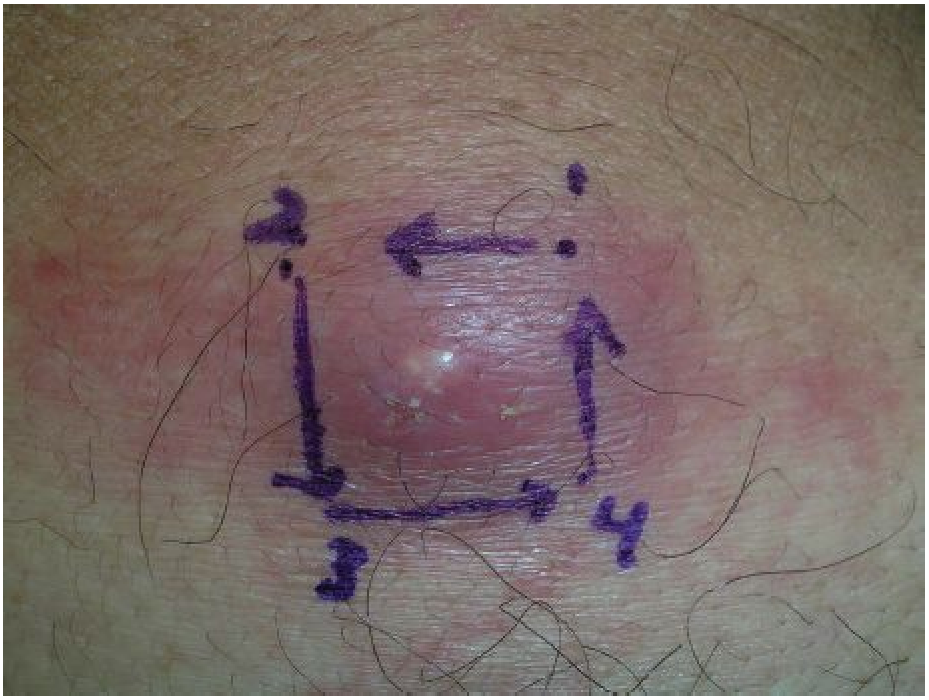

FIGURE 104-3 MRSA abscess on the back of the neck that patient thought was a spider bite. Note that a ring block was drawn around the abscess with a surgical marker to demonstrate how to perform this block. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

Skin abscesses can be found anywhere from head to feet. Frequent sites include the hands, feet, extremities (**Figure 104-2**), head, neck, buttocks, and breast.

One type of abscess occurring in the pulp of a distal digit (usually a finger) is called a felon (**Figures 104-4**). This is particularly painful and requires a digital block for incision and drainage.

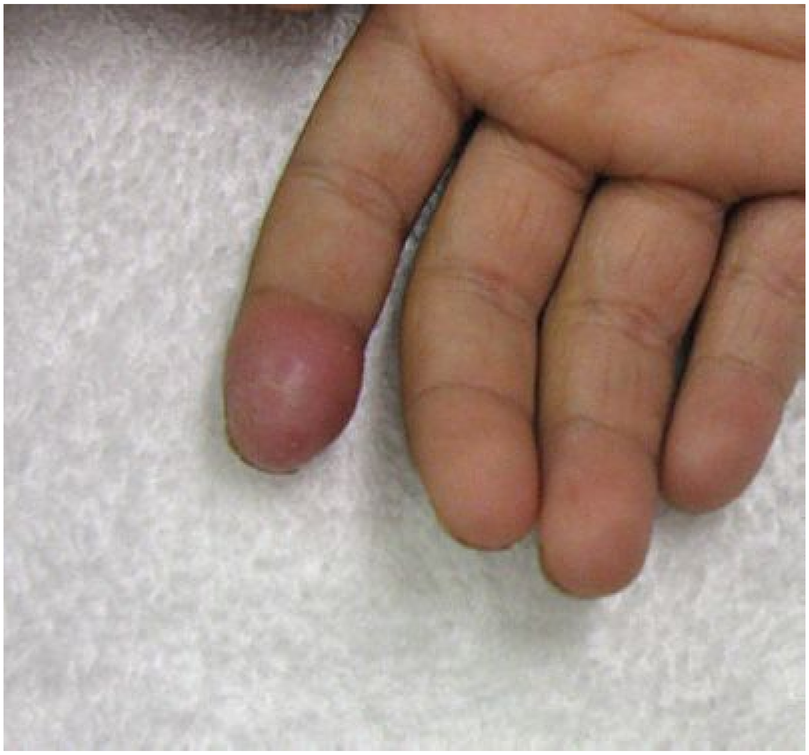

FIGURE 104-4 Felon. An abscess in the pulp of the distal finger. A digital block was required to incise and drain this soft tissue abscess. (*Used with permission from Emily Scott, MD.*)

LABORATORY STUDIES

Clinical cure is often obtained with incision and drainage alone so the benefits of pathogen identification and sensitivities are low in low-risk patients.[3] Most clinical studies have excluded patients who were immunocompromised, diabetic, or had other significant comorbidities.[3] Consequently, it may be reasonable to obtain wound cultures in high-risk patients, those with signs of systemic infection, and in patients with history of high recurrence rates.[3,5]

DIFFERENTIAL DIAGNOSIS

- Epidermal inclusion cyst with inflammation/infection—These cysts (also known as sebaceous cysts) can become inflamed, swollen, and superinfected. Although the initial erythema may be sterile inflammation, these cysts can become infected with *S. aureus*. The treatment consists of incision and drainage and antibiotics if cellulitis is also present. If these are removed before they become inflamed, the cyst may come out intact (**Figure 104-5**).

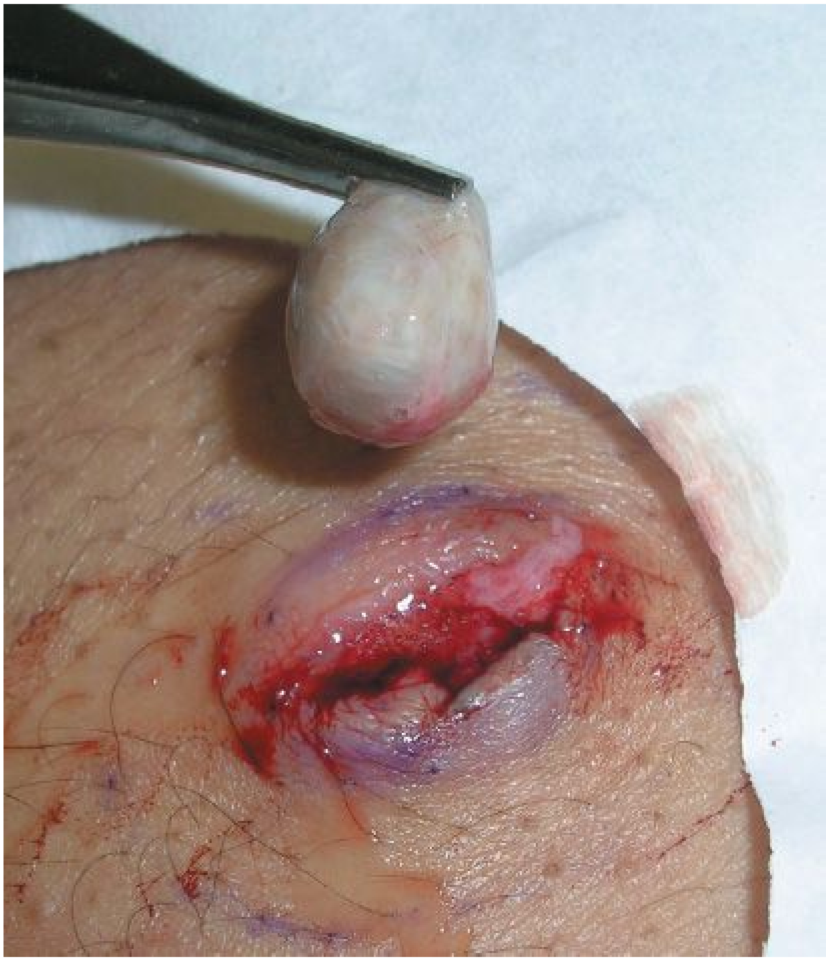

FIGURE 104-5 Epidermal inclusion cyst removed intact. There is no need for antibiotics in this case. (*Used with permission from Richard P. Usatine, MD.*)

- Cellulitis with swelling and no pocket of pus—When it is unclear if an area of infected skin has an abscess, needle aspiration with a large-gauge needle may be helpful to determine whether to incise the skin. Cellulitis alone should have no area of fluctuance (see Chapter 103, Cellulitis).

- Hidradenitis suppurativa—Recurrent inflammation surrounding the apocrine glands of the axilla and inguinal areas (see Chapter 98, Hidradenitis Suppurativa).
- Furuncles and carbuncles—A furuncle or boil is an abscess that starts in hair follicle or sweat gland. A carbuncle occurs when the furuncle extends into the subcutaneous tissue.
- Acne cysts—More sterile inflammation than true abscess, often better to inject with steroid rather than incise and drain (see Chapter 96, Acne Vulgaris).

MANAGEMENT

- The evidence strongly supports the incision and drainage of an abscess.[3,6] SOR Ⓐ Inject 1 percent lidocaine with epinephrine into the skin at the site you plan to open using a 27-gauge needle. A ring block can be helpful rather than injecting into the abscess itself (**Figure 104-3**). Open the abscess with a linear incision using a #11 blade scalpel following skin lines if possible.[7]
- Although many physicians still pack a drained abscess with ribbon gauze, there is limited data on whether or not packing of an abscess cavity improves outcomes. A small study concluded that routine packing of simple cutaneous abscesses is painful and probably unnecessary.[8] SOR Ⓒ The author of this chapter often packs abscesses lightly and has the patient remove the packing in the shower 2 days later, avoiding additional visits and painful repacking of the healing cavity. SOR Ⓒ However, if a large abscess is not packed it can seal over and the pus may reaccumulate.
- Routine use of antibiotics for an initial abscess in addition to incision and drainage is not supported by current evidence.[3,9–11] SOR Ⓐ Three randomized controlled trials (RCTs) performed since the emergence of CA-MRSA have demonstrated that antibiotics do not significantly improve healing rates of superficial skin abscesses, but two of these

studies suggest that antibiotics do decrease short-term rates of new lesion development.[9–11]

- A recent meta-analysis of systemic antibiotics after incision and drainage of simple abscess in children and adults showed that antibiotics did not significantly improve the percentage of patients with complete resolution of their abscesses 7–10 days after treatment.[12]
- Consider the use of oral antibiotics to treat an abscess with suspected CAMRSA in patients who are febrile or have systemic symptoms, have significant surrounding cellulitis, have failed incision and drainage alone, have frequent recurrences, or have a history of close contacts with abscesses.3SOR Ⓒ
- If an antibiotic is to be used, CA-MRSA is close to 100 percent sensitive to trimethoprim-sulfamethoxazole.3SOR Ⓑ Alternative antibiotics include oral clindamycin, tetracycline (for children 8 years of age and older), or doxycycline (for children 8 years of age and older). Local sensitivity data should be consulted when available.3SOR Ⓑ
- There is no current data to support the use of an antimicrobial medication (mupirocin or rifampin) in the eradication of MRSA colonization.[3]SOR Ⓒ

PATIENT EDUCATION

Patients may shower daily 24 to 48 hours after incision and drainage and then reapply dressings. Patients should be given return precautions for worsening of symptoms or continued redness, pain, or pus.

FOLLOW-UP

In patients or wounds at higher risk for complications, follow-up should be scheduled in 24 to 48 hours. If packing was placed, it can be removed by the patient or a family member.

105 STAPHYLOCOCCAL SCALDED SKIN SYNDROME

Camille Sabella, MD
Charles B. Foster, MD

PATIENT STORY

An 18-month-old girl is admitted to the hospital with fever, irritability, and a tender skin rash on her face. She also has developed facial swelling bilaterally and perioral crusting (**Figure 105-1**). Over the next 24 hours, the rash spreads to her neck and trunk and she develops flaccid blisters on the areas of rash on her neck and trunk. When gentle friction is applied to involved areas of the skin, the skin easily sloughs superficially (Nikolsky sign). She is treated with intravenous anti-staphylococcal antibiotics and recovers completely. A culture taken from her nares grows *Staphylococcal aureus*.

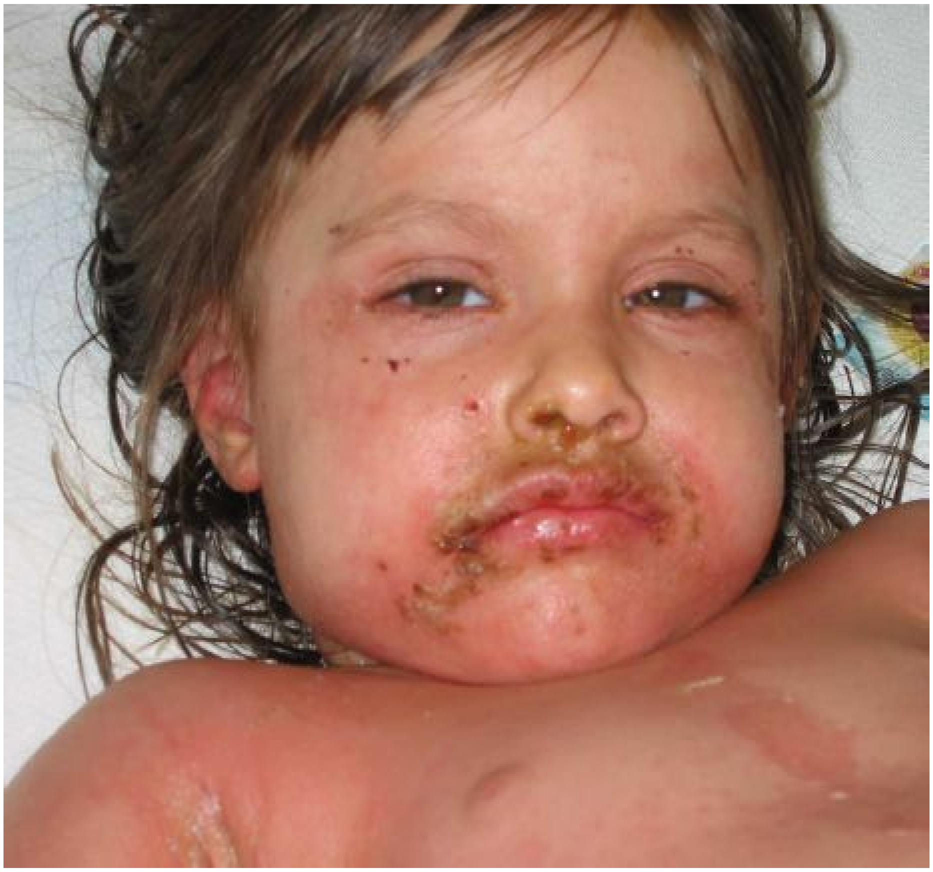

FIGURE 105-1 18-month-old girl with SSSS. Note the edema of the face, perioral crustiness, and extension of the erythema to the neck and trunk. Also note the thin desquamation on the chest and axilla. (*Used with permission from Camille Sabella, MD.*)

INTRODUCTION

Staphylococcal scalded skin syndrome (SSSS) is a toxin-mediated illness mediated by exfoliative toxins A and B of *Staphylococcus aureus*.

SYNONYMS

Ritter syndrome (SSSS in neonates and young infants).

EPIDEMIOLOGY

- Occurs mainly in children under 5 years of age.
- May also occur in neonates after becoming colonized or infected with a toxin-producing strain of *S aureus* (Ritter syndrome).

ETIOLOGY AND PATHOPHYSIOLOGY

- Exfoliative toxins A and B of *S aureus* are responsible for the manifestations of the illness.[1,2]
- Mostly caused by *S aureus* belonging to phage group II, types 71 and 55.
- Toxins are hematogenously spread and produce the fever and characteristic rash.
- Toxin targets desmoglein 1, resulting in cleavage of the epidermis in a superficial location.[3,4]

RISK FACTORS

- Primary infection with toxin-producing *S aureus* at sites other than the skin, such as the umbilicus (in neonates), nasopharynx, or conjunctiva.

DIAGNOSIS

CLINICAL FEATURES

- Fever, irritability, and tender erythema of the skin are common.
- Facial edema with perioral and periocular crustiness is typical and may be the primary clinical features (**Figures 105-2** to **105-4**).

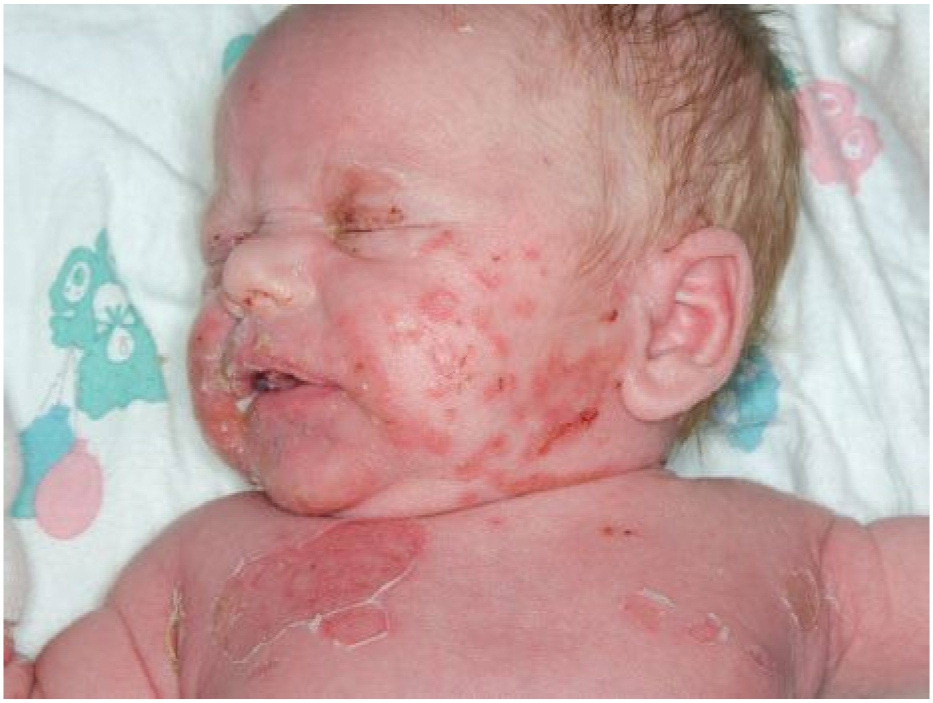

FIGURE 105-2 One-month-old infant with SSSS. Note the crustiness on the face and facial edema. (*Used with permission from Charles B. Foster, MD.*)

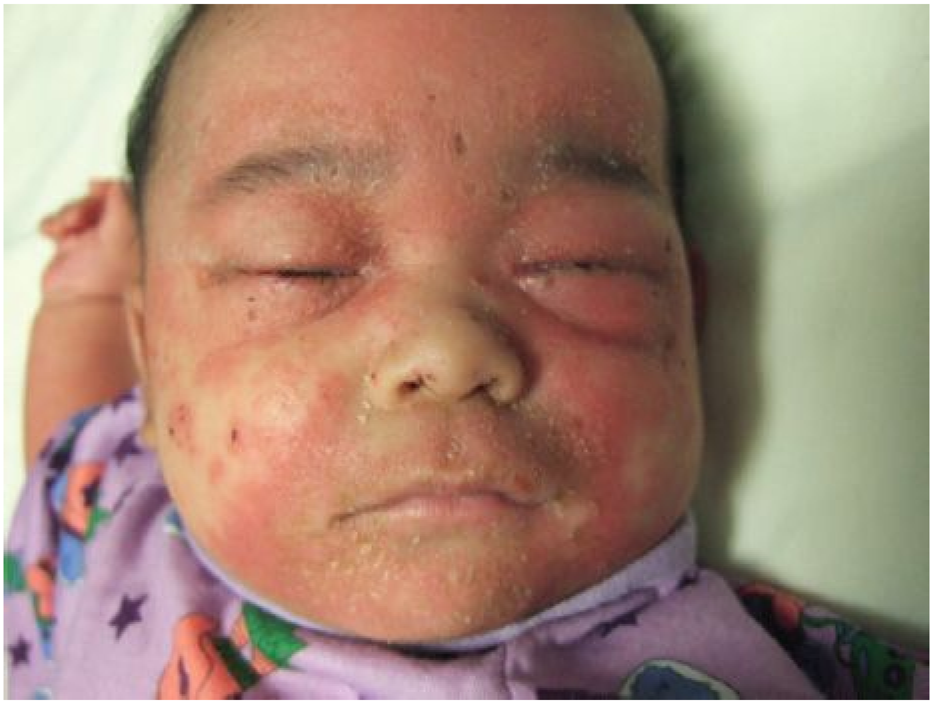

FIGURE 105-3 Infant with edema and crustiness on the face typical for SSSS. (*Used with permission from John C Browning, MD.*)

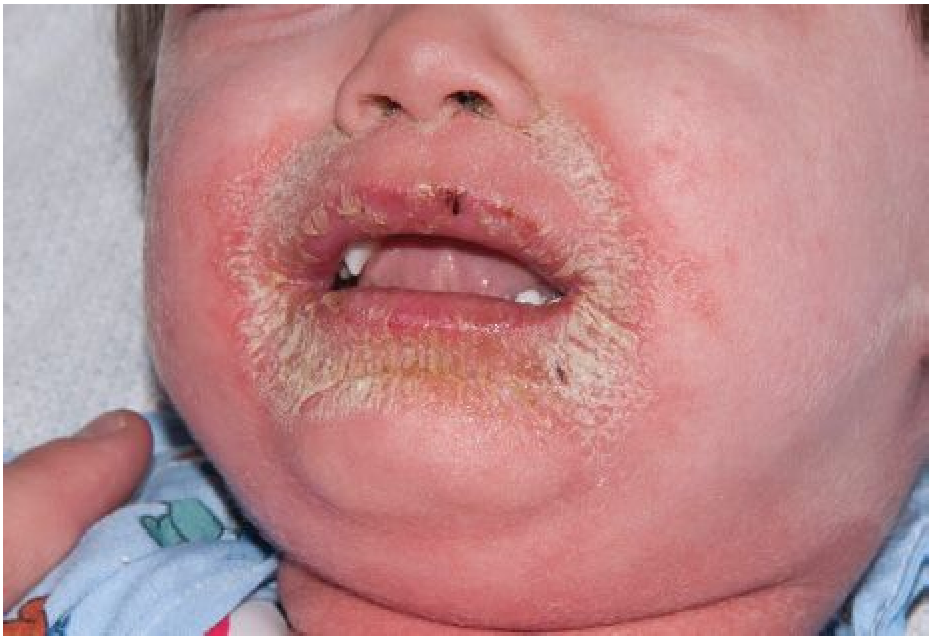

FIGURE 105-4 Toddler with SSSS and marked perioral crustiness, erythema, and edema. (*Used with permission from Camille Sabella, MD.*)

- Flaccid blisters and superficial erosions form within 12 to 24 hours, and which progress to become widespread superficial peeling of the skin (**Figure 105-5**).

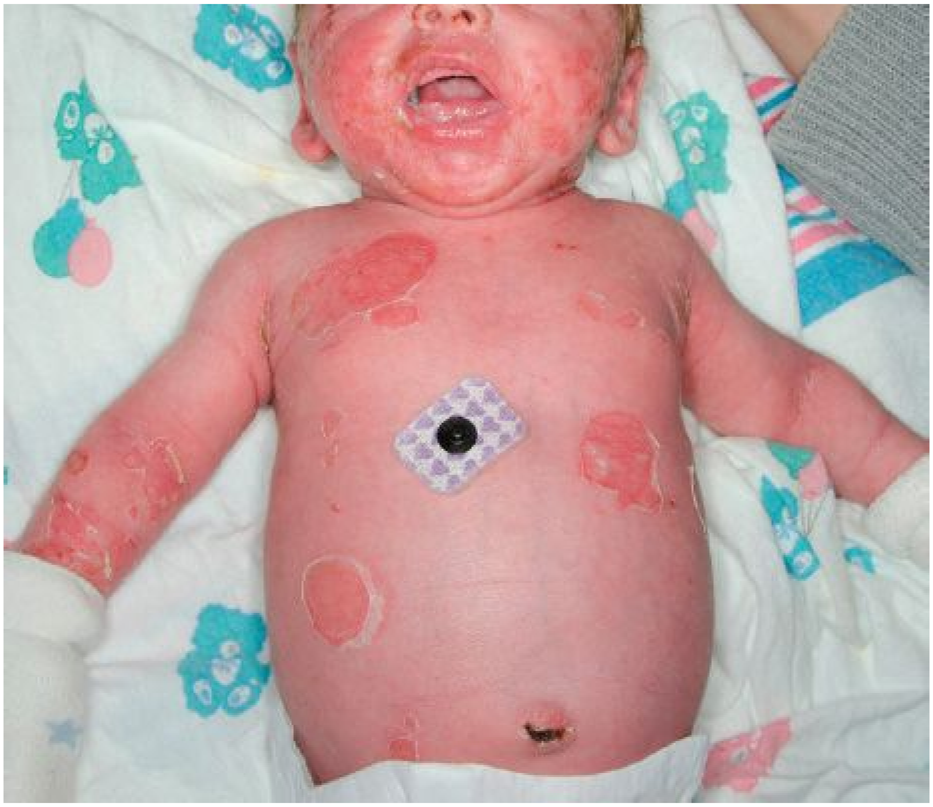

FIGURE 105-5 Same infant as in Figure 105-2, with thin widespread blisters on the trunk. (*Used with permission from Charles B. Foster, MD.*)

- Gentle sheering of the skin often results in widespread separation (Nikolsky sign).
- Desquamation of the skin often follows at the involved skin sites (**Figure 105-6**).[5,6]

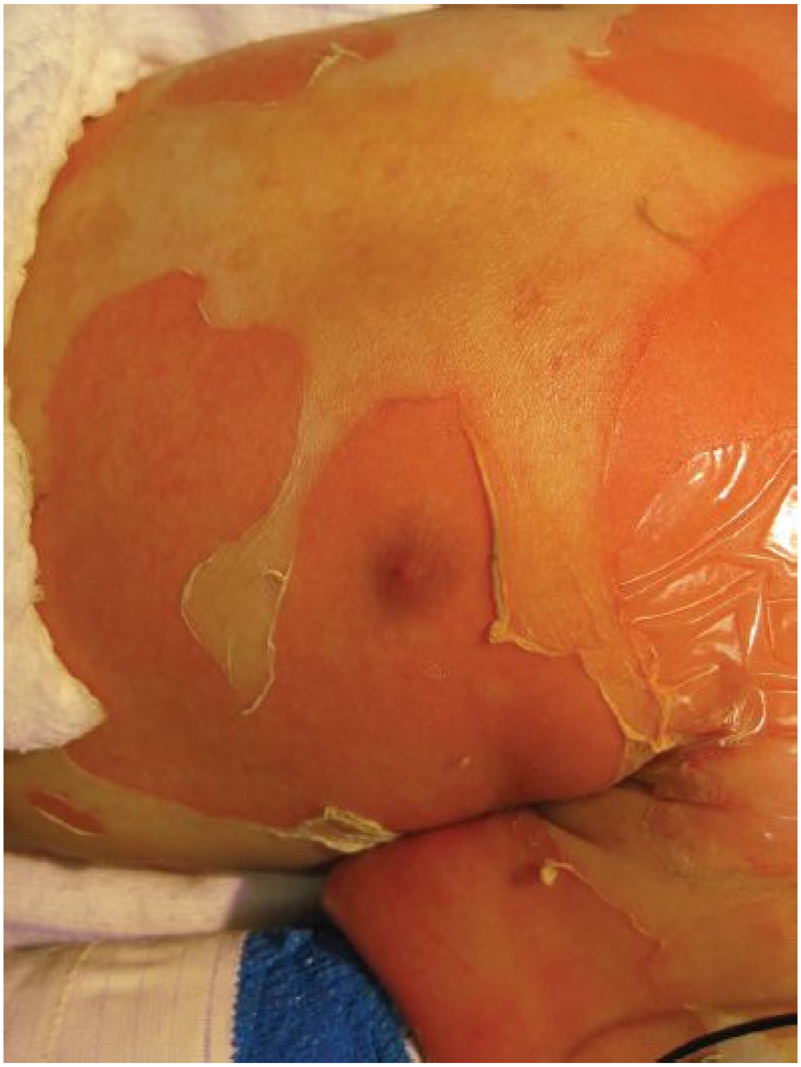

FIGURE 105-6 Desquamation of the skin in this infant with SSSS. (*Used with permission from John C Browning, MD.*)

DISTRIBUTION

- The face, neck, and trunk are most often involved.
- Mucosal surfaces are spared.

LABORATORY TESTING

- The diagnosis is usually made clinically, based on the characteristic features and response to conventional therapy.
- Isolation of *S aureus* from a site distant to the skin—usually the nasopharynx, conjunctiva, site of circumcision, umbilicus (in neonates)—helps to support the diagnosis. Demonstration of toxin production by the isolate provides more definitive diagnosis, but this is rarely performed or required.
- Cultures from the skin lesions and blister fluid are negative for *S aureus*.
- Bacteremia is rare.

SURGERY

- Skin biopsy is usually not necessary for the diagnosis.
- When performed, skin biopsy reveals separation of skin layers at the granular layer within the epidermis.[7]

DIFFERENTIAL DIAGNOSIS

- Drug-induced toxic epidermal necrolysis—Inciting agent often present; mucus membranes usually involved; biopsy shows separation of the skin between the epidermis and the dermis (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis).[7]
- Scarlet fever—Rash rough, “sandpapery;” pharyngitis and strawberry tongue often present; school aged children are most commonly affected (see Chapter 28, Scarlet Fever and Strawberry Tongue).
- Kawasaki disease—More persistent and higher fever, mucus membrane involvement; rash polymorphous, extremity changes, and lymphadenopathy usually present (see Chapter 177, Kawasaki Disease).
- Toxic Shock Syndrome—Hemodynamic changes present by definition with significant drop in blood pressure (see Chapter 185, Toxic Shock

Syndromes).

MANAGEMENT

NONPHARMACOLOGIC

- Supportive—Careful attention to hydration status, electrolyte levels, antipyretics, and anti-analgesics.
- Meticulous attention to wound care and antiseptic measures to prevent superinfection of the skin.
- The skin can be gently moistened and cleansed with isotonic saline or aluminum acetate solution.

MEDICATIONS

- Systemic intravenous anti-staphylococcal antibiotics (such as Nafcillin) is utilized to reduce bacterial burden. This results in prompt clinical improvement. SOR Ⓒ
- Oral anti-staphylococcal agents are not effective initially.
- Transition from an intravenous to an oral agent can be undertaken after there is clear clinical improvement, to complete a 7- to 10-day course of therapy. SOR Ⓒ
- Topical antibiotics are not effective and not necessary.
- Application of an emollient, such as petrolatum ointment, can provide lubrication and decreases discomfort.

PROGNOSIS

- The majority of affected children do well and recover without sequelae.
- Healing of the skin occurs without scarring.
- Dehydration and superinfection can occur with major exfoliation.

106 NECROTIZING FASCIITIS

Richard P. Usatine, MD
Jeremy A. Franklin, MD
Camille Sabella, MD

PATIENT STORIES

A 9-day-old neonate presented with high fever, moaning, and slightly indurated swelling with bluish discoloration on the back (**Figure 106-1**). Within 12 hours, there was vesiculation and purplish discoloration. The infant was diagnosed with necrotizing fasciitis and surgery was consulted immediately. The first surgical exploration and débridement and shows the underlying muscle and necrotic borders. Both blood and tissue cultures grew *Staphylococcus aureus*. Multiple surgical explorations and débridement were performed followed by skin grafting during recovery. The infant survived with scarring but no other sequelae.

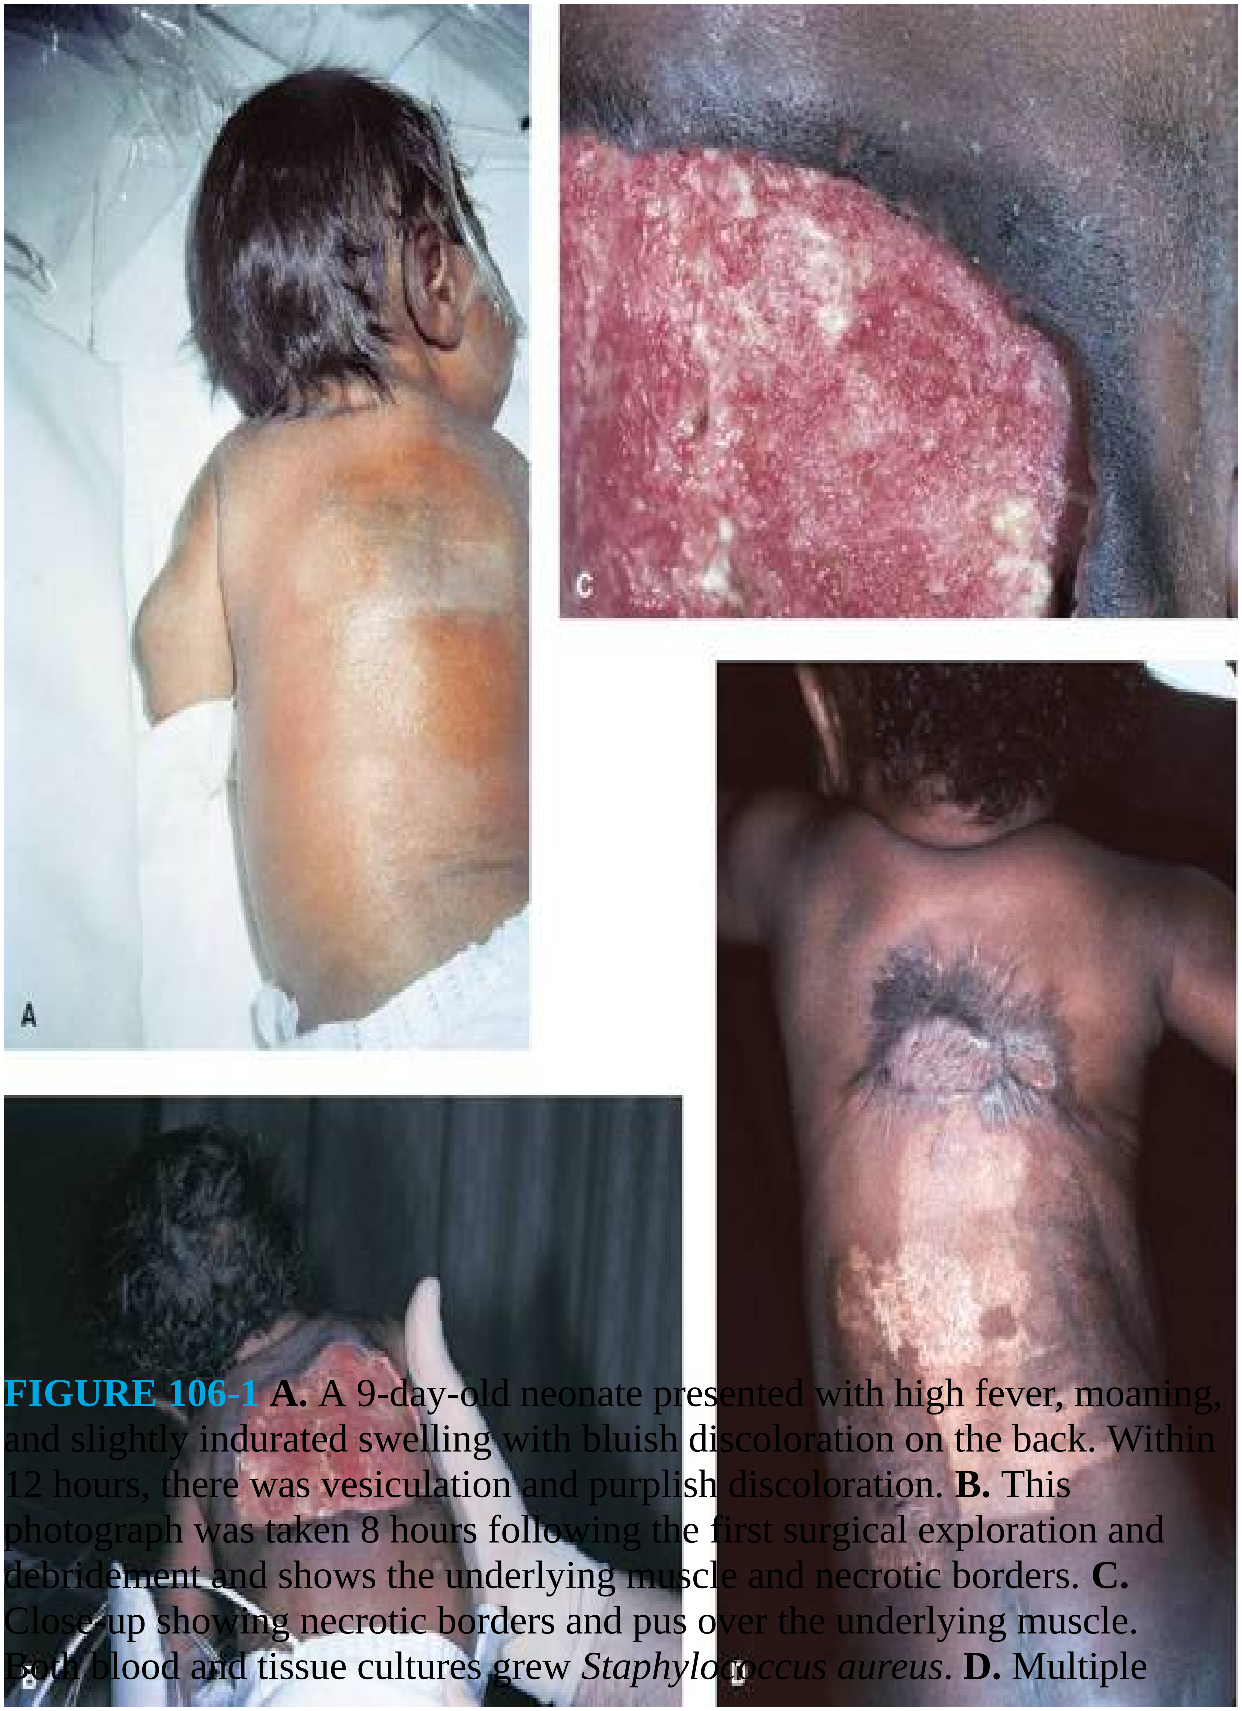

FIGURE 106-1 **A.** A 9-day-old neonate presented with high fever, moaning, and slightly indurated swelling with bluish discoloration on the back. Within 12 hours, there was vesiculation and purplish discoloration. **B.** This photograph was taken 8 hours following the first surgical exploration and debridement and shows the underlying muscle and necrotic borders. **C.** Close-up showing necrotic borders and pus over the underlying muscle. Both blood and tissue cultures grew *Staphylococcus aureus*. **D.** Multiple

surgical explorations and débridement were performed followed by skin grafting during recovery. (*Used with permission from Shah BR, Lucchesi M. The Atlas of Pediatric Emergency Medicine, McGraw-Hill, 2006, p. 87*.)

A 16-year-old female presented with necrotizing fasciitis of the left gluteal region following an intramuscular injection received in rural India. She was febrile and in septic shock. The entire left gluteal region had full thickness necrosis and was emitting a foul odor. The skin was violaceous with purple bullae and areas of exfoliation. Previous attempts at incision and drainage were not helpful. She was treated with intravenous fluids, antibiotics and full-thickness extensive surgical debridement in the operating room. She became afebrile and hemodynamically stable. Her subsequent treatment consisted of negative pressure wound therapy followed by skin grafting. She survived with scarring and contour deformities but no other sequelae (**Figure 106-2**).

INTRODUCTION

Necrotizing fasciitis (NF) is a rapidly progressive infection of the deep fascia, with necrosis of the subcutaneous tissues. In children, it usually occurs after surgery, trauma, or varicella infection. Patients have erythema and pain disproportionate to the physical findings. Immediate surgical debridement and antibiotic therapy should be initiated.[1]

SYNONYMS

- Flesh-eating bacteria, necrotizing soft-tissue infection (NSTI), suppurative fasciitis, hospital gangrene, and necrotizing erysipelas. Fournier gangrene is a type of NF or NSTI in the genital and perineal region.[2]

EPIDEMIOLOGY

- Overall incidence of NF in children (<16 years of age) is 2.93 cases per million population per year, according to a recent population-based active surveillance study from Canada; incidence is 0.81 per million for non–Group A Streptococcus-related cases, and 2.12 per million for Group A Streptococcus (GAS)-related cases.[3]
- For non-GAS-related cases, NF typically occurs in children with underlying medical conditions, such as diabetes mellitus, trauma or recent surgery.[3]

- NF caused by *Streptococcus pyogenes* is the most common form of NF in children and adults.[3]
- Non-GAS-related cases are most common in infants less than one-year of age; pre-existing risk factors, such as prematurity, are common, and many of these cases occur in association with omphalitis or circumcision.
- Most cases of GAS-related NF are associated with varicella (**Figure 106-3**).[3,4]

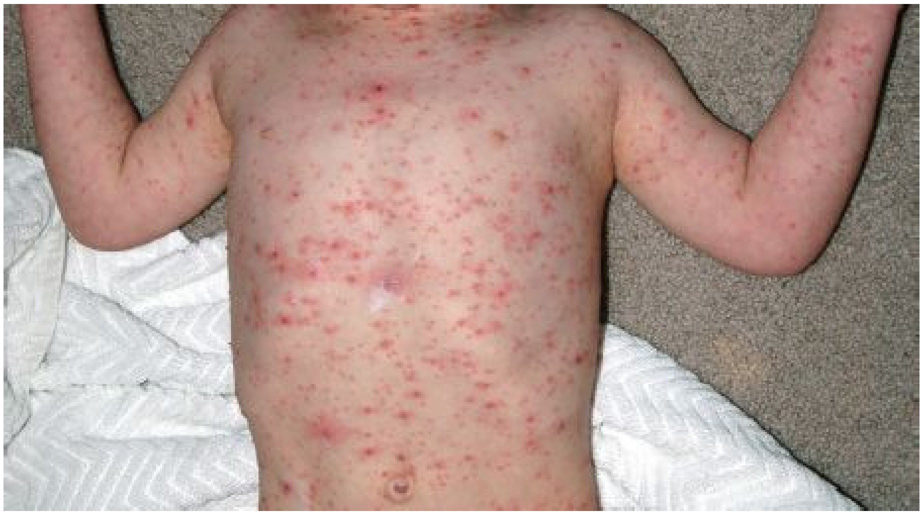

FIGURE 106-3 Varicella in an unimmunized toddler. Although this child did not develop necrotizing fasciitis, bacterial superinfection with Streptococcus pyogenes of varicella lesions is one of the most important predisposing factors for necrotizing fasciitis in children. (*Used with permission from Camille Sabella, MD.*)

ETIOLOGY AND PATHOPHYSIOLOGY

- Type I NF is a polymicrobial infection with aerobic and anaerobic bacteria:
  - Frequently caused by enteric Gram-negative pathogens including *Enterobacteriaceae* organisms and *Bacteroides*.
  - Can occur with Gram-positive organisms such as non-group A streptococci and *Peptostreptococcus*.[5]

  - Saltwater variant can occur with penetrating trauma or an open wound contaminated with saltwater containing marine vibrios. *Vibrio vulnificus* is the most virulent.[6]
  - Up to 15 pathogens have been isolated in a single wound.
  - Average of five different isolates per wound.[7]
- Type II NF is the most common form in children and is generally a monomicrobial infection caused by GAS:
  - May occur in combination with Staphylococcus aureus.
  - Methicillin-resistant S. aureus is no longer a rare cause of NF.5
  - GAS may produce pyrogenic exotoxins, which act as superantigens to stimulate production of tumor necrosis factor (TNF)-a, TNF-b, interleukin (IL)-1, IL-6, and IL-2.[7]

RISK FACTORS

- Risk factors for type I NF (polymicrobial):
  - Diabetes mellitus.
  - Prematurity.
  - Severe peripheral vascular disease.
  - Obesity.
  - Alcoholism and cirrhosis.
  - Intravenous drug use.
  - Decubitus ulcers.
  - Poor nutritional status.
  - Postoperative patients or those with penetrating trauma.
  - Abscess of the female genital tract.
- Risk factors of type II NF (GAS and *S. aureus*):
  - Varicella.[3,4]
  - Burns.
  - Penetrating trauma.

DIAGNOSIS

Early recognition based on signs and symptoms is potentially life saving. Although lab tests and imaging studies can confirm ones' clinical impression, rapid treatment with antibiotics and surgery are crucial to improving survival.

CLINICAL FEATURES

- Soft tissue swelling and pain often appears at the site of trauma or a varicella lesion. This becomes apparent 3 to 4 days after the onset of the exanthem.
- Infants and young children are often irritable and fussy; older children may refuse to bear weight on an involved extremity or refuse to walk.
- Rapid progression of erythema to bullae (**Figure 106-2**), ecchymosis, and necrosis or gangrene.
- The erythematous skin may develop a dusky violaceous discoloration. Vesicular and bullous lesions form over the erythematous skin, with some serosanguineous drainage. The bullae may become violaceous (**Figure 106-2**). The skin can become gangrenous and develop a black eschar.[2]
- Edematous, wooden feel of subcutaneous tissues extending beyond the margin of erythema.
- High fevers and severe systemic toxicity.
- Unrelenting intense pain out of proportion to cutaneous findings.
- Pain progresses to cutaneous anesthesia as disease evolves. Anesthesia of the skin develops as a result of infarction of cutaneous nerves.[2]
- Crepitus occurs when there is gas in the soft tissues.
- Unresponsive to empiric antimicrobial therapy.
- May progress to toxic shock syndrome, especially with associated with GAS infection.[5]

TYPICAL DISTRIBUTION

- May occur at any anatomic location.
- Common sites of involvement include the lower extremities (**Figures 106-2**), trunk (**Figure 106-1**), abdomen, gluteal region, upper extremities, and perineum (Fournier gangrene).

LABORATORY AND IMAGING

- Routine laboratory tests are nonspecific but common findings include an elevated white blood cell count (WBC), a predominance of immature neutrophils, a low serum sodium, and a high blood urea nitrogen (BUN).
- Histology and culture of deep tissue biopsy are essential; surface cultures cannot be relied on alone. Gram staining of the exudate may provide clues about the pathogens while awaiting culture results.[2]
- Aerobic and anaerobic blood cultures should be obtained in an attempt to identify the causative organism.
- Standard radiographs are of little value unless air is demonstrated in the tissues.
- CT, ultrasonography, and MRI can be used to assess the level of tissue involvement and to detect gas within soft tissues or muscles.
- Although imaging may help delineate the extent of disease, it should not delay surgical consultation.

BIOPSY

- Gross examination reveals swollen, dull, gray fascia with stringy areas of necrosis.
- Necrosis of superficial fascia and fat produces watery, foul-smelling “dishwater pus.”
- Histology demonstrates subcutaneous fat necrosis, vasculitis, and local hemorrhage.

DIFFERENTIAL DIAGNOSIS

- Cellulitis—Acute spreading infection of skin and soft tissues characterized by erythema, edema, pain, and calor. Rapid progression of disease despite antibiotics, systemic toxicity, intense pain, and skin necrosis suggest NF rather than cellulitis (see Chapter 103, Cellulitis).
- Pyomyositis—Suppuration within individual skeletal muscle groups. Synergistic necrotizing cellulitis involves muscle groups in addition to superficial tissues and fascia.[7] Although pyomyositis may occur with NF, it can occur independent of cutaneous and soft-tissue infections. Imaging of the muscle confirms the diagnosis.
- Clostridial myonecrosis—Acute necrotizing infection of muscle tissue caused by clostridial organisms. Surgical exploration and cultures are required to differentiate from NF.
- Streptococcal or staphylococcal toxic shock syndrome—Systemic inflammatory response to a toxin-producing bacteria characterized by fever, hypotension, generalized erythroderma, myalgia, and multisystem organ involvement. NF may occur as part of the toxic shock syndrome.[5]

MANAGEMENT

Start by maintaining a high index of suspicion for NF. If the first debridement occurs within 24 hours from the onset of symptoms, there is a significantly improved chance of survival.[8]

- Surgical debridement is the primary therapeutic modality.[7–10] SOR Ⓐ
    - Extensive, definitive debridement should be the goal with the first surgery. This may require amputation of an extremity to control the disease. Surgical debridement is repeated until all infected devitalized tissue is removed.

- Antibiotics are the main adjunctive therapy to surgery. Broad-spectrum empiric antibiotics should be started immediately when NF is suspected and should include coverage of Gram-positive, Gram-negative, and anaerobic organisms.[7] SOR A
    - Antimicrobial therapy must be directed at the known or suspected pathogens and used in appropriate doses until repeated operative procedures are no longer needed, the patient has demonstrated obvious clinical improvement, and fever has been absent for 48 to 72 hours.[7] SOR A
    - Clindamycin is useful for coverage of anaerobes and aerobic Gram-positive cocci, including most *S. aureus* serogroups.
    - Clindamycin should be considered in initial coverage for its effects on exotoxin production in group A *Streptococcus* (GAS) infections. NF and/or streptococcal toxic shock syndrome caused by group A streptococci should be treated with clindamycin and penicillin.[7] SOR A
        - The rationale for clindamycin is based on in vitro studies demonstrating both toxin suppression and modulation of cytokine (i.e., TNF) production, on animal studies demonstrating superior efficacy versus that of penicillin, and on two observational studies demonstrating greater efficacy for clindamycin than for b-lactam antibiotics.[7] SOR A
    - Metronidazole has the greatest anaerobic spectrum against the enteric Gram-negative anaerobes, but it is less effective against the Gram-positive anaerobic cocci. Gentamicin, ticarcillin-clavulanate, or piperacillin-sulbactam is useful for coverage against resistant Gram-negative rods.[7]
    - A common choice of empiric antibiotics for community-acquired mixed infections is a combination of ampicillin-sulbactam or pipercillin-tazobactam plus clindamycin.[7] Aminoglycosides or ciprofloxacin can be used to provide gram-negative coverage for patients who cannot be treated with beta-lactam antibiotics or who are suspected of having multi-drug resistant gram-negative infections. SOR C
    - Empiric vancomycin should be considered during pending culture results to cover for the increasing incidence of community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA).[7]

  - For NF due to *V. vulnificus* infection, doxycycline in combination with a third-generation cephalosporin is preferred for children 8 years of age and older, while a combination of trimethorprim sulfamethoxazole and an aminoglycoside is recommended for younger children.[11]
  - Hyperbaric oxygen (HBO_2) may have beneficial effects when used postoperatively in NSTIs. One recent study demonstrated decreased morbidity (amputations 50% versus 0%) and mortality (34% versus 11.9%) with the use of postoperative HBO_2.[12] SOR B

- Aggressive fluid resuscitation is often necessary because of massive capillary leak syndrome. Supplemental enteral nutrition is often necessary for patients with NSTIs.
- Vacuum-assisted closure devices may be helpful in secondary wound management after debridement of NSTIs.[10]
- A recommendation to use intravenous gammaglobulin (IVIG) to treat NF or toxic shock syndrome cannot be made with certainty.[7] SOR B

PROGNOSIS AND FOLLOW-UP

- Overall case fatality rate in adults remains 20 to 47 percent despite aggressive, modern therapy.[6,7]
  - However, in a retrospective chart review of patients with NSTIs treated at six academic hospitals in Texas between 2004 and 2007 mortality rates varied between hospitals from 9 to 25 percent (n = 296).[13]
- The case fatality rate was 5 percent in the recent pediatric active surveillance study from Canada.[3]
  - Early diagnosis and treatment appears to reduce the case fatality rate.
- Carrying out the first fasciotomy and radical debridement within 24 hours of symptom onset is associated with significantly improved survival.[8]

PATIENT EDUCATION

The serious life-threatening nature of NF should be explained to the patient and family when informed consent is given prior to surgery. The risk of losing life and limb should be explained while giving hope for recovery. For those patients who survive but have lost a limb, counseling should be offered to help them deal with the psychological effects of the amputation.

107 ECTHYMA GANGRENOSUM

Aron Flagg, MD
Camille Sabella, MD

PATIENT STORY

A 13-year-old boy is hospitalized while receiving induction therapy for acute myelogenous leukemia. During a period of profound neutropenia, he develops a fever of 39°C associated with rigors. Blood cultures are taken and he is given broad-spectrum antibiotics. Over the next 48 hours, a tender, erythematous 2 ¥ 2 cm papule develops on his arm, the center of which becomes vesicopustular (**Figure 107-1**). Blood cultures from the initial febrile period are subsequently positive for *Pseudomonas aeruginosa*. He is treated with combination therapy including piperacillin/tazobactam and gentamicin for two weeks until neutrophil recovery.

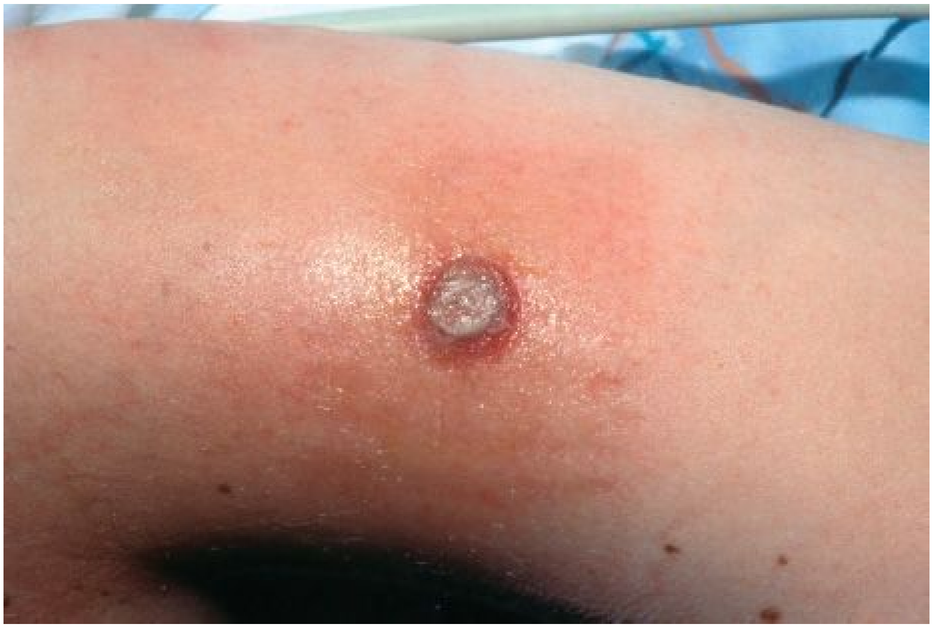

FIGURE 107-1 Ecthyma gangrenosum on the arm of this 13-year-old boy with acute myelogenous leukemia. This lesion is at a vesicopustular stage of formation. Blood cultures grew Pseudomonas aeruginosa. (*Used with permission from Johanna Goldfarb, MD.*)

INTRODUCTION

Ecthyma gangrenosum is an infectious lesion of the skin with a characteristic necrotic center. It is seen predominantly in the immunocompromised patients related to Gram-negative bacteremia, typically *Pseudomonas aeruginosa*.

EPIDEMIOLOGY

- Infrequent condition that is most prevalent in severely immunocompromised hosts with fever.
- The skin lesions may be a presenting feature of acute leukemia.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Ecthyma gangrenosum is most commonly associated with disseminated *P aeruginosa* infection; however, it has also been described with other Gram-negative bacilli and fungi, including *Aeromonas hydrophila*, *Enterobacter*, *Escherichia coli*, *Morganella*, *Serratia marcescens*, *Stenotrophomonas maltophilia*, *Aspergillus*, *Candida*, *Fusarium*, and *Mucor*.[1,3]
- Necrotizing, hemorrhagic vasculitis is seen on histopathology.

- Organisms are often seen, particularly within the medial blood vessel layers.[2,4]

RISK FACTORS

- Compromised host immunity, often from malignancy or chemotherapy, is the most significant risk factor. Neutrophil defects may also be seen.[1]

DIAGNOSIS

CLINICAL FEATURES

- Lesions begin as erythematous macules with rapid progression to papules (**Figure 107-2**), then pustules, vesiculopustules **(Figure 107-1**), or bullae. Some lesions may be more nodular in appearance. Central necrosis and ulceration may develop in the later stages of formation (**Figure 107-3**).

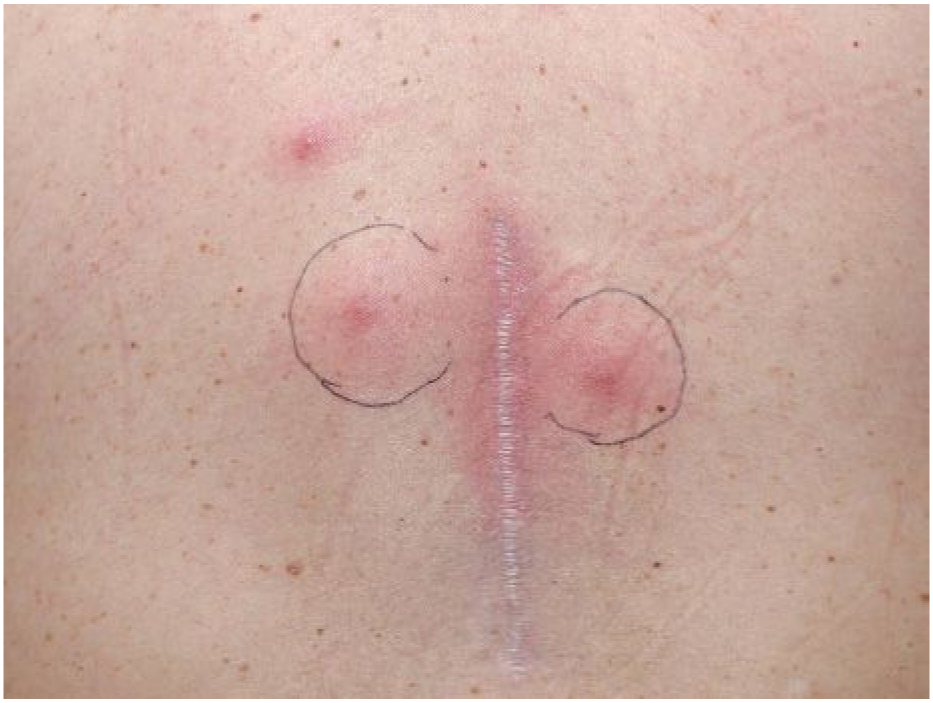

FIGURE 107-2 Ecthyma gangrenosum in the early stage of development. Note the papular lesions surrounding a previous wound in this patient with chemotherapy-induced neutropenia. (*Used with permission from Camille Sabella, MD.*)

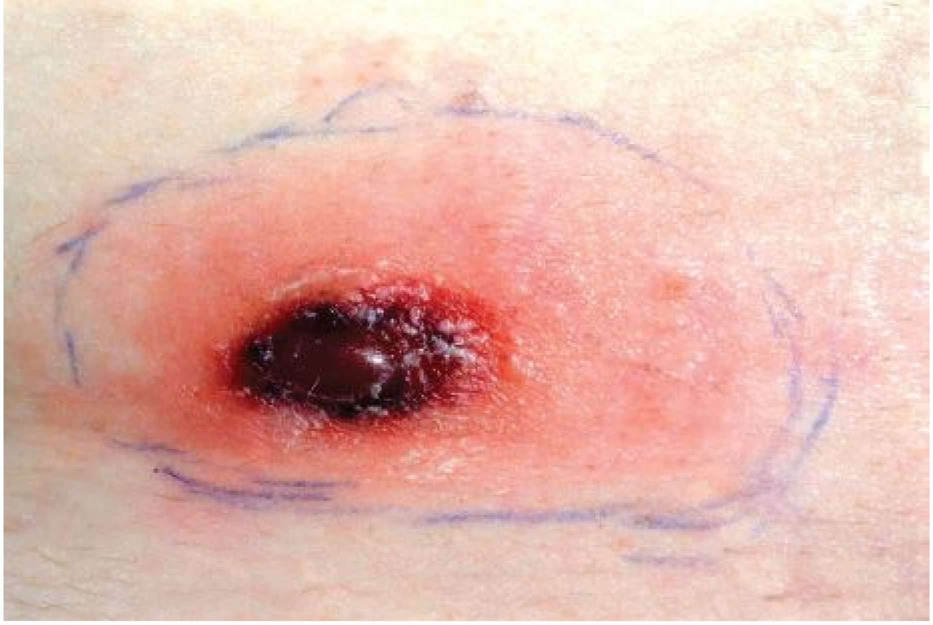

FIGURE 107-3 Ecthyma gangrenosum in a 14-year-old girl with acute myelogenous leukemia. Note the necrotic appearing center of the lesion and

surrounding erythema. Blood culture from this patient grew Pseudomonas aeruginosa. (*Used with permission from Camille Sabella, MD. From Sabella C, Cunningham RJ III. Intensive Review of Pediatrics, 4th edition. Lippincott Williams Wilkins, p 453*.)

- May appear anywhere on the body; multiple, simultaneous lesions are common.

LABORATORY TESTING

- Blood cultures are usually diagnostic of Gram-negative septicemia.
- Biopsy can confirm the diagnosis and tissue culture may also yield a bacteriologic diagnosis.

IMAGING

- Not specifically indicated.

DIFFERENTIAL DIAGNOSIS

- Ecthyma—Community-acquired infection related to *Staphylococcus aureus* or group A streptococcus can be seen in otherwise healthy children, older adults, or diabetics.
- Cutaneous anthrax—Often associated with significant surrounding edema, and with suggestive occupational exposure.[1]
- Sweet syndrome—An acute, febrile, neutrophilic dermatosis not associated with infection usually requiring biopsy diagnosis.
- Leukemia cutis—May be present at leukemia diagnosis or relapse and is not related to infection. Biopsy is required.

MANAGEMENT

MEDICATIONS

- Empiric antibiotic therapy should be directed against *Pseudomonas aeruginosa* and tailored once a bacteriologic diagnosis is made.[1–3] SOR A
- Experts recommend double-coverage, at least initially, for serious gram-negative infections in immunocompromised patients to provide synergy and to prevent the development of resistance.[1,2] SOR A
- Typical agents used in combination include penicillins (piperacillin, ticarcillin), cephalosporins (ceftazidime, cefepime), carbapenems (imipenem, meropenem), fluoroquinolones (ciprofloxacin), and aminoglycosides (amikacin, gentamicin).[2]

SURGERY

- Rarely, surgical debridement may be necessary in cases of necrosis, abscess formation, or extensive disease.

REFERRAL

- Dermatology consultation may be warranted to confirm the diagnosis or obtain biopsy specimens when required.
- Surgical consultation is warranted when there is extensive necrosis requiring surgical debridement.

PROGNOSIS

- Ecthyma gangrenosum in the immunocompromised host can carry a high mortality, ranging from 30 to 70 percent.[2]

FOLLOW-UP

- Close follow-up is warranted to assure the bacteremia, sepsis, and the ecthymatous lesions have cleared with therapy and recovery of neutropenia.

PATIENT EDUCATION

- As for all patients with chemotherapy-induced neutropenia, fever and/or characteristic lesion or rash warrants immediate medical care.

SECTION 4 VIRAL

108 VARICELLA

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 12-year-old girl presents with a 3-day history of a body-wide pruritic vesicular rash (**Figure 108-1**). The episode started 24 hours before the rash with fever and malaise. The patient is diagnosed with varicella and no antiviral medications are given. Acetaminophen or ibuprofen are recommended for fever and comfort, avoiding aspirin to prevent Reyes syndrome.

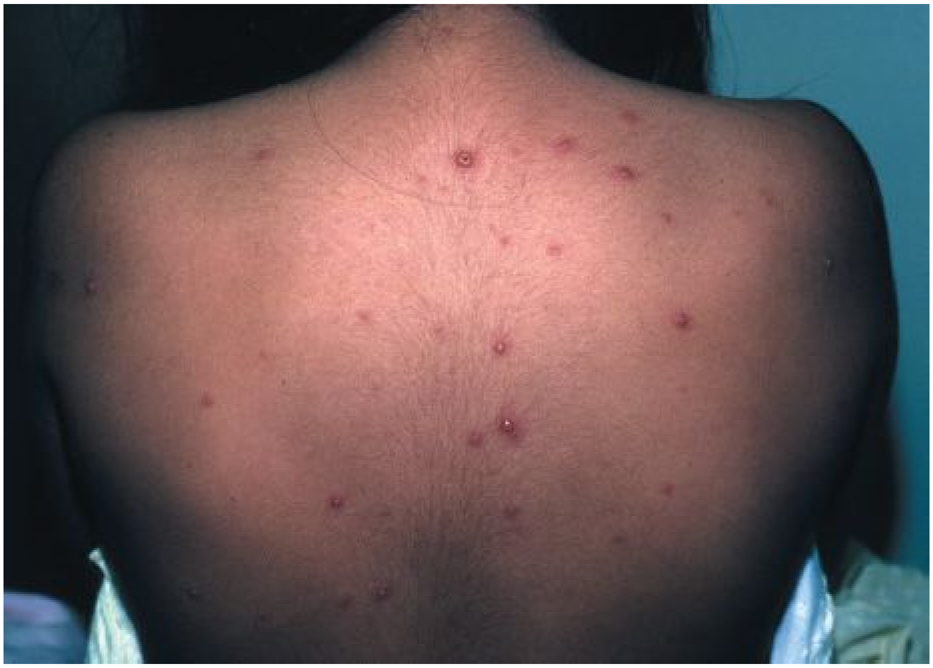

FIGURE 108-1 Chickenpox in a child. Note lesions in various stages (papules, intact vesicles, pustules, and crusted papules) caused by multiple crops of lesions. The vesicles are on a red base. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Varicella (chickenpox) is a highly contagious viral infection that can become reactivated in the form of zoster.

EPIDEMIOLOGY

- Varicella-zoster virus (VZV) is distributed worldwide.
- The rate of secondary household attack is more than 90 percent in susceptible individuals (**Figure 108-2**).[1]

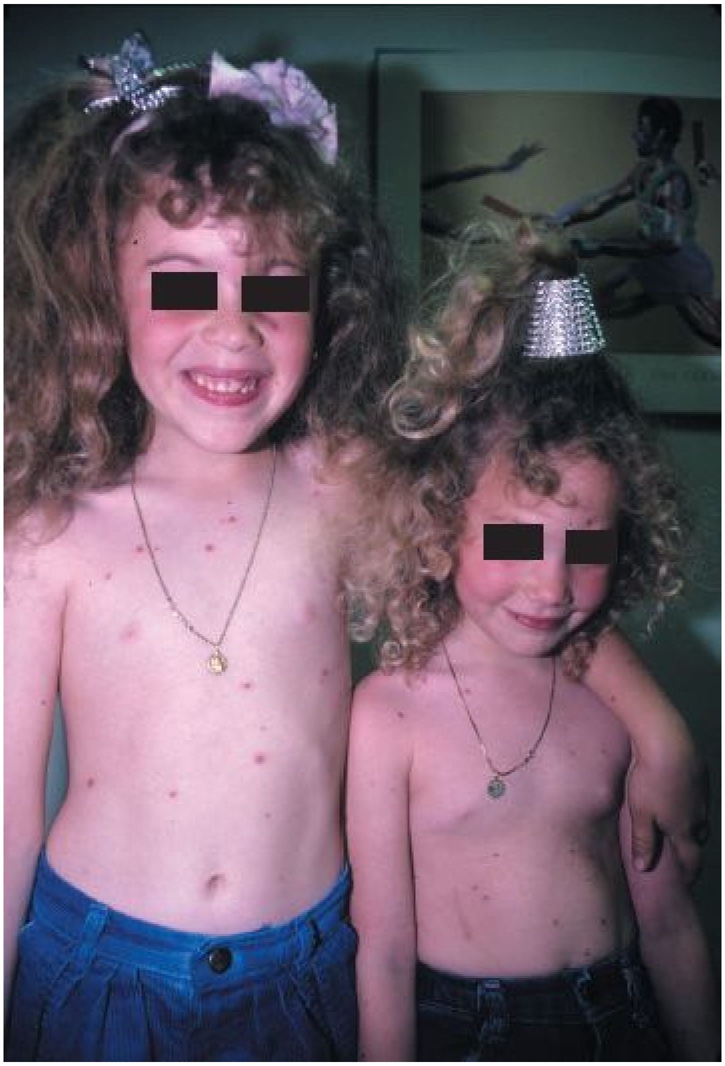

FIGURE 108-2 Chickenpox in sisters seen before the varicella vaccine was available. The girls are feeling better now that the disease is resolving. (*Used with permission from Richard P. Usatine, MD.*)

- Adults and immunocompromised patients generally develop more severe disease than normal children.
- Traditionally, primary infection with VZV occurs during childhood (**Figure 108-3**). In childhood, it is usually a benign, self-limited illness in immunocompetent hosts. It occurs throughout the year in temperate regions, but the incidence peaks in the late spring and summer months.

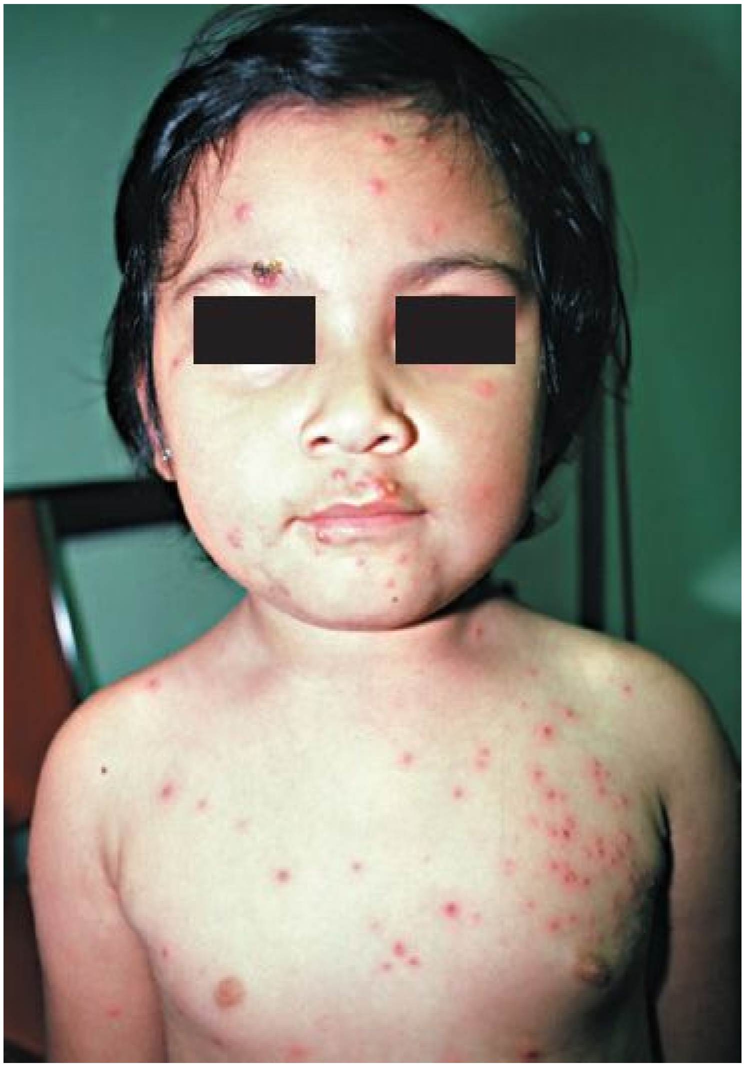

FIGURE 108-3 Chickenpox in a child. Note the widespread distribution of the lesions. The honey-crusted lesion on the eyebrow suggests a secondary bacterial infection (impetigo) has developed. (*Used with permission from Richard P. Usatine, MD.*)

- Neonatal varicella is a serious illness with a mortality rate up to 30 percent.[2] The risk of infection and the case fatality rate are significantly increased if a mother has symptoms less than five days prior to delivery. The time to delivery allows insufficient time for the development of maternal IgG and passive transfer of protection to the fetus.[3] Postnatally acquired varicella that occurs beyond 10 days after birth usually is mild.[4]
- Prior to the introduction of the varicella vaccine in 1995, the yearly incidence of chickenpox in the US was approximately 4 million cases

with approximately 11,000 hospital admissions and 100 deaths.[5]

- As the vaccination rates steadily increased in the US, there has been a corresponding fourfold decrease in the number of cases of chickenpox cases down to disease rates of from 0.3 to 1.0 per 1000 population in 2001.[5]

ETIOLOGY AND PATHOPHYSIOLOGY

- Chickenpox is caused by a primary infection with the VZV, which is a double-stranded, linear DNA herpesvirus.
- Transmission occurs via contact with aerosolized droplets from nasopharyngeal secretions or by direct cutaneous contact with vesicle fluid from skin lesions.
- The incubation period for VZV is approximately 15 days, during which the virus undergoes replication in regional lymph nodes, followed by two viremic phases, the second of which persists through the development of skin lesions generally by day 14.[6]
- The vesicular rash appears in crops for several days. The lesions start as vesicle on a red base, which is classically described as a dewdrop on a rose petal (**Figure 108-4**). The lesions gradually develop a pustular component (**Figure 108-5**) followed by the evolution of crusted papules (**Figure 108-6**). The period of infectivity is generally considered to last from 48 hours prior to the onset of rash until skin lesions have fully crusted.

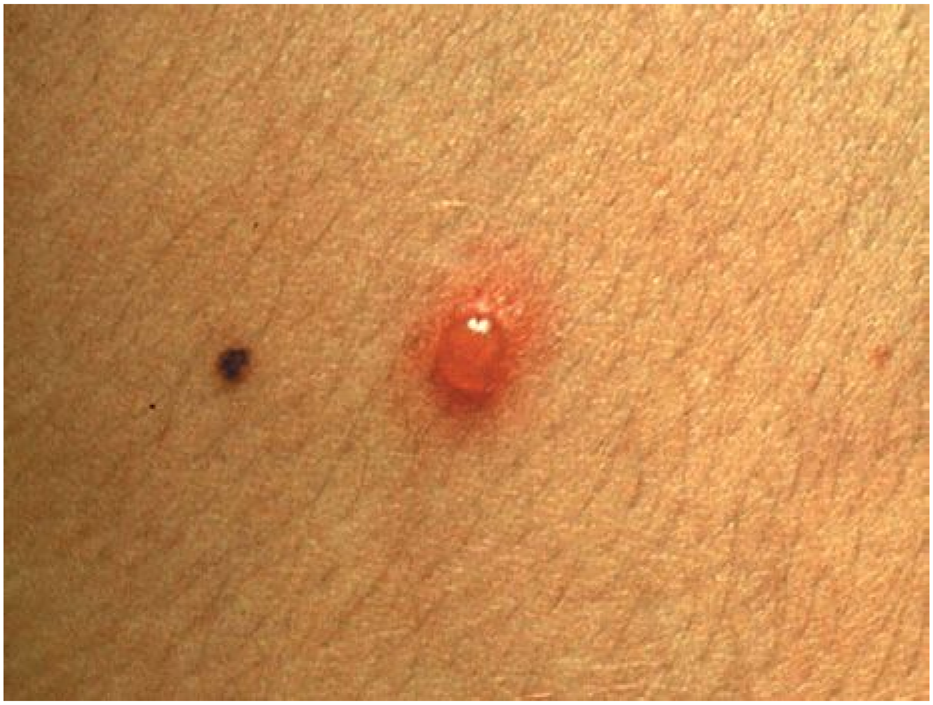

FIGURE 108-4 Dewdrop on a rose petal is the classic description of a varicella vesicle on a red base. (*Used with permission from Richard P. Usatine, MD.*)

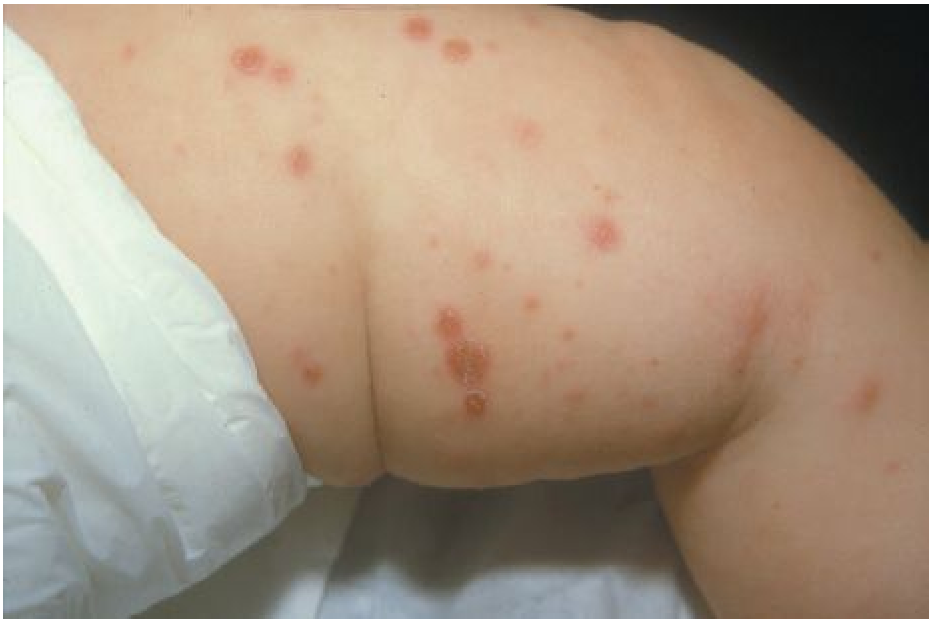

FIGURE 108-5 Varicella on the leg of an infant after the lesions have crusted over. The patient is probably not contagious at this time. (*Used with*

permission from the University of Texas Health Sciences Center, Division of Dermatology.)

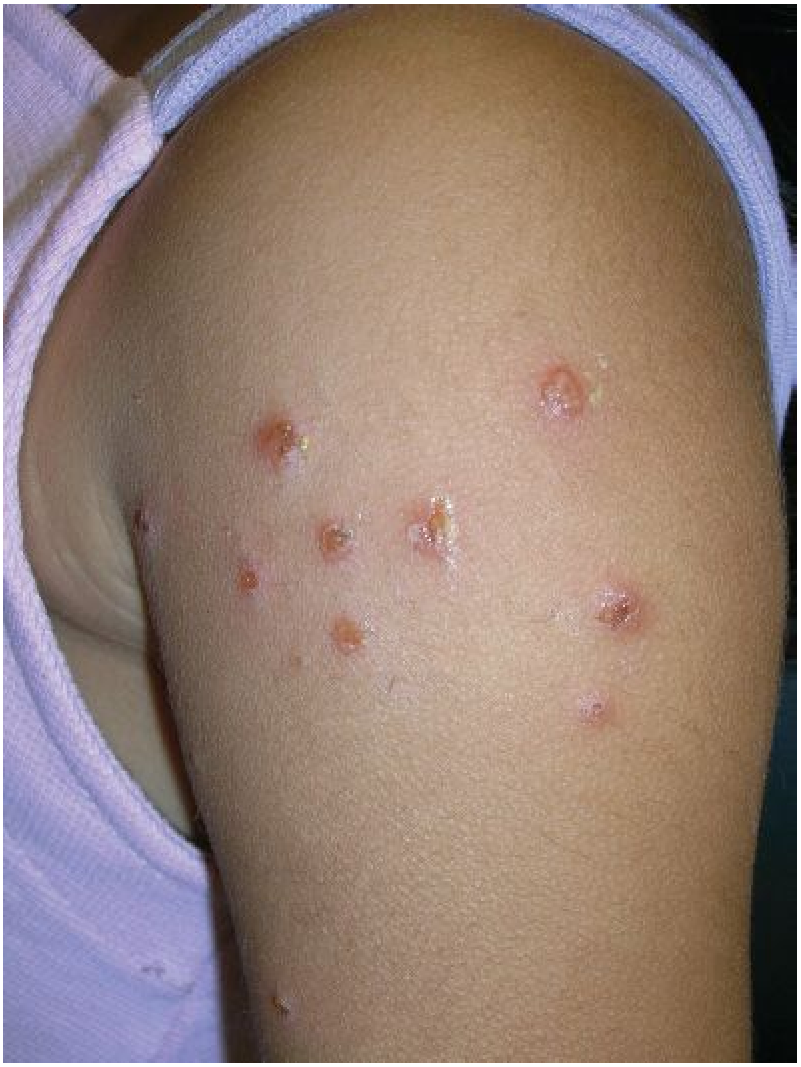

FIGURE 108-6 Honey-crusted lesions of superinfected varicella. This is impetiginized chickenpox caused by a secondary bacterial infection (impetigo). (*Used with permission from Richard P. Usatine, MD*.)

- The most frequent complication in healthy children is bacterial skin superinfection (**Figure 108-6**). Less common skin complications (seen more frequently in immunosuppressed hosts) include bullous varicella, purpura fulminans, and necrotizing fasciitis.
- Encephalitis is a serious potential complication of chickenpox that develops toward the end of the first week of the exanthema. One form,

acute cerebellar ataxia, occurs mostly in children and is generally followed by complete recovery. A more diffuse encephalitis most often occurs in adults and may produce delirium, seizures, and focal neurologic signs. It has significant rates of long-term neurologic sequelae and death.

- Pneumonia is rare in healthy children but accounts for the majority of hospitalizations in adults, where it has up to a 30 percent mortality rate.[7] It usually develops insidiously within a few days after the rash has appeared with progressive tachypnea, dyspnea, and dry cough. Chest x-rays reveal diffuse bilateral infiltrates. Treat with prompt administration of intravenous acyclovir. The use of adjunctive steroid therapy is controversial.
- Varicella hepatitis is rare, and typically only occurs in immunosuppressed individuals. It is frequently fatal.
- Reactivation of latent VZV results in herpes zoster or shingles.

DIAGNOSIS

CLINICAL FEATURES

- The typical clinical manifestations of chickenpox include a prodrome of fever, malaise, or pharyngitis, followed in 24 hours by the development of a generalized vesicular rash.
- The lesions are pruritic and appear as successive crops of vesicles more than 3 to 4 days.
- Coexisting lesions in different stages of development on the face, trunk, and extremities are common (**Figure 108-7**).

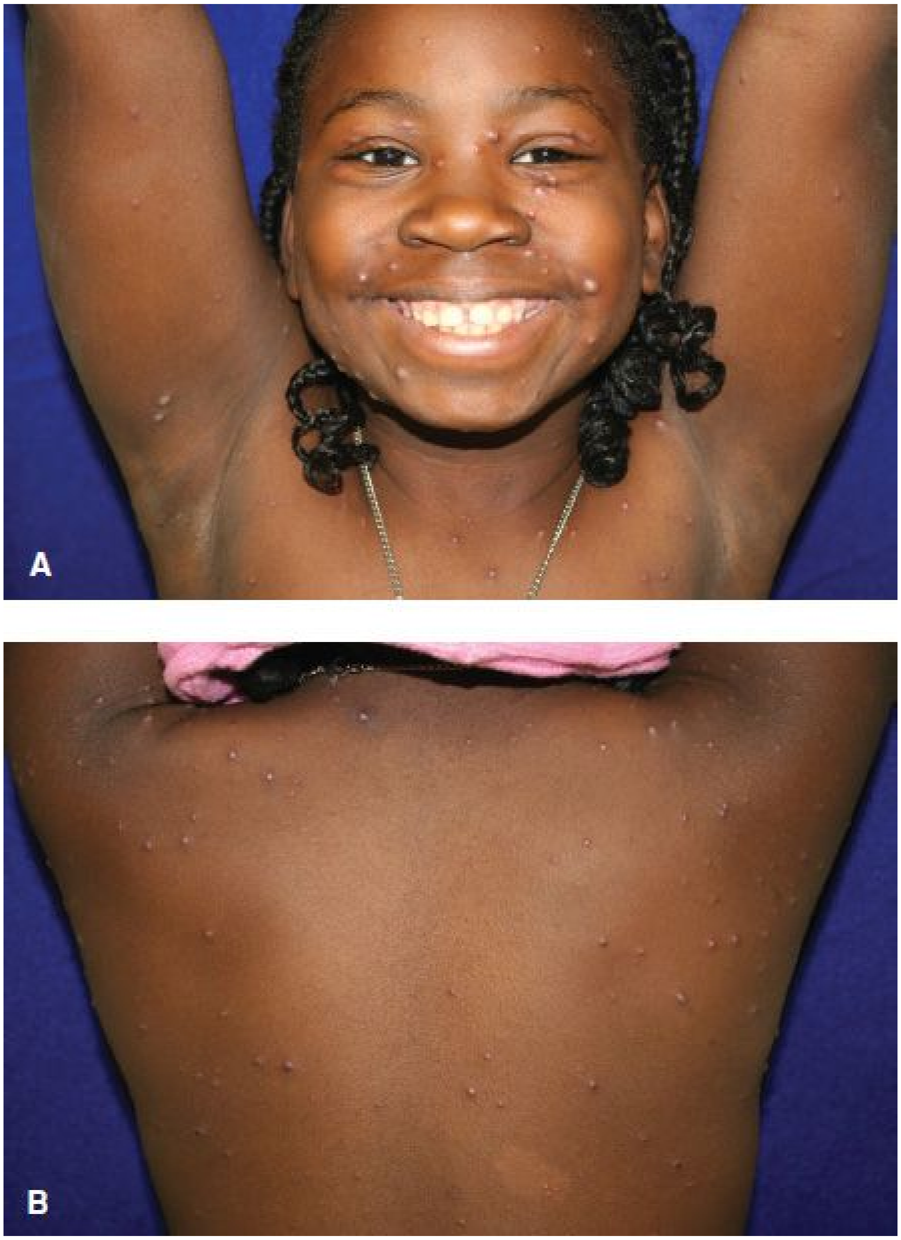

FIGURE 108-7 **A.** Varicella in a young girl that was previously immunized with the varicella vaccine. Note the papules and pustules present. **B.** The back has small evenly distributed pustules. (*Used with permission from Richard P. Usatine, MD.*)

- New lesions stop forming in approximately 4 days, and most lesions have fully crusted by 7 days.

TYPICAL DISTRIBUTION

- Bodywide—No laboratory tests are needed unless the diagnosis is uncertain. For children or adults in which there is uncertainty about previous disease and it is important to establish a quick diagnosis, a direct fluorescent antibody test can be done on a scraping of a lesion. In many laboratories, a result can be obtained within 24 hours (**Figure 108-8**).

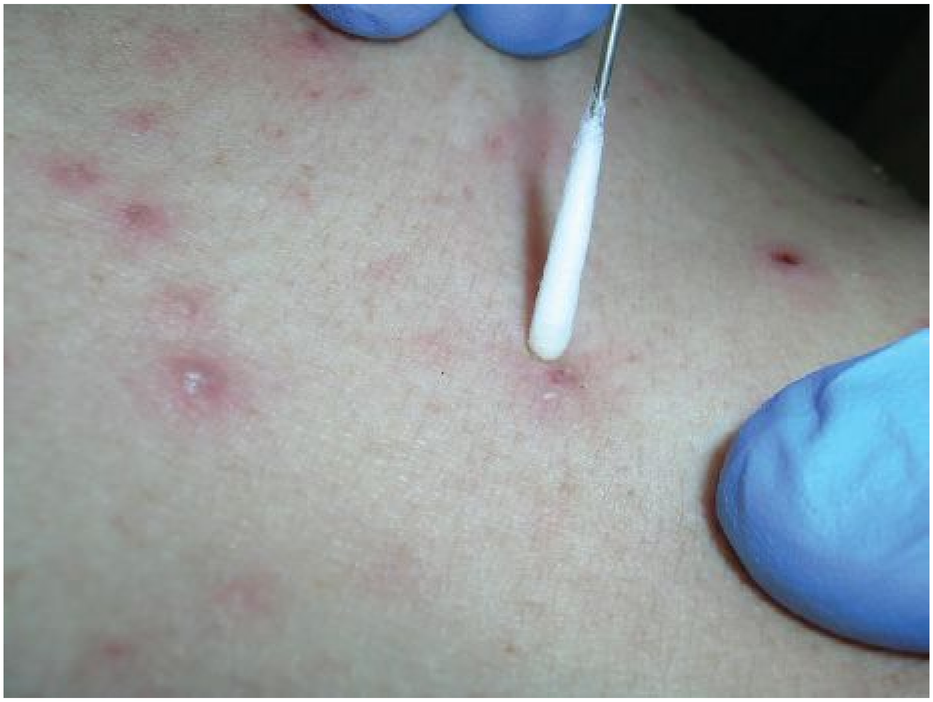

FIGURE 108-8 Direct scraping of a lesion was performed and the varicella virus was identified quickly with a direct fluorescent antibody test. (*Used with permission from Richard P. Usatine, MD.*)

LABORATORY TESTING

- Diagnosis is usually based on classic presentation. Culture of vesicular fluid provides a definitive diagnosis, but is positive in less than 40 percent of cases. Direct immunofluorescence has good sensitivity and is more rapid than tissue culture. Latex agglutination blood testing may be used to determine exposure and immunity to VZV.

DIFFERENTIAL DIAGNOSIS

- Pemphigus and bullous pemphigoid are usually seen in adults, whereas varicella is a disease of children.
- Dermatitis herpetiformis is characterized by pruritic papulovesicles over the extremities and on the trunk, and granular immunoglobulin (Ig) A deposits on the basement membrane (see Chapter 155, Chronic Bullous Disease of Childhood).
- Herpes simplex infection presents with similar lesions, but is generally restricted to the genital and oral areas. The vesicles of herpes simplex tend to be more clustered in a group rather than the wide distribution of varicella (see Chapter 114, Herpes Simplex).
- Impetigo can have bullous or crusted lesions anywhere on the body. The lesions often have mild erythema and a yellowish color to the crusts (see Chapter 99, Impetigo).
- Insect bites are often suspected by history and can occur on the entire body.

MANAGEMENT

NONPHARMACOLOGIC

- Pruritus can be treated with calamine lotion, pramoxine gel, or powdered oatmeal baths.
- Fingernails should be closely cropped to avoid significant excoriation and secondary bacterial infection.

MEDICATIONS

- Antihistamines are helpful in the symptomatic treatment of pruritus.

- Acetaminophen should be used to treat fever in children, as aspirin use is associated with Reye syndrome in the setting of viral infections.[8] SOR Ⓐ
- Superinfection may be treated with topical or oral antibiotics.
- Prophylactic use of varicella zoster immune globulin (125 U/10 kg, up to 625 U IM) in recently exposed susceptible individuals can prevent or attenuate the disease. However, the immune globulin is extremely hard to obtain at times and is indicated only for those who are at risk for developing severe varicella, such as neonates (see the following section) and immunocompromised individuals.[9]
- Acyclovir (20 mg/kg PO 4 times daily) is US Food and Drug Administration approved for treatment of varicella in healthy children. It should be given during the first 24 hours of rash.[1] However, the Committee on Infectious Disease of the American Academy of Pediatrics issued a statement saying they did not consider the routine administration of acyclovir to all healthy children with varicella to be justified.[10] SOR Ⓒ
- Management of newborns exposed to VZV includes isolation and postexposure prophylaxis with Varicella-zoster immune globulin (VariZIG). The Advisory Committee on Immunization Practices (ACIP) recommends administration within 96 hours to the following newborns:[11] SOR Ⓐ
    - Infants who mothers have signs and symptoms of varicella within five days before or two days after delivery.
    - Premature infants born at >28 weeks of gestation who are exposed during the neonatal period and whose mothers do not have signs of immunity.
    - Premature infants born at <28 weeks of gestation or who weigh <1000 grams at birth and were exposed during the neonatal period, regardless of maternal history of varicella or vaccination.
- Early treatment with intravenous acyclovir may be effective for treatment of varicella hepatitis and pneumonia, and may also be useful in the treatment of immunosuppressed patients. SOR Ⓑ
- Adults who get varicella should be assessed for neurologic and pulmonary disease.

PREVENTION

- Varicella immunization (Varivax) can be used to prevent chickenpox. SOR A It is contraindicated in individuals allergic to gelatin or neomycin and in immunosuppressed individuals (it is a live vaccine). In 2006, and again in 2010, the Advisory Committee on Immunization Practices recommended that all children younger than 13 years of age should be routinely administered 2 doses of varicella-containing vaccine, with the first dose administered at 12 to 15 months of age and the second dose at 4 to 6 years of age (i.e., before first grade). The second dose can be administered at an earlier age provided the interval between the first and second dose is at least 3 months.[12]

FOLLOW-UP

- Follow-up is unnecessary for immunocompetent children and adults who are having no complications. All patients or parents should report any respiratory or neurologic problems immediately.

PATIENT EDUCATION

- Avoid scratching the blisters and keep fingernails short. Scratching may lead to superinfection.
- Calamine lotion and oatmeal (Aveeno) baths may help relieve itching.
- Do not use aspirin or aspirin-containing products to relieve fever. The use of aspirin is associated with development of Reye syndrome, which may cause death.

109 HERPES ZOSTER

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 14-year-old boy presents with deep burning pain and a vesicular eruption in a band starting at the left chest and ending just across the midline of the back (**Figure 109-1**). The varicella-zoster virus (VZV) leaves the dorsal root ganglion to travel down the spinal nerves to the cutaneous nerves of the skin. The vesicles do cross the midline by a few centimeters because the posterior primary ramus of the spinal nerve includes a small cutaneous medial branch that reaches across the midline.[1] The boy was treated with analgesics and an antiviral medication. The zoster healed with scarring.

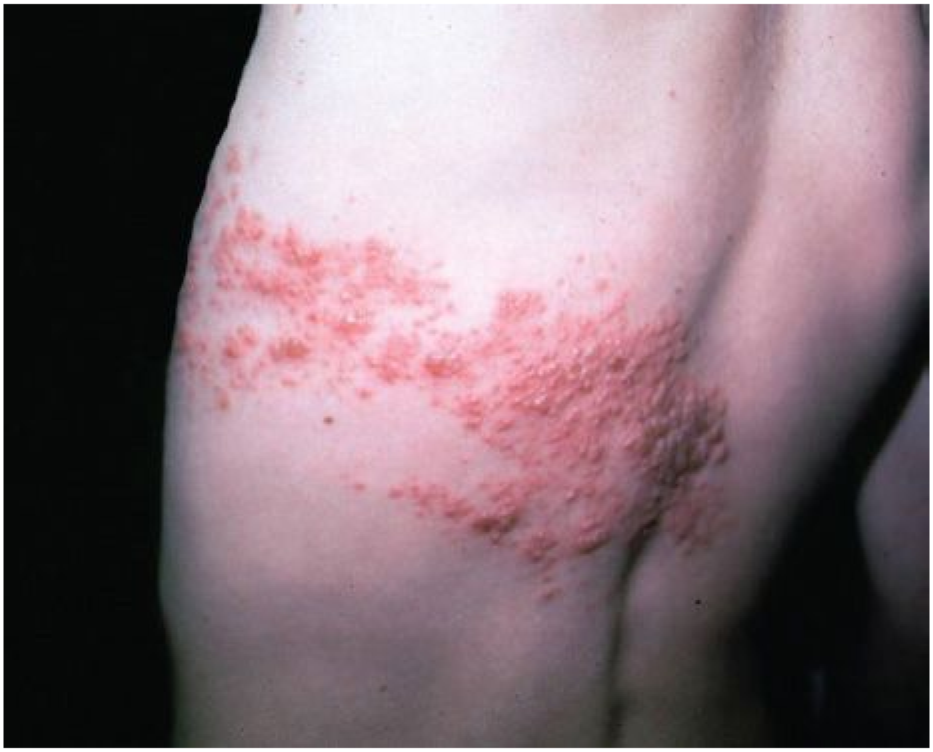

FIGURE 109-1 A 14-year-old boy with severe case of herpes zoster in a thoracic distribution. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Herpes zoster (shingles) is a syndrome characterized by a painful, usually unilateral vesicular eruption that develops in a restricted dermatomal distribution (**Figures 109-1** and **109-2**).[2,3]

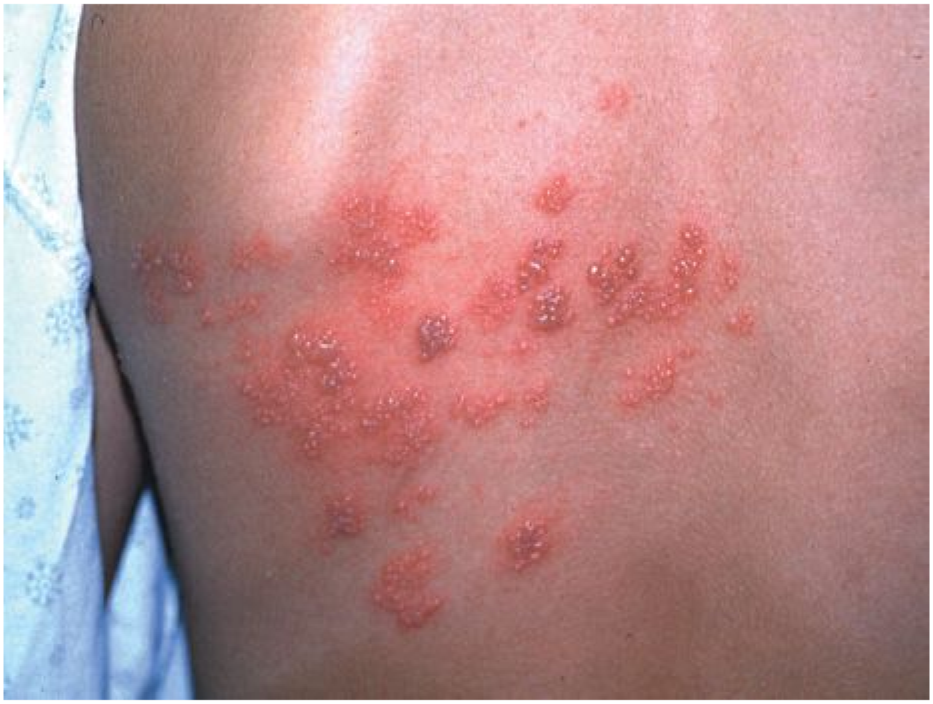

FIGURE 109-2 Close-up of herpes zoster lesions. Note grouped vesicles on a red base. (*Used with permission from Richard P. Usatine, MD.*)

SYNONYMS

Shingles.

EPIDEMIOLOGY

- According to the Centers for Disease Control and Prevention (CDC), 32 percent of persons in the US will experience zoster during their lifetimes accounting for about 1 million cases annually.[4] Older age groups account for the highest incidence of zoster. Approximately 4 percent of patients will experience a second episode of herpes zoster.[5]
- Herpes zoster is uncommon in healthy children; most cases are seen in immunocompromised patients, including children who have received solid organ and hematologic transplants.

ETIOLOGY AND PATHOPHYSIOLOGY

- After primary infection with either chickenpox or vaccine-type VZV, a latent infection is established in the sensory dorsal root ganglia. Reactivation of this latent VZV infection results in herpes zoster (shingles).
- Both sensory ganglia neurons and satellite cells surrounding the neurons serve as sites of VZV latent infection. During latency, the virus only expresses a small number of viral proteins.
- How the virus emerges from latency is not clearly understood. Once reactivated, virus spreads to other cells within the ganglion. The dermatomal distribution of the rash corresponds to the sensory fields of the infected neurons within the specific ganglion.[3]
- Loss of VZV-specific cell-mediated immune response is responsible for reactivation.[3]
- The pain associated with zoster infections and postherpetic neuralgia (PHN) is thought to result from injury to the peripheral nerves and altered central nervous system processing.

- The most common complication is bacterial superinfection that can delay healing and cause scarring of the zoster lesions.
- Complications may include:[6]
  - PHN—Uncommon in the pediatric population.
  - Ocular complications, including uveitis and keratitis (see Chapter 110, Zoster Ophthalmicus).
  - Bell palsy and other motor nerve plastic.
  - Bacterial skin infection.
  - Meningitis caused by central extension of the infection.
  - Herpes zoster oticus (Ramsay Hunt syndrome; **Figure 109-3**) includes the triad of ipsilateral facial paralysis, ear pain, and vesicles in the auditory canal and auricle.[8] Disturbances in taste perception, hearing (tinnitus or hyperacusis), lacrimation, and vestibular function (vertigo) may occur.

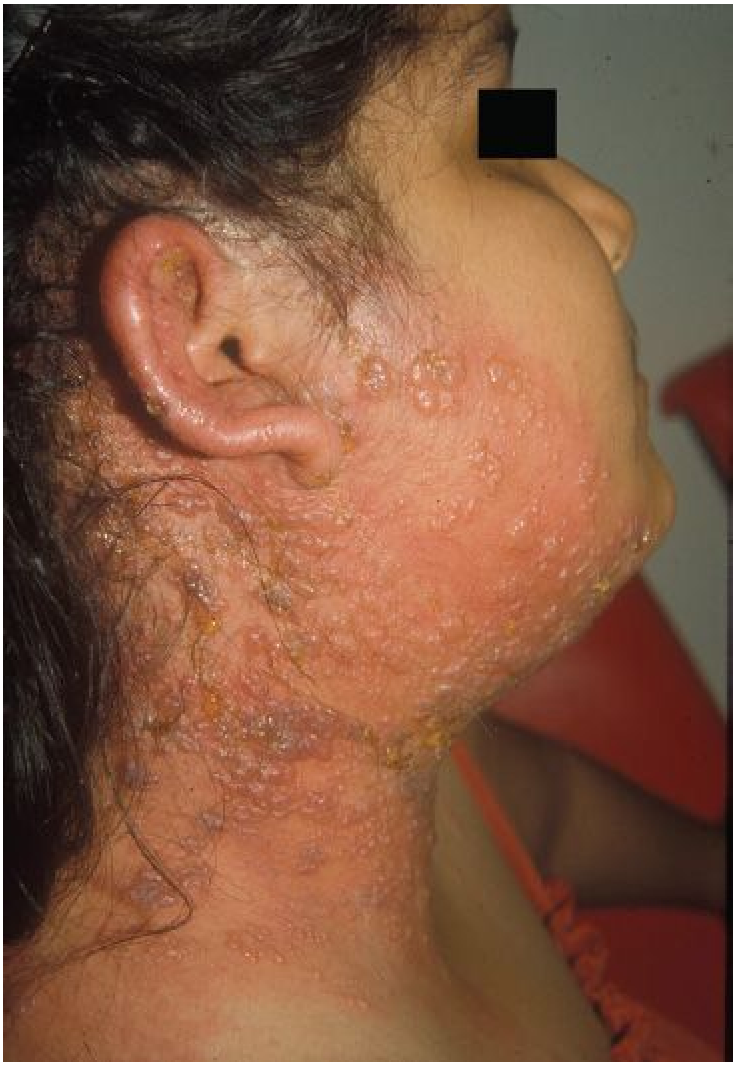

FIGURE 109-3 Herpes zoster oticus (Ramsay Hunt syndrome) with the classic presentation of vesicles on the auricle. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

  - Other rare complications may include acute retinal necrosis, transverse myelitis, encephalitis, leukoencephalitis, contralateral thrombotic stroke syndrome, and granulomatous vasculitis.[7]

- Immunosuppressed patients are at increased risk for complications, including severe complications such as broader dermatomal involvement (**Figure 109-4**), disseminated infection, visceral involvement, pneumonitis, and/or meningoencephalitis.

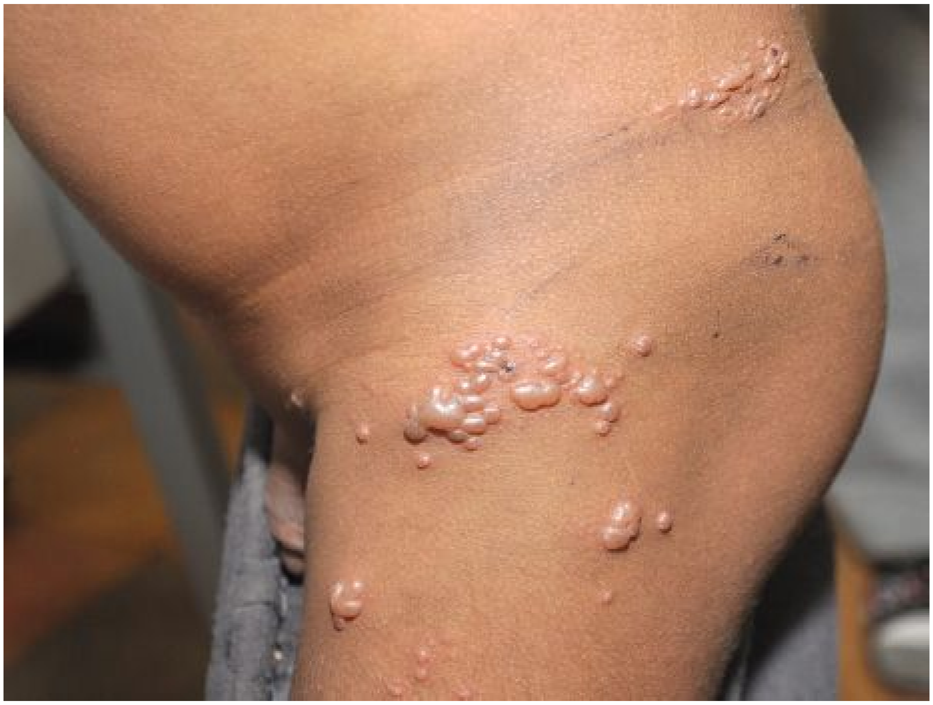

FIGURE 109-4 Herpes zoster in a 4-year-old boy with HIV disease. Note multiple dermatomes are involved. (*Used with permission from Richard P. Usatine, MD.*)

- PHN is the persistence of pain, numbness, and/or dysesthesias precipitated by movement or in response to non-noxious stimuli in the affected dermatome for more than 1 month after the onset of zoster. The incidence of PHN in the general population is 1.38 per 1000 person-years, and it occurs more commonly in individuals older than age 60 years and in immunosuppressed individuals.[3] This is rare in the pediatric population.

RISK FACTORS

ZOSTER[3]

- Older age.

- Underlying malignancy.
- Disorders of cell-mediated immunity, including organ and hematologic transplantation.
- Chronic lung or kidney disease.
- Autoimmune disease.

DIAGNOSIS

CLINICAL FEATURES

- Pediatric patients who develop zoster do not usually experience significant pain or disability.
- Mild tingling or redness in a dermatomal pattern may be the first symptom and can precede the rash.
- A prodrome of fever, dysesthesias, malaise, and headache leads in several days to a dermatomal vesicular eruption. The rash starts as grouped vesicles or bullae, which evolve into pustular or hemorrhagic lesions within 3 to 4 days (**Figures 109-1** to **109-6**). The lesions typically crust in approximately a week, with complete resolution within 3 to 4 weeks.[5]

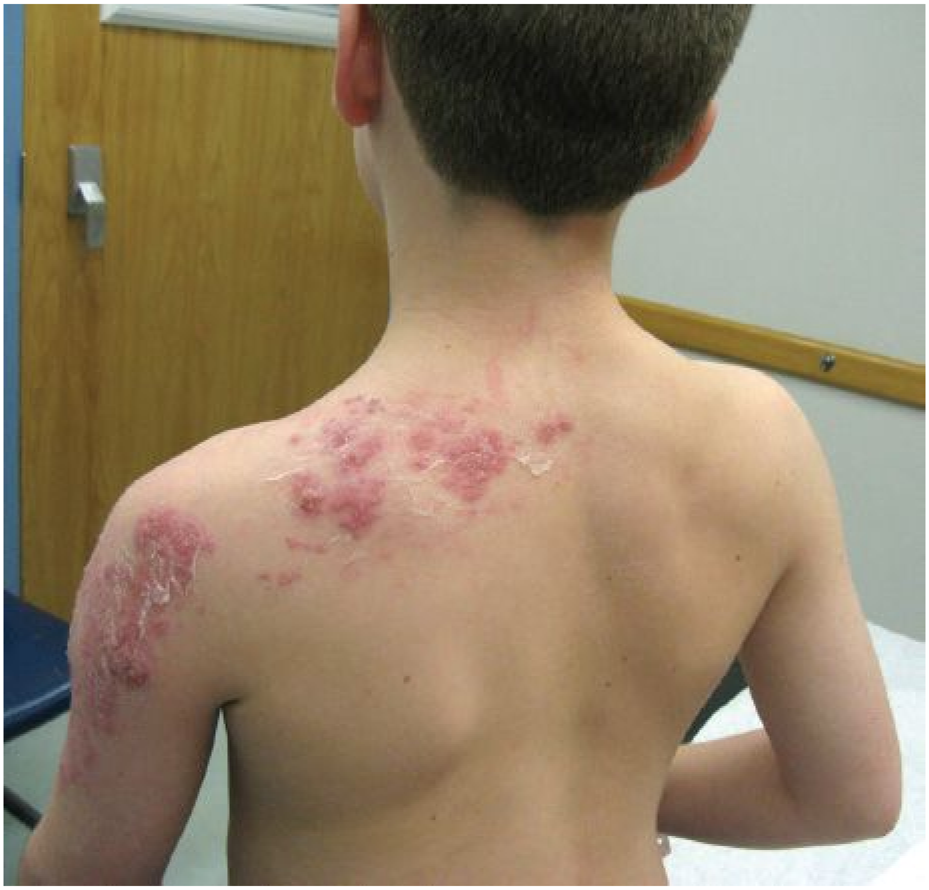

FIGURE 109-5 Herpes zoster following the C6 dermatome in a young otherwise healthy boy. Not all children that have zoster are immunocompromised. (*Used with permission from Emily Scott, MD.*)

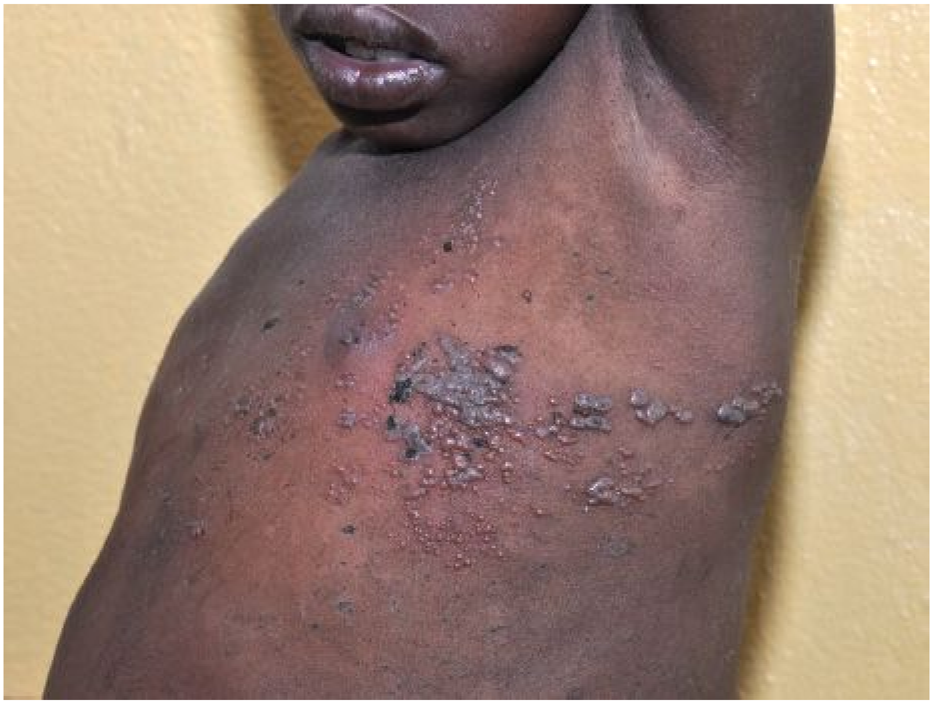

FIGURE 109-6 Herpes zoster in the thoracic distribution in an African child. An HIV serology was ordered because of the various risk factors involved. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

- Generally limited to one dermatome in immunocompetent patients, but sometimes affects neighboring dermatomes. Rarely, a few scattered vesicles located away from the involved dermatome as a result of release of VZV from the infected ganglion into the bloodstream.[3] If there are more than 20 lesions distributed outside the dermatome affected, the patient has disseminated zoster. The thoracic and lumbar dermatomes are the most commonly involved. Occasionally zoster will be seen on the extremities (**Figure 109-5**).

LABORATORY TESTING

- Meningitis associated with VZV infection can be diagnosed by cerebrospinal fluid showing pleocytosis.

- If HIV is suspected, serology for HIV antibodies should be ordered (**Figures 109-4** and **109-6**).

DIFFERENTIAL DIAGNOSIS

- Pemphigus and other bullous diseases present with blisters, but not in the classic dermatomal distribution (see Chapter 155, Chronic Bullous Disease of Childhood and Chapter 156, Pemphigus).
- Molluscum contagiosum presents with white or yellow flat-topped papules with central umbilication caused by a pox virus. The lesions are more firm and unless irritated do not have a red base as seen with zoster (see Chapter 115, Molluscum Contagiosum).
- Scabies may present as a pustular rash that is not confined to dermatomes and usually has characteristic lesions in the webs of the fingers (see Chapter 128, Scabies).
- Insect bites are often suspected by history and can occur over the entire body.
- Folliculitis presents with characteristic pustules arising from hair shafts (see Chapter 100, Folliculitis).
- Zoster mimics coronary artery disease when it presents with chest pain before the vesicles are visible.
- Herpes simplex infection presents with similar lesions but is usually restricted to the perioral region, genital area, buttocks, and fingers (see Chapter 114, Herpes Simplex).

MANAGEMENT

NONPHARMACOLOGIC

- Calamine lotion and topically administered lidocaine may be used to reduce pain and itching. SOR Ⓒ

MEDICATIONS

- Healthy children who develop zoster can be treated with analgesics for comfort.
- Acyclovir is not generally recommended in healthy children but may lead to faster resolution of the lesions if started within 48 hours of the onset of the rash. SOR Ⓒ
- Intravenous Acyclovir is indicated for immunocompromised patients to speed recovery and to prevent dissemination. SOR Ⓒ

PREVENTION

- Use of varicella (chickenpox) vaccine has not led to an increase in vaccine-associated herpes zoster in immunized patients or in the general population, and has led to an overall decrease in herpes zoster.[8]

FOLLOW-UP

- Follow-up is based on the severity of the case and the immune status of the patient.

PATIENT EDUCATION

- Herpes zoster in an immunocompetent host is only contagious from contact with open lesions.

- Patients with disseminated zoster or with zoster and are immunocompromised should be isolated from nonimmune individuals with primary varicella infection (in which airborne spread is possible).
- Individuals who have not had varicella and are exposed to a patient with herpes zoster are only at risk of developing primary varicella and not herpes zoster.

110 ZOSTER OPHTHALMICUS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

This 5-year-old girl developed redness and pain on the right side of her forehead. Later a vesicular rash developed (**Figure 110-1**). She was diagnosed with herpes zoster involving the first (ophthalmic) branch of the trigeminal nerve. Note the vesicles and bullae on the forehead and eyelid and the crust on the nasal tip (Hutchinson sign). Fortunately, she did not have ocular complications and her case of zoster fully healed with systemic acyclovir and acyclovir eye ointment.

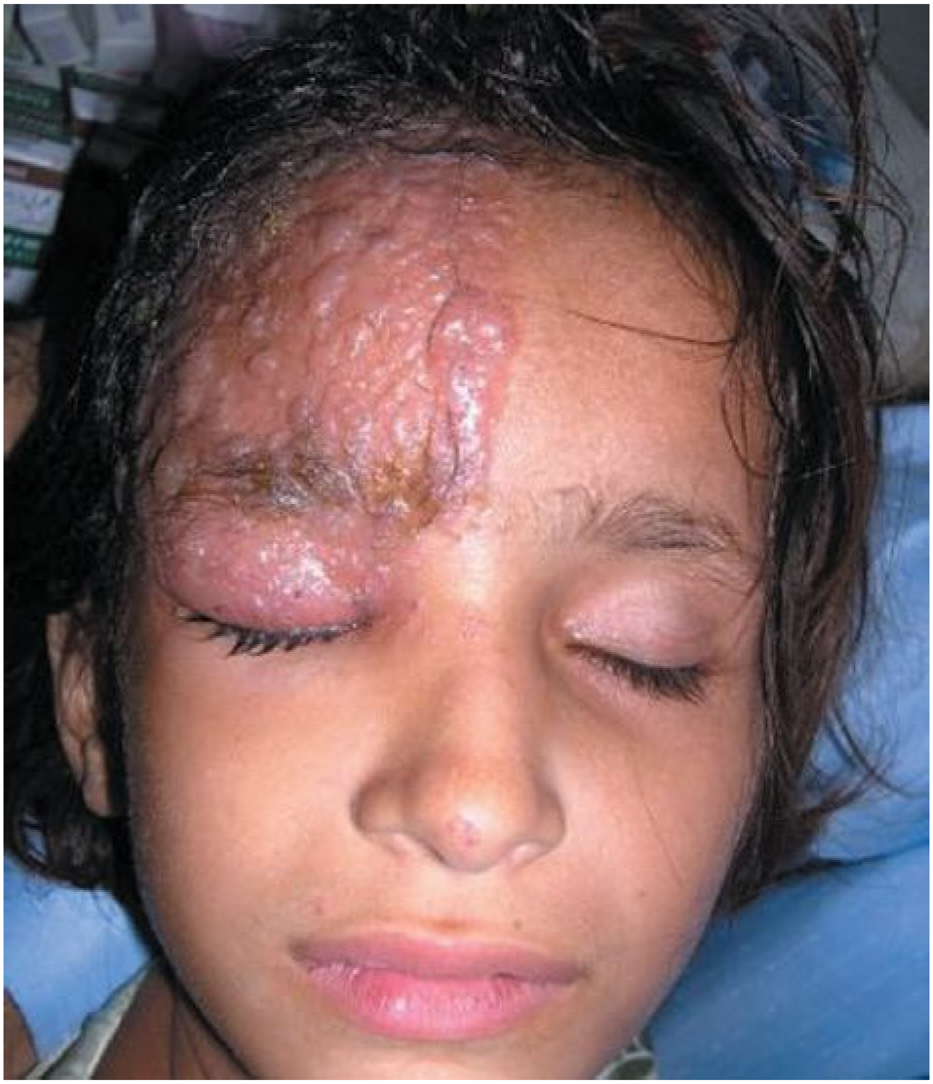

FIGURE 110-1 A 5-year-old girl with herpes zoster involving the ophthalmic branch of the trigeminal nerve. Note the vesicles and bullae on the forehead and eyelid and the crust on the nasal tip (Hutchinson sign). Fortunately, she did not have ocular complications and her case of zoster fully healed with oral acyclovir and acyclovir eye ointment. (*Used with permission from Amor Khachemoune, MD.*)

INTRODUCTION

Herpes zoster is a common infection caused by varicella-zoster virus, the same virus that causes chickenpox. Reactivation of the latent virus in neurosensory ganglia produces the characteristic manifestations of herpes zoster (shingles). Herpes zoster outbreaks may be precipitated by aging, poor nutrition, immunocompromised status (**Figures 110-2** to **110-4**), physical or emotional stress, and excessive fatigue. Although zoster most commonly involves the thoracic and lumbar dermatomes, reactivation of the latent virus in the trigeminal ganglia may result in herpes zoster ophthalmicus (HZO) (**Figures 110-1** to **110-5**).

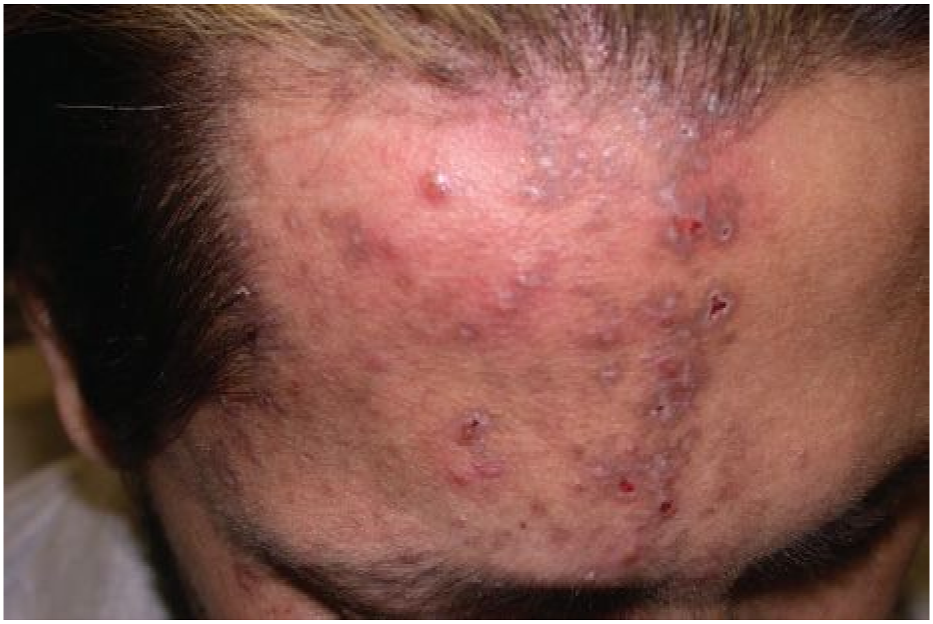

FIGURE 110-2 An HIV-positive Hispanic man with painful herpes zoster of his right forehead. His right eye was red, painful, and very sensitive to light. (*Used with permission from Paul Comeau*.)

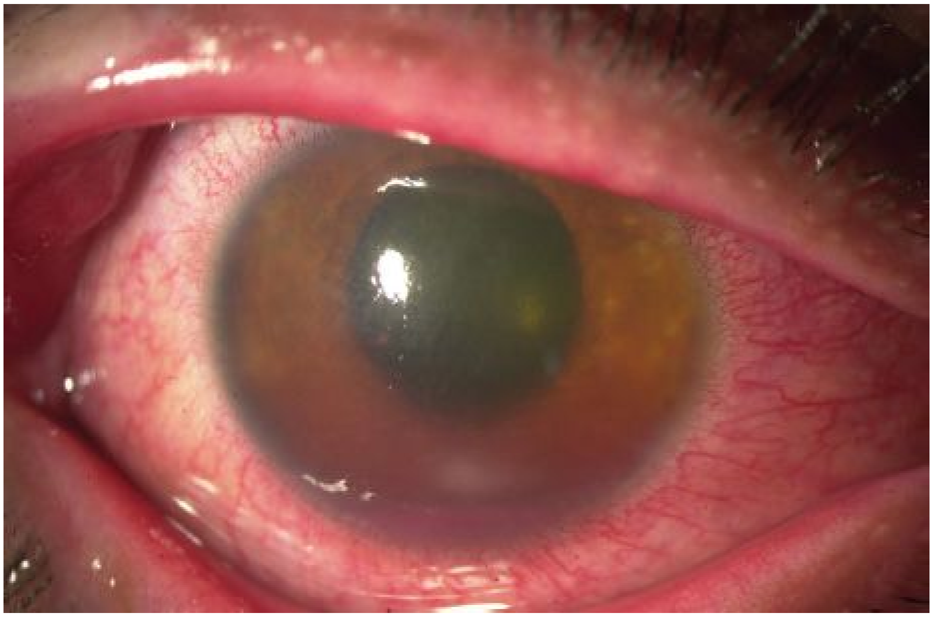

FIGURE 110-3 Acute zoster ophthalmicus of the patient in Figure 110-2. Note the conjunctival injection, corneal punctation (keratitis), and a small layer of blood in the anterior chamber (hyphema). A diagnosis of anterior uveitis was suspected based on the irregularly shaped pupil, the hyphema, and ciliary flush. A slit-lamp examination confirmed the anterior uveitis (iritis). (*Used with permission from Paul Comeau*.)

with permission from Paul Comeau.)

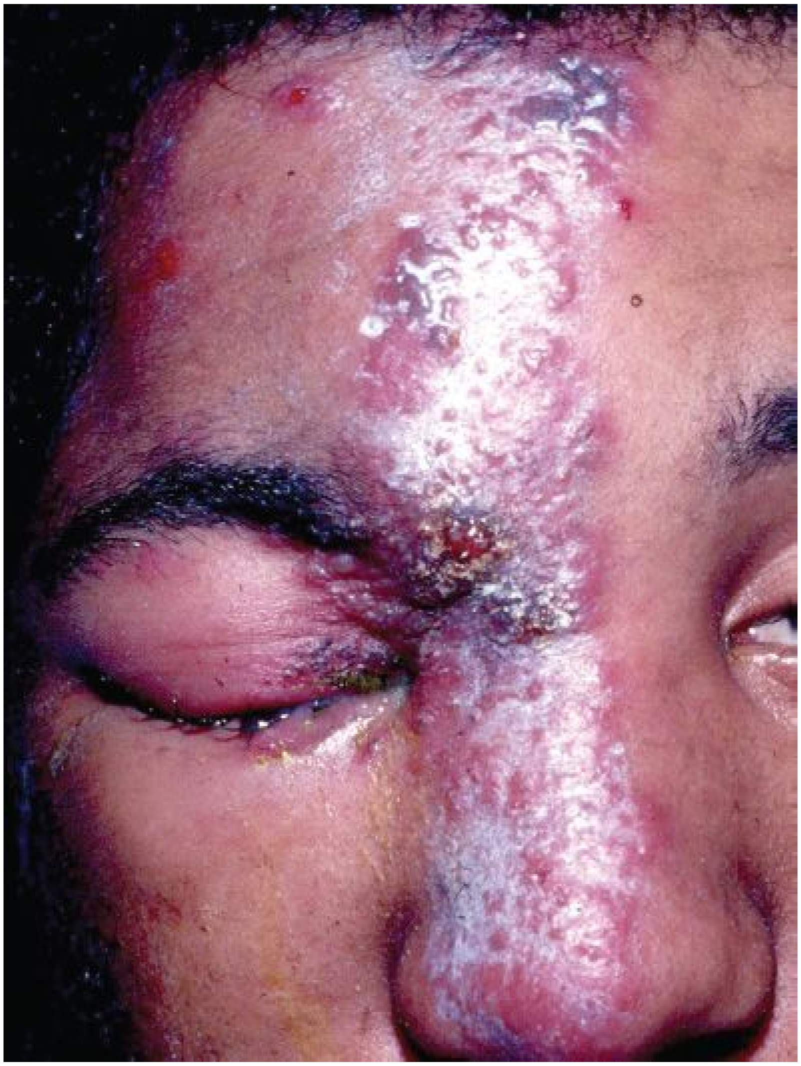

FIGURE 110-5 Herpes zoster ophthalmicus causing eyelid swelling and ptosis. Note the positive Hutchinson sign. (*Used with permission from Richard P. Usatine, MD.*)

SYNONYMS

Ocular herpes zoster.

EPIDEMIOLOGY

- Incidence rates of HZO complicating herpes zoster range from 8 to 56 percent.[1]
- Ocular involvement is not correlated with age, gender, or severity of disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Serious sequelae may occur including chronic ocular inflammation, vision loss (**Figures 110-2** to **110-4**), and disabling pain. Early diagnosis is important to prevent progressive corneal involvement and potential loss of vision.[2]
- Because the nasociliary branch of the first (ophthalmic) division of the trigeminal (fifth cranial) nerve innervates the globe (**Figure 110-6**), the most serious ocular involvement develops if this branch is involved.

FIGURE 110-6 Diagram demonstrating the sensory distribution of the trigeminal (fifth cranial) nerve, and major peripheral nerves of the first (ophthalmic) division that may be involved with herpes zoster ophthalmicus. The infraorbital nerve from the second division is also shown. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

- Classically, involvement of the side of the tip of the nose (Hutchinson sign) has been thought to be a clinical predictor of ocular involvement via the external nasal nerve (**Figures 110-1** and **110-5**). The Hutchinson sign is a powerful predictor of ocular inflammation and corneal denervation with relative risks of 3.35 and 4.02, respectively. In one study, the manifestation of herpes zoster skin lesions at the dermatomes of both nasociliary branches (at the tip, the side, and the root of the nose) was invariably associated with the development of ocular inflammation.[3]
- Epithelial keratitis is the earliest potential corneal finding (**Figure 110-3**). On slit-lamp examination, it appears as multiple, focal, swollen spots on the cornea that stain with fluorescein dye. They may either resolve or progress to dendrite formation. Herpes zoster virus dendrites form branching or frond-like patterns that have tapered ends and stain with fluorescein dye. These lesions can lead to anterior stromal corneal infiltrates.
- Stromal keratitis occurs in 25 to 30 percent of patients with HZO, and is characterized by multiple fine granular infiltrates in the anterior corneal stroma. The infiltrates probably arise from antigen–antibody reaction and may be prolonged and recurrent.[4]
- Anterior uveitis evolves to inflammation of the iris and ciliary body and occurs frequently with HZO (**Figure 110-3**). The inflammation is usually mild, but may cause a mild intraocular pressure elevation. The course of disease may be prolonged, especially without timely treatment, and may lead to glaucoma and cataract formation.
- Herpes zoster virus is the most common cause of acute retinal necrosis. Symptoms include blurred vision and/or pain in one or both eyes and signs include peripheral patches of retinal necrosis that rapidly coalesce, occlusive vasculitis, and vitreous inflammation. It commonly causes retinal detachment. Bilateral involvement is observed in 1/3 of patients,

but may be as high as 70 percent in patients with untreated disease. Treatment includes long courses of oral and intravenous acyclovir, and corticosteroids.[5]

- Varicella-zoster virus is a member of the same family (Herpesviridae) as herpes simplex virus, Epstein-Barr virus, and cytomegalovirus.
- The virus damages the eye and surrounding structures by neural and secondary perineural inflammation of the sensory nerves. This often results in corneal anesthesia.
- Conjunctivitis, usually with *Staphylococcus aureus*, is a common complication of HZO.

RISK FACTORS

- Immunocompromised persons, especially when caused by human immunodeficiency virus infection, have a much higher risk of developing zoster complications, including HZO.

DIAGNOSIS

CLINICAL FEATURES

- The syndrome usually begins with a prodrome of low-grade fever, headache, and malaise that may start up to 1 week before the rash appears.
- Unilateral pain or hypesthesia in the affected eye, forehead, top of the head, and/or nose may precede or follow the prodrome. The rash starts with erythematous macules along the involved dermatome, then rapidly progresses over several days to papules, vesicles and pustules (**Figures 110-5** to **110-5**). The lesions rupture and typically crust over, requiring several weeks to heal completely.

- With the onset of a vesicular rash along the trigeminal dermatome, hyperemic conjunctivitis, episcleritis, and lid droop (ptosis) can occur (**Figure 110-5**).
- Approximately 2/3 of patients with HZO develop corneal involvement (keratitis).[1] The epithelial keratitis may feature punctate or dendritiform lesions (**Figure 110-3**). Complications of corneal involvement can lead to corneal scarring (**Figure 110-4**).[6]
- Iritis (anterior uveitis) occurs in approximately 40 percent of patients and can be associated with hyphema and an irregular pupil (**Figure 110-3**).[1]
- Rarely, zoster can be associated with cranial nerve palsies.

TYPICAL DISTRIBUTION

- The frontal branch of the first division of the trigeminal nerve (which includes the supraorbital, supratrochlear, and external nasal branch of the anterior ethmoidal nerve) is most frequently involved, and 50 to 72 percent of patients experience direct eye involvement (**Figure 110-6**).[1]
- Although HZO most often produces a classic dermatomal rash in the trigeminal distribution, a minority of patients may have only cornea findings.

DIFFERENTIAL DIAGNOSIS

- Bacterial or viral conjunctivitis presents as eye pain and foreign body sensation associated with discharge but no rash (see Chapter 12, Conjunctivitis).
- Trigeminal neuralgia presents with facial pain but without the rash or conjunctival findings.
- Glaucoma that presents as inflammation, pain, and injection, but without the rash or conjunctival findings.

- Traumatic abrasions usually present with a history of trauma and corneal findings but no other zoster findings (see Chapter 11, Corneal Foreign Body and Abrasion).
- Pemphigus and other bullous diseases present with blisters, but not in a dermatomal distribution (see Section 13: Bullous Diseases).

MANAGEMENT

MEDICATIONS

- The standard treatment for HZO is to initiate antiviral therapy with acyclovir (<12 yo: 20 mg/kg/dose IV Q8 hour or >12 yo: 800 mg orally 5 times daily for 7 to 10 days or 10 mg/kg intravenously every 8 hours for 7 to 10 days).[7] SOR Ⓐ
- Topical steroid ophthalmic drops are applied to the involved eye, by the examining ophthalmologist, to reduce the inflammatory response and control immune keratitis and iritis.[1,2] SOR Ⓑ
- The ophthalmologist may prescribe a topical cycloplegic (such as atropine) to treat the ciliary muscle spasm that is painful in iritis. SOR Ⓒ
- Topical ophthalmic antibiotics may also be prescribed to prevent secondary infection of the eye. SOR Ⓒ
- As in all cases of zoster, pain should be treated effectively with oral analgesics.
- Topical anesthetics should never be used with ocular involvement because of their corneal toxicity. SOR Ⓑ
- Secondary infection, usually *S. aureus*, may develop and should be treated with broad-spectrum topical and/or systemic antibiotics.

REFERRAL OR HOSPITALIZATION

- Referral to an ophthalmologist urgently should be initiated when eye involvement is seen or suspected.
- Hospital admission should be considered for patients with loss of vision, severe symptoms, immunosuppression, involvement of multiple dermatomes, or with significant facial bacterial superinfection.

PROGNOSIS

- HZO can become chronic or relapsing. Recurrence is a characteristic feature of HZO.
- Approximately 50 percent of patients with HZO develop complications. Systemic antiviral therapy can lower the emergence of complications.[10,11]

FOLLOW-UP

- Early diagnosis is critical to prevent progressive corneal involvement and potential loss of vision. Patients with herpes zoster should be informed that they should present for medical care with any zoster involving the first (ophthalmic) division of the trigeminal nerve or the eye itself.

PATIENT EDUCATION

- Zoster of the eye is a very serious vision-threatening illness that requires strict adherence to medical therapy and close follow-up.
- Viral transmission to nonimmune individuals from patients with herpes zoster can occur, but it is less frequent than with chickenpox. Virus can be transmitted through contact with secretions.

111 MEASLES

E.J. Mayeaux, Jr., MD
Luke Baudoin, MD

PATIENT STORY

An 18-month-old boy, who is visiting family in San Antonio with his parents from Central America, presents with a 3-day history of fever, malaise, conjunctivitis, coryza, and cough. He had been exposed to a child with similar symptoms approximately 2 weeks prior. A day before, he developed a maculopapular rash that blanches under pressure (**Figures 111-1** and **111-2**). His shot records are unavailable but his mother states that his last vaccine was before age 1 year. He is diagnosed with measles and supportive care is provided.

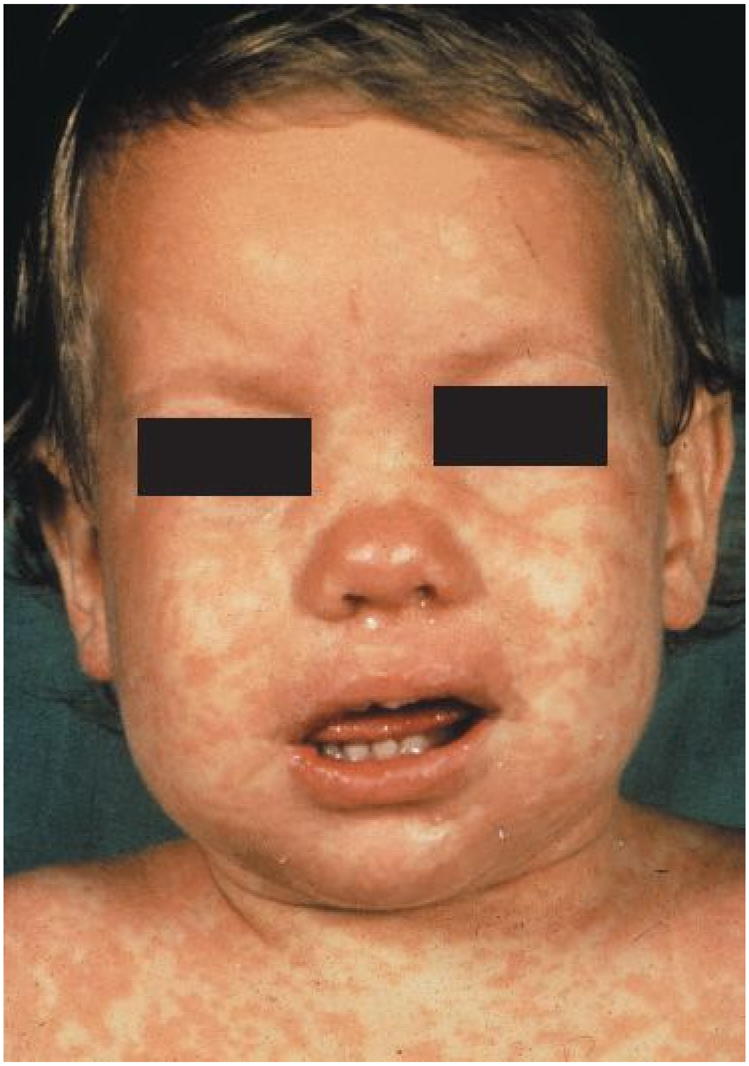

FIGURE 111-1 Typical measles rash that began on the face and became confluent. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

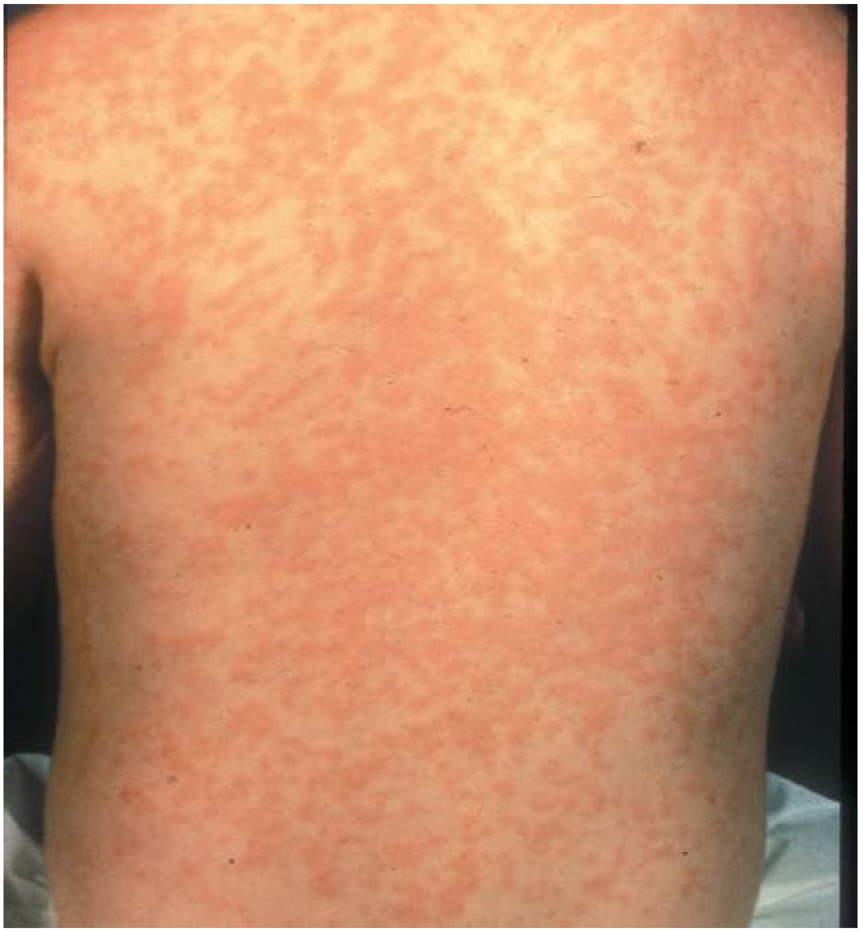

FIGURE 111-2 The typical measles rash on the trunk. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

INTRODUCTION

Measles is a highly communicable, acute viral illness that is still one the most serious infectious diseases in human history. Until the introduction of the measles vaccination, it was responsible for millions of deaths worldwide annually. Although the epidemiology of this disease makes eradication a possibility, the ease of transmission and the low percentage of non immunized population that is required for disease survival have made eradication of measles extremely difficult.

EPIDEMIOLOGY

- Last major outbreak in the US was during 1989 to 1990 and prompted a change in immunization policy in 1991, so that all children are to have two measles-mumps-rubella (MMR) vaccines before starting kindergarten.
- This practice interrupted the transmission of indigenous measles in the US by 1993 and reduced incidence of measles to an historic low (<0.5 cases per million persons) by 1997 to 1999.[1]
- After an all-time low of 34 cases were reported in 2004 in the US, the annual incidence began to increase with most cases linked to international travel of inadequately vaccinated Americans to endemic areas. Incomplete vaccination rates facilitate the spread once the virus is imported to the US causing clusters of periodic outbreaks.[1]
- The worldwide incidence of death from measles was effectively reduced from an estimated 733,000 deaths in 2000 to an estimated 164,000 deaths in 2008 with mass vaccination campaigns by the member countries of the World Health Assembly.[2] In 2008, about 83 percent of the world's children received one dose of measles vaccine by their first birthday through routine health services—up from 72 percent in 2000.[3]
- Measles elimination is now considered a feasible target. The World Health Organization have renewed their commitment to eliminate measles transmission by 2015. This will require greater than 95 percent of the population receives two doses of the MMR vaccine.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Measles is caused by the measles virus, a member of the family paramyxoviridae, genus *Morbillivirus* (hence the name, morbilliform rash).

- It is highly contagious, transmitted by airborne droplets, and commonly causes outbreaks.
- Classic measles infection starts with the incubation phase that is usually asymptomatic and lasts for 10 to 14 days. It starts after entry of the virus into the respiratory mucosa with local viral replication. The infection then spreads to regional lymphatic tissues, and then throughout the body through the bloodstream.
- The prodrome phase starts with the appearance of systemic symptoms including fever, malaise, anorexia, conjunctivitis, coryza, and cough (**Figure 111-3**). The respiratory symptoms are caused by mucosal inflammation from viral infection of epithelial cells. Patients may develop Koplik's spots, which are small whitish, grayish, or bluish papules with erythematous bases that develop on the buccal mucosa usually near the molar teeth (**Figure 111-4**). The prodrome usually lasts for 2 to 3 days.

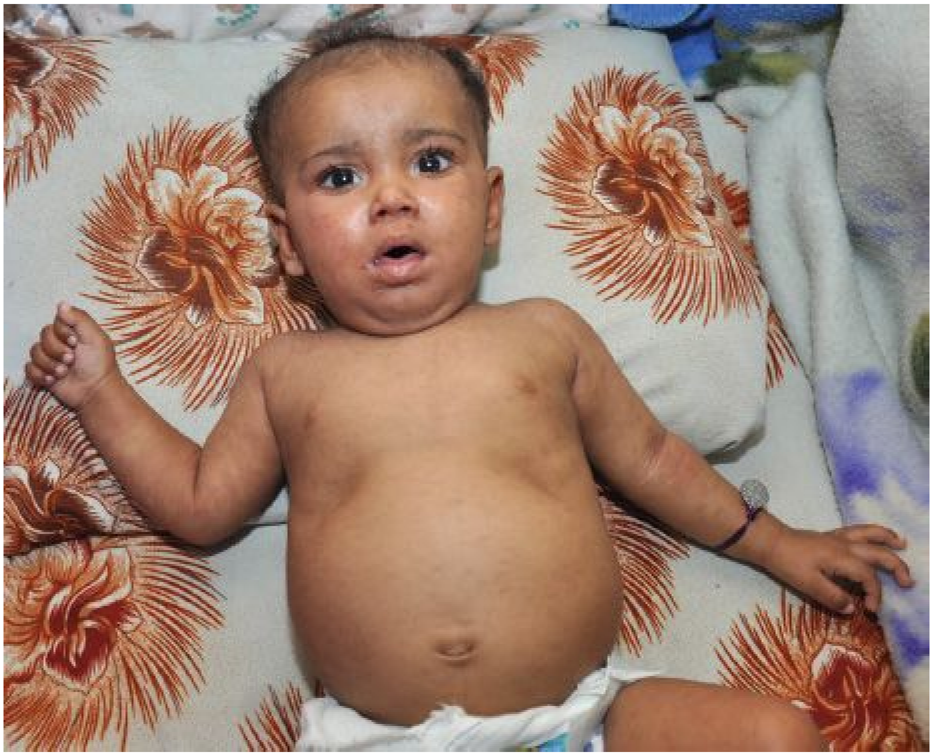

FIGURE 111-3 Measles in an Ethiopian infant during a measles outbreak. The rash is faint but her cough is prominent and subcostal retractions are

seen during this cough. She also has rhinorrhea and conjunctivitis. (*Used with permission from Richard P. Usatine, MD.*)

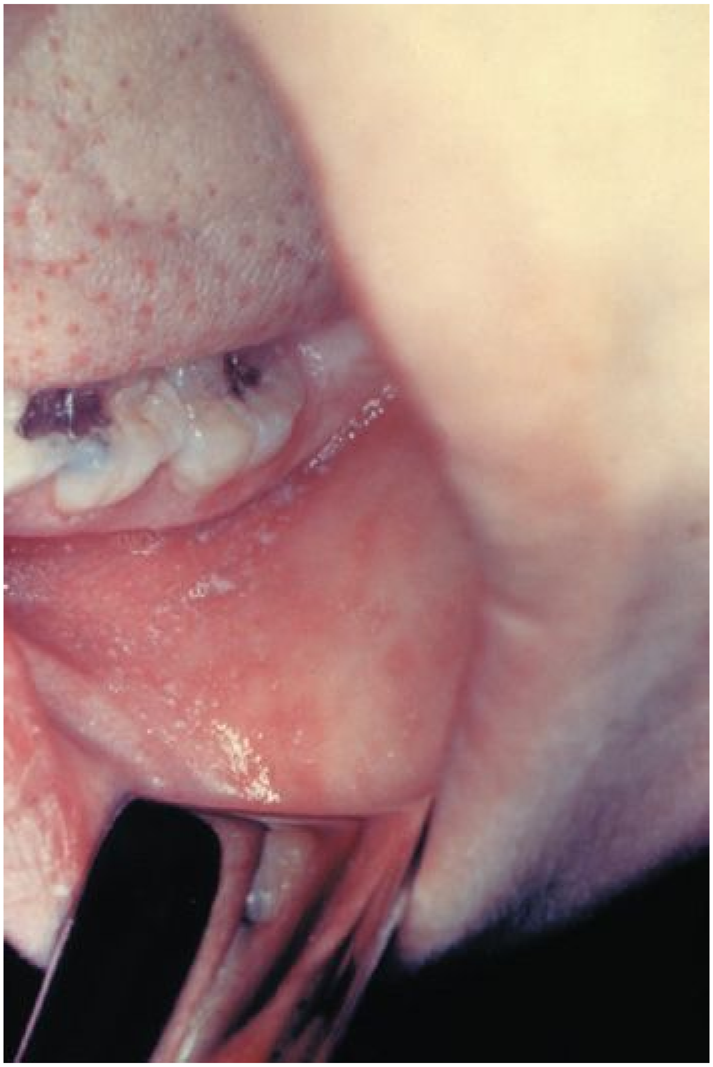

FIGURE 111-4 Koplik's spots occur 1 to 2 days before to 1 to 2 days after the cutaneous rash. Their presence is considered to be pathognomonic for measles, and appear as punctate blue-white spots on the bright red background of the oral buccal (cheek) mucosa. (*Used with permission from the Centers for Disease Control and Prevention*.)

- The classic measles rash (**Figures 111-1**, **111-2**, and **111-5**) is maculopapular and blanches under pressure. Clinical improvement in symptoms typically ensues within 2 days. Three to 4 days after the rash first appears, it begins to fade to a brownish color which is followed by fine flaking. The cough may persist for up to 2 weeks.

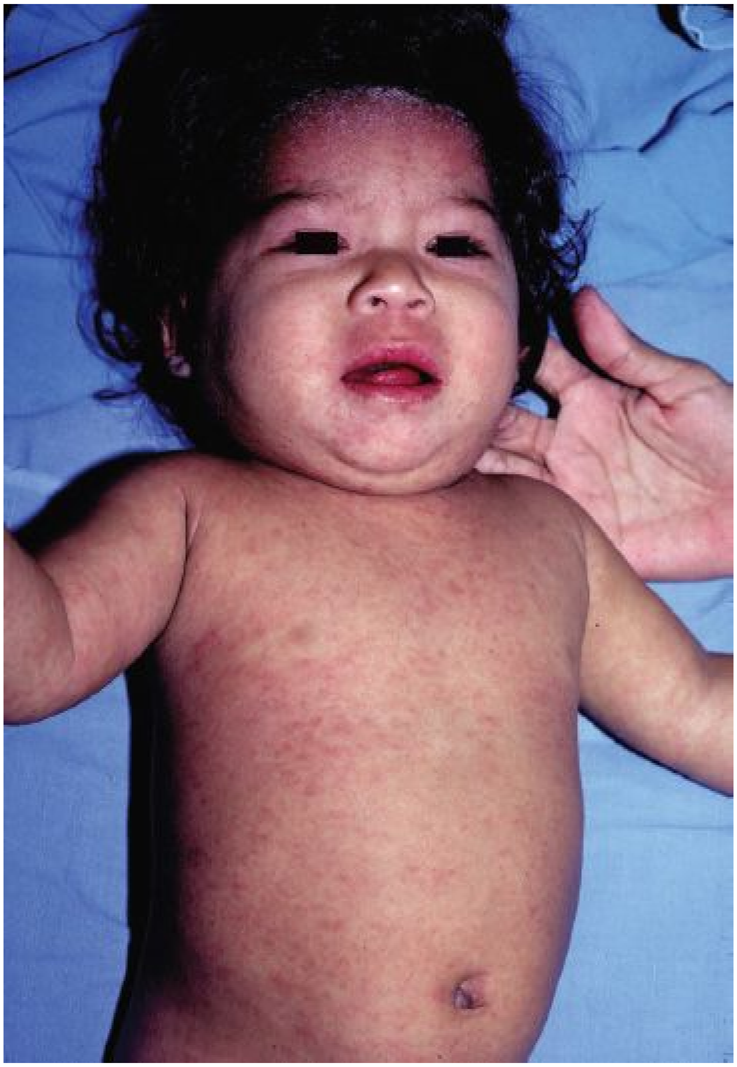

FIGURE 111-5 A South American child with an advanced measles exanthem. (*Used with permission from Eric Kraus*.)

- Fever persisting beyond the third day of rash suggests a measles-associated complication.
- Immunity after measles infection is thought to be lifelong in most cases. Measles reinfection occasionally occurs, but it is extremely rare.
- Atypical measles is a measles variant that occurs in previously-vaccinated persons. Patients develop high fever and headache 7 to 14 days after exposure, and often present with a dry cough and pleuritic chest pain.

Two to three days later, a rash develops that spreads from the extremities to the trunk. The rash may be vesicular, petechial, purpuric, or urticarial. Patients may develop respiratory distress, peripheral edema, hepatosplenomegaly, paresthesias, or hyperesthesia.

- The measles virus can cause a variety of clinical syndromes including the classic childhood illness and a less intense form in persons with suboptimal levels of anti measles antibodies.
- Measles virus infection can also result in more severe illness, including lymphadenopathy, splenomegaly, laryngotracheobronchitis (croup), giant cell pneumonia, and measles inclusion body encephalitis in immunocompromised patients.[5] This form occurs in the very young, those with vitamin A deficiency, and in pregnant women.
- Postinfection neurologic syndromes can occur. Postinfectious encephalomyelitis is a demyelinating disease that presents during the recovery phase, and is thought to be caused by a postinfectious autoimmune response.[6] The major manifestations include fever, headache, neck stiffness, ataxia, mental status changes, and seizures. CSF analysis demonstrates lymphocytosis and elevated proteins. Postinfectious encephalomyelitis has a 10 to 20 percent mortality rate, and residual neurologic abnormalities are common.[6]
- Subacute sclerosing panencephalitis (SSPE) is a progressive, fatal, neurological degenerative disease that may represent a persistent infection of the central nervous system with a variant of the virus. It usually occurs in patients younger than 20 years of age and 7 to 10 years after natural measles.[7] Patients develop neurologic symptoms, myoclonus, dementia, and eventually flaccidity or decorticate rigidity.
- Measles in pregnancy is a rare entity in areas that practice vaccination. Premature births may be more common in gravid women with measles, but there is no clear evidence of teratogenicity.[8,9]
- When measles occurs during pregnancy, maternal and fetal morbidity is increased. The virus is not responsible for congenital defects but can induce placental damage which may lead to fetal death. Major perinatal risks are also miscarriage and prematurity. When measles occurs in late pregnancy, congenital infection is possible.[8]

RISK FACTORS

For developing measles:

- Failure to receive immunization.
- Failure to receive second immunization dose.
- Travel to endemic areas.
- Exposure to travelers from endemic areas.

For developing severe measles or for developing complications:

- Immunodeficiency.
- Malnutrition.
- Pregnancy.
- Vitamin A deficiency.
- Age younger than 5 years or older than 20 years.

DIAGNOSIS

Measles is a distinct disease characterized by fever, malaise, conjunctivitis, coryza, cough, rash, and Koplik's spots.

CLINICAL FEATURES

Koplik's spots appear during the prodrome phase and are pathognomonic for measles infection and occur approximately 48 hours before the characteristic measles exanthem. The classic blanching rash, along with the prodrome and Koplik spots, is usually adequate to make a tentative diagnosis. The most rapid and accurate test to confirm acute measles is a blood test for measles specific IgM antibodies. By waiting until the third day of the rash, a false-negative IgM result can be avoided.[1]

TYPICAL DISTRIBUTION

The rash begins on the face and spreads centrifugally to involve the neck, trunk, and finally the extremities. The lesions may become confluent, especially on the face. This cranial-to-caudal rash progression is characteristic of measles.

DIFFERENTIAL DIAGNOSIS

- Upper respiratory tract infections—The prodrome stage of measles can be confused with a URI except that significant fever is typically present with measles infection.
- Fordyce spots—Tiny yellow-white granules on the buccal or lip mucosa caused by benign ectopic sebaceous glands, may be mistaken for Koplik's spots. Fordyce spots do not have an erythematous base.
- Alternative diagnoses that may be confused with the measles rash include Rocky Mountain spotted fever, infectious mononucleosis, scarlet fever, Kawasaki disease, toxic shock syndrome, dengue fever, and simple drug eruption (see Chapter 154, Cutaneous Drug Reactions).
- Measles can usually be distinguished clinically from rubella, erythema infectiosum (parvovirus B19 infection), roseola, and enteroviral infection by the intensity of the measles rash, its subsequent brownish coloration, the classic prodrome, and the severe disease course.

MANAGEMENT

NONPHARMACOLOGIC

- The treatment of measles is mostly supportive. Suspected cases of measles should be immediately reported to the local or state department of health.

MEDICATIONS

- Measures to control spread of infection should not be delayed for laboratory confirmation. Vaccine should be promptly administered to all susceptible persons, or they should be removed from the outbreak setting for a minimum of 3 weeks. SOR C
- Giving serum immune globulin 0.25 mL/kg of body weight to a maximum dose of 15 mL to a susceptible person within 6 days of exposure to measles, can prevent or modify disease. This is especially important in patients in whom the risk of complications of measles is higher such as pregnant women, children younger than 1 year of age, and immunocompromised patients. SOR C
- The World Health Organization recommends vitamin A for all children with acute measles, regardless of their country of residence, to reduce risk of complications. Vitamin A is administered once a day for 2 days at the following doses:
    - 50,000 IU for infants aged <6 months.
    - 100,000 IU for infants aged 6 to 11 months.
    - 200,000 IU for children aged ≥12 months.
    - A third, age-specific dose of vitamin A is given 2 to 4 weeks later to patients with clinical signs and symptoms of vitamin A deficiency.[1] SOR B

REFERRAL OR HOSPITALIZATION

Consider hospitalization in the following scenarios:

- Difficulty breathing or noisy breathing—Bronchopneumonia occurs in 5 to 10 percent of patients.

- Changes in behavior, confusion—May be a harbinger of acute disseminated encephalomyelitis.
- There is dehydration, which can be the result of diarrhea, vomiting, and poor oral intake.

Refer to ophthalmology if there are changes in vision as measles keratitis can lead to permanent scarring and blindness.

PREVENTION

- Measures to control spread of infection should not be delayed for laboratory confirmation. Vaccine should be promptly administered to all susceptible persons, or they should be removed from the outbreak setting for a minimum of 3 weeks.
- Initial and booster immunization.
- Avoidance of endemic areas without being fully immunized.
- If traveling overseas, the CDC recommends infants 6 to 11 months receive 1 dose of MMR prior to travel (even though the first dose is routinely not recommended until 12 months of age). The MMR given prior to 12 months of age should not be counted as part of the routine vaccination.
- CDC recommends that children over 12 months old traveling overseas should receive the second MMR vaccine at least 28 days apart from the initial vaccination.[1]
- Adequate nutrition including Vitamin A.
- Hand washing.

PROGNOSIS

- The disease is typically self-limited. Measles typically lasts approximately 10 to 14 days from the beginning of the prodrome to the fading of the eruption.
- Approximately 30 percent of measles cases have one or more complications. Complications of measles are more common among patients younger than 5 years of age and adults 20 years of age and older. Centers for Disease Control and Prevention (CDC) reported measles complications include:[6]
  - Diarrhea—8 percent.
  - Otitis media—7 percent.
  - Pneumonia—6 percent.
  - Encephalitis—0.1 percent.
  - Seizures—0.6 to 0.7 percent.
  - Death—0.2 percent.

FOLLOW-UP

- Have patients watched for changes that indicate more severe disease or complications.
- Make sure return appointments for full vaccination is scheduled.

PATIENT EDUCATION

- Avoid exposure to other individuals, particularly unimmunized children and adults, pregnant women, and immunocompromised persons, until at least 4 days after rash onset.
- Avoid contact with potential sources of secondary bacterial pathogens until respiratory symptoms resolve.

112 FIFTH DISEASE

E.J. Mayeaux, Jr., MD
John H. Haynes, Jr., MD
Mathew Prine, MD

PATIENT STORY

A 2-year-old boy presents with mild flu-like symptoms and a rash. He had an erythematous malar rash and a “lace-like” erythematous rash on the trunk and extremities (**Figures 112-1** and **112-2**). The “slapped cheek” appearance made the diagnosis easy for fifth disease. The parents were reassured that this would resolve spontaneously. The child returned to daycare the next day.

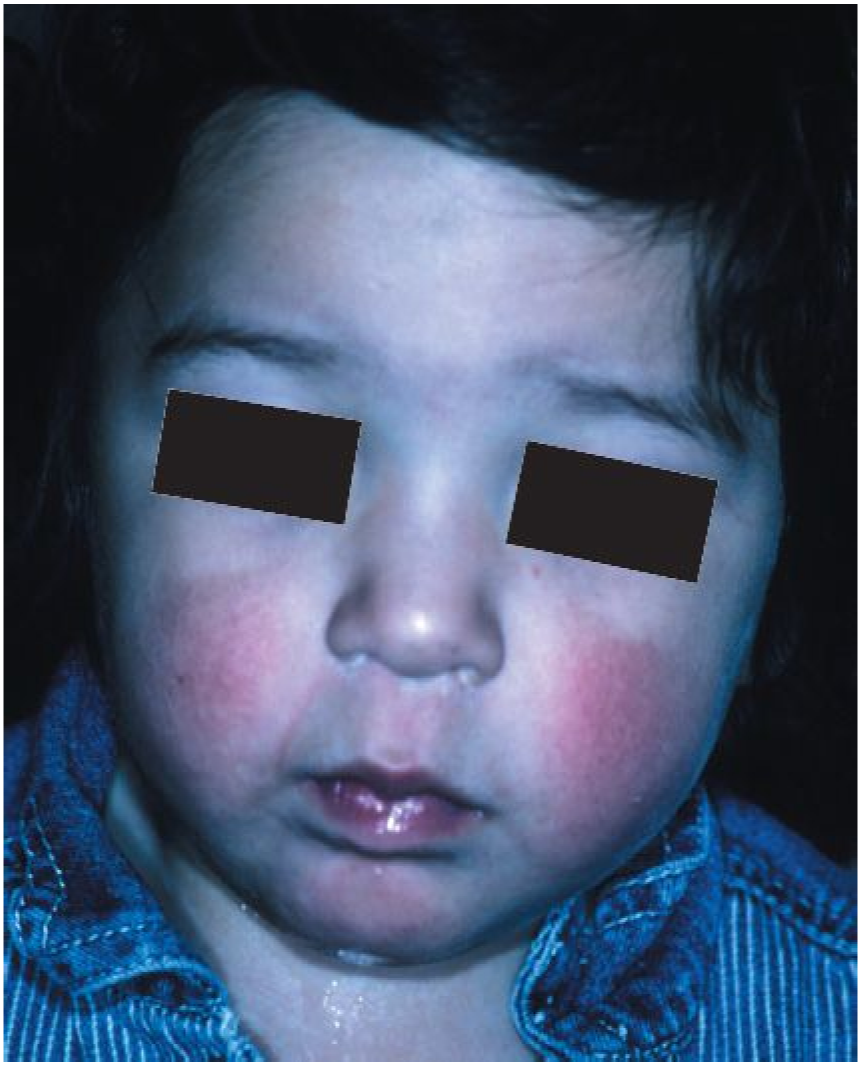

FIGURE 112-1 Classic erythematous malar rash with “slapped cheek” appearance of fifth disease (erythema infectiosum). (*Used with permission from Richard P. Usatine, MD.*)

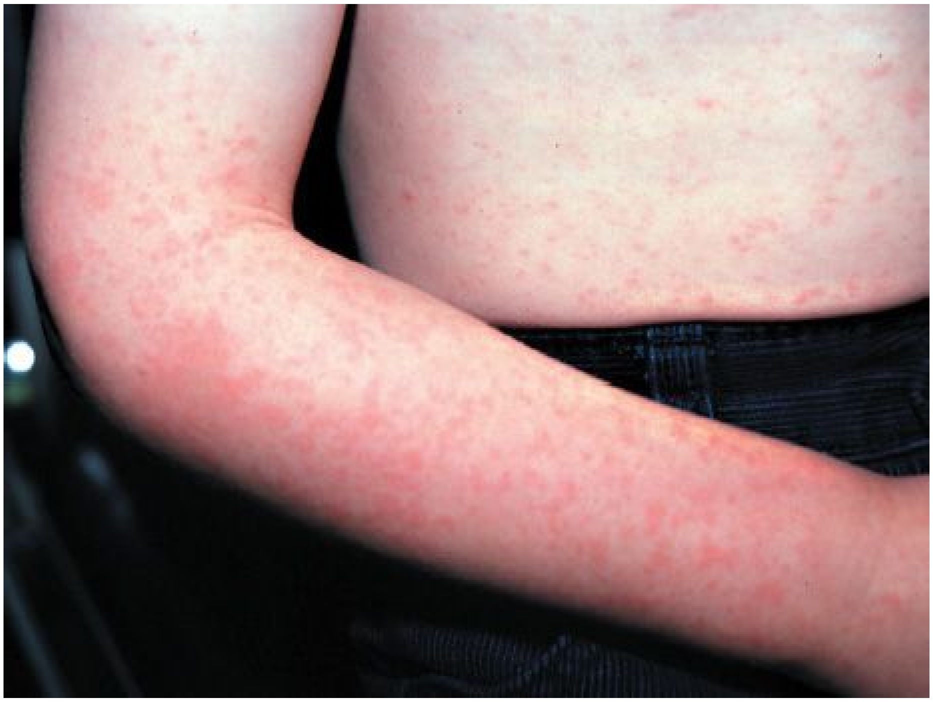

FIGURE 112-2 Classic fifth disease “lace-like” erythematous rash on the trunk and extremities. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Fifth disease is also commonly referred to as erythema infectiosum. The name derives from the fact that it represents the fifth of the 6 common childhood viral exanthems described. Transmission occurs through respiratory secretions, possibly through fomites, and parenterally via vertical transmission from mother to fetus and by transfusion of blood or blood products.

SYNONYMS

Erythema infectiosum, parvovirus B19 infections, slapped cheek disease.

EPIDEMIOLOGY

- Fifth disease is common throughout the world. Antiparvovirus B19 immunoglobulin (Ig) G is found equally among Americans, Asians, and Europeans.[1] The only known host for B19 is humans.
- Most individuals become infected during their school-age years.
- Fifth disease is very contagious via the respiratory route and occurs more frequently between late winter and early summer. Up to 60 percent of the population is seropositive for antiparvovirus B19 IgG by age 20 years.[2] In some communities, there are cycles of local epidemics every 4 to 10 years.[3]
- Thirty to forty percent of pregnant women lack measurable IgG to the infecting agent and are, therefore, presumed to be susceptible to infection. Infection during pregnancy can in some cases lead to fetal death.

ETIOLOGY AND PATHOPHYSIOLOGY

- Fifth disease is a mild viral febrile illness with an associated rash caused by parvovirus B19 (**Figure 112-3**).

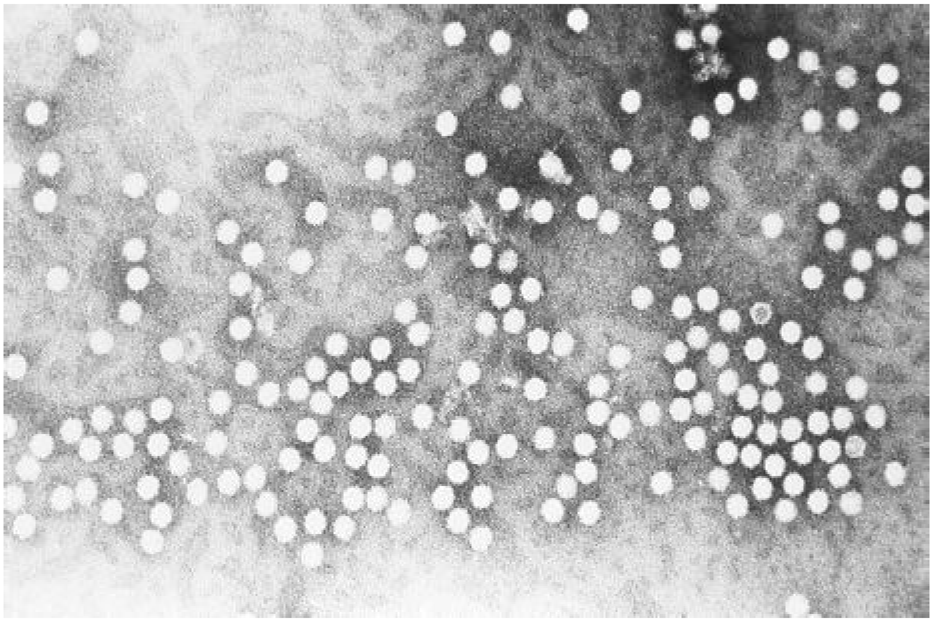

FIGURE 112-3 Transmission electron microscopy of parvovirus B19. (*Used with permission from the Centers for Disease Control and Prevention.*)

- Most persons with parvovirus B19 infection never develop the clinical picture of fifth disease.
- Parvovirus B19 infects rapidly dividing cells and is cytotoxic for erythroid progenitor cells.
- After initial infection, a viremia occurs with an associated precipitous drop in the reticulocyte count and anemia. The anemia is rarely clinically apparent in healthy patients, but can cause serious anemia if the red blood cell count is already low. Patients with a chronic anemia such as sickle cell or thalassemia may experience a transient aplastic crisis.[4]
- Vertical transmission can result in congenital infection if a woman becomes infected during her pregnancy.[5] The risk of a fetal loss or hydrops fetalis is greatest (loss rate of 11%) when the infection occurs within the first 20 weeks of gestation.[6]

RISK FACTORS

- Exposure to infected children.
- Reception of blood products.

DIAGNOSIS

CLINICAL FEATURES HISTORY AND PHYSICAL

- Fifth disease is usually a biphasic illness, starting with upper respiratory tract symptoms that may include headache, fever, sore throat, pruritus, coryza, abdominal pain, diarrhea, and/or arthralgias. These constitutional symptoms coincide with onset of viremia and they usually resolve for about a week before the next stage begins. Associated hematologic abnormalities may be seen with this stage.
- The second stage is characterized by a classic erythematous malar rash with relative circumoral pallor or “slapped cheek” appearance in children (**Figures 112-1** and **112-4**) followed by a “lace-like” erythematous rash on the trunk and extremities (**Figures 112-2** and **112-5**). Arthropathy affecting the hands, wrists, knees, and ankles may precede the development of a rash in adults. The course is usually self-limited.

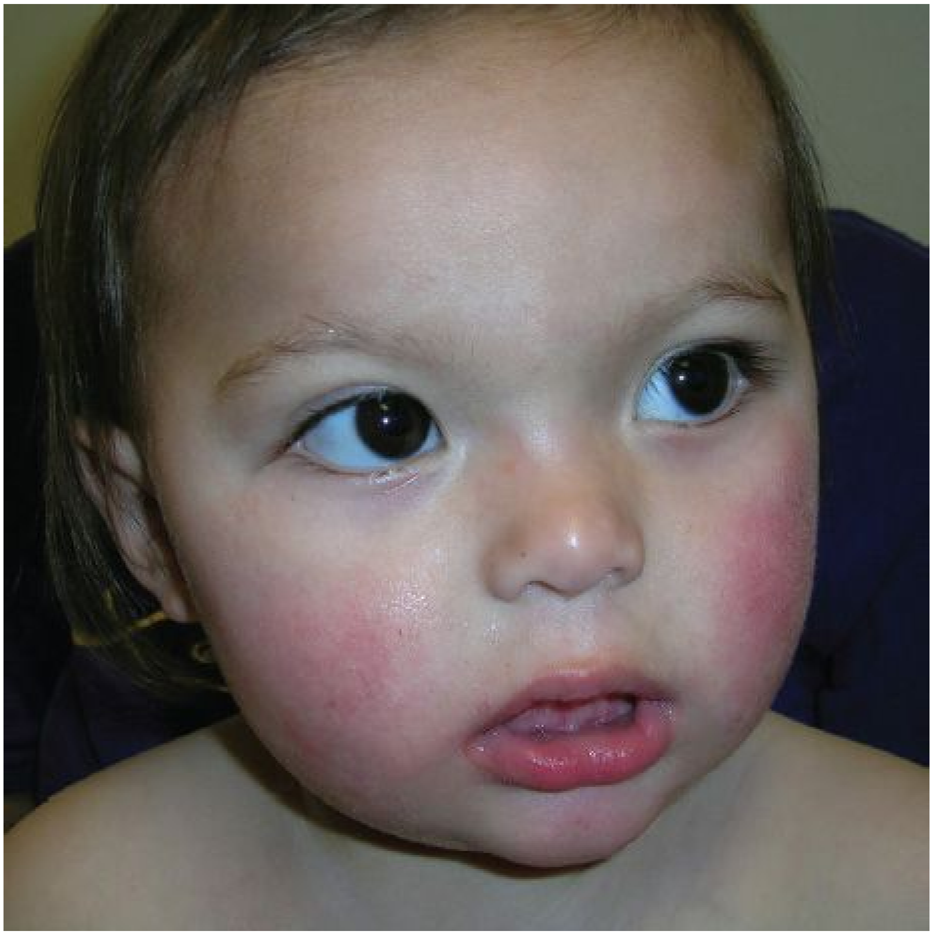

FIGURE 112-4 Classic erythematous malar rash with “slapped cheek” appearance of fifth disease in an 18-month-old child. (*Used with permission from Richard P. Usatine, MD.*)

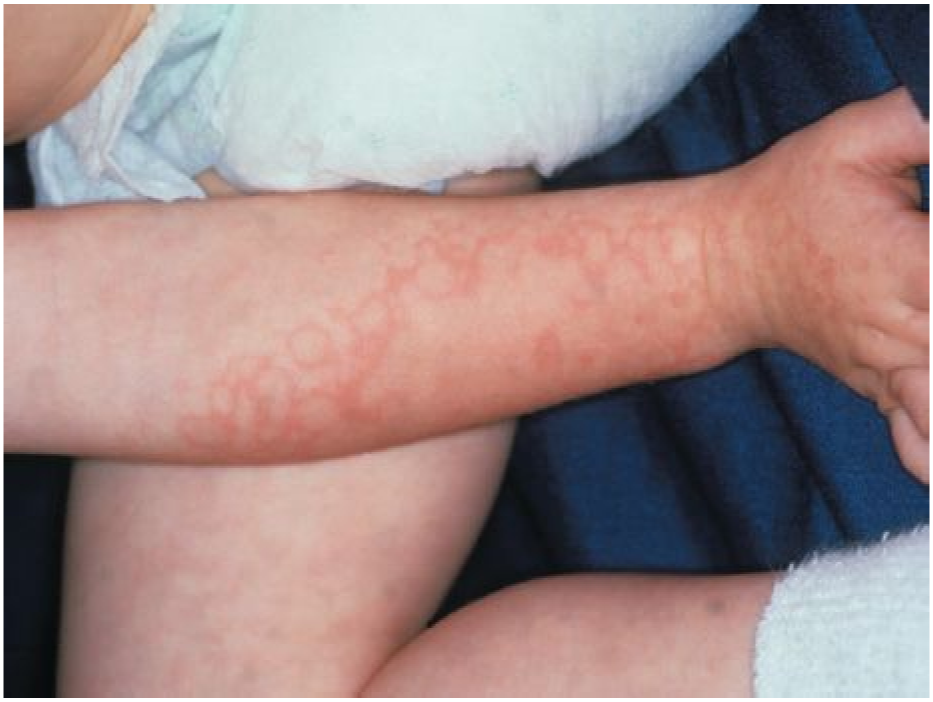

FIGURE 112-5 Classic reticular eruption on the extremities. (*Used with permission from Jeffrey Meffert, MD.*)

TYPICAL DISTRIBUTION

- The rash starts with the classic slapped-cheek appearance (**Figures 112-1** and **112-4**). Then an erythematous macular rash occurs on the extremities. After several days, the extremities rash fades into a lacy pattern (**Figures 112-2** and **112-5**). The exanthem may recur over several weeks in association with exercise, sun exposure, bathing in hot water, or stress.

LABORATORY TESTING

- Laboratory studies are not usually needed as the diagnosis can be made by history and physical exam. Serum B19-specific IgM may be ordered in pregnant women exposed to fifth disease. After 3 weeks, infection is also indicated by a 4-fold or greater rise in serum B19-specific IgG antibody titers.

- Patients with symptoms of anemia, a history of increased red blood cell (RBC) destruction (e.g., sickle cell disease, hereditary spherocytosis), or with decreased RBC production (e.g., iron-deficiency anemia) should be tested to determine the degree of anemia.
- Pregnant women who are exposed to or have symptoms of parvovirus infection should have serologic testing. Prior to 20 weeks' gestation, women testing positive for acute infection (i.e., positive IgM and negative IgG) should be counseled concerning the low risk of fetal loss and congenital anomalies. There are currently no proven associations with congenital abnormalities, but there is low risk of fetal loss.[7]

IMAGING

- If serologic testing in pregnant women is positive, some experts recommend that the patient should receive ultrasounds to look for signs of fetal hydrops. Intrauterine transfusion is currently the only effective treatment to alleviate fetal anemia.[8]

DIFFERENTIAL DIAGNOSIS

- Scarlet fever presents as a fine papular (sandpaper) rash in association with a *Streptococcus* infection (see Chapter 28, Scarlet Fever and Strawberry Tongue).
- Allergic-hypersensitivity reactions (erythema multiforme, erythema nodosum and cutaneous vasculitis) often involve the arms and legs but rarely affect the face (see Section 12: Hypersensitivity Syndromes and Drug Reactions).
- Lyme disease presents with an expanding rash with central clearing (see Chapter 183, Lyme Disease).
- Measles produces a blanching rash that begins on the face and spreads centrifugally to involve the neck, trunk, and finally the extremities. It

tends to become more confluent instead of lacy with time (see Chapter 111, Measles).

MANAGEMENT

NONPHARMACOLOGIC

- Fifth disease is usually self-limited and requires no specific therapy.
- See the following “Patient Education” section for further information about parvovirus B19 infections in pregnancy.

MEDICATIONS

- NSAID or acetaminophen therapy may alleviate fevers and arthralgias.
- Transient aplastic anemia occurs in individuals who have baseline anemia and may be severe enough to require transfusion until the patient’s red cell production recovers.

PREVENTION

- Because it is spread through respiratory secretions and possibly through fomites, good hand sanitation and infection-control techniques are recommended.
- Infected individuals should avoid excessive heat or sunlight, which can cause rash flare-ups.

PROGNOSIS

- The rash of erythema infectiosum usually is self-limiting, but may last weeks to months with exacerbations.
- Aplastic anemia usually lasts up to 2 weeks but may become chronic. The onset of erythema infectiosum rash usually indicates that reticulocytosis has returned and aplastic crisis will not occur.

PATIENT EDUCATION

- Explain to parents that the disease is usually self-limited. Normal activities may be pursued as tolerated with sun protection or avoidance.
- Children who present with the classic findings of fifth disease are past the infectious state and can attend school and day care.
- During pregnancy, a woman who has an acute infection prior to 20 weeks' gestation should be counseled concerning the low risks of fetal loss and congenital anomalies. Beyond 20 weeks' gestation, some physicians recommend repeated ultrasounds to look for signs of fetal hydrops.

113 HAND FOOT MOUTH SYNDROME

E.J. Mayeaux, Jr., MD
Steven N. Bienvenu, MD

PATIENT STORY

A 4-year-old boy presents to a free clinic for homeless families with a low-grade fever and lesions on his hands and feet (**Figures 113-1** and **113-2**). The mother notes that two other kids in the transitional living center also have a similar rash. Upon further investigation, mouth lesions are noted (**Figure 113-3**). The mother is reassured that this is nothing more than hand, foot, and mouth disease and will go away on its own. Treatment includes fluids and antipyretics as needed.

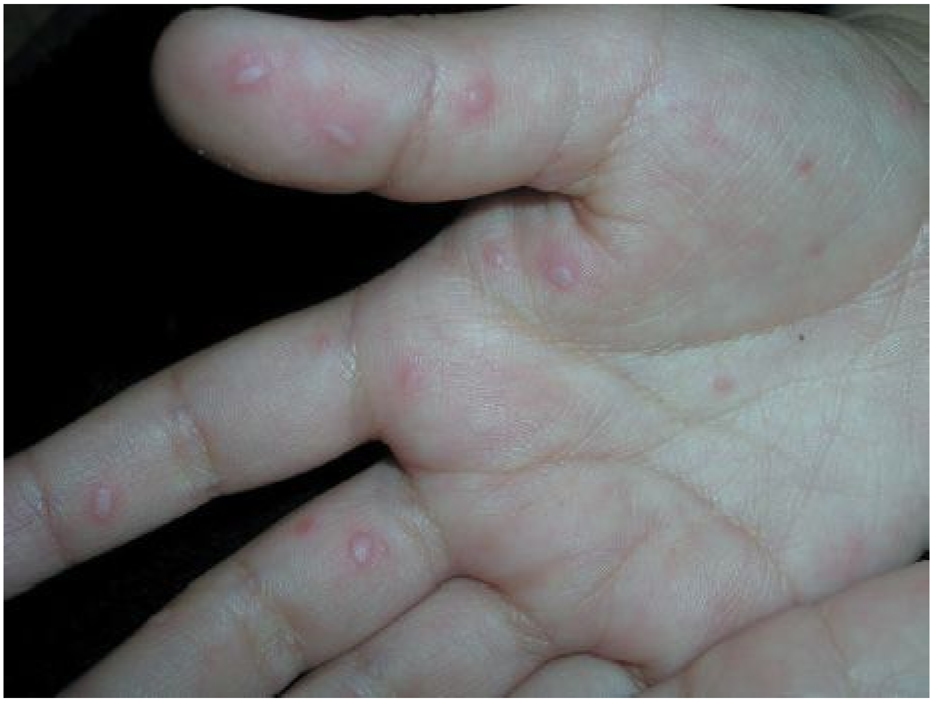

FIGURE 113-1 Typical flat vesicular lesions on the hand of a 4-year-old boy with hand, foot, and mouth disease. (*Used with permission from Richard P. Usatine, MD.*)

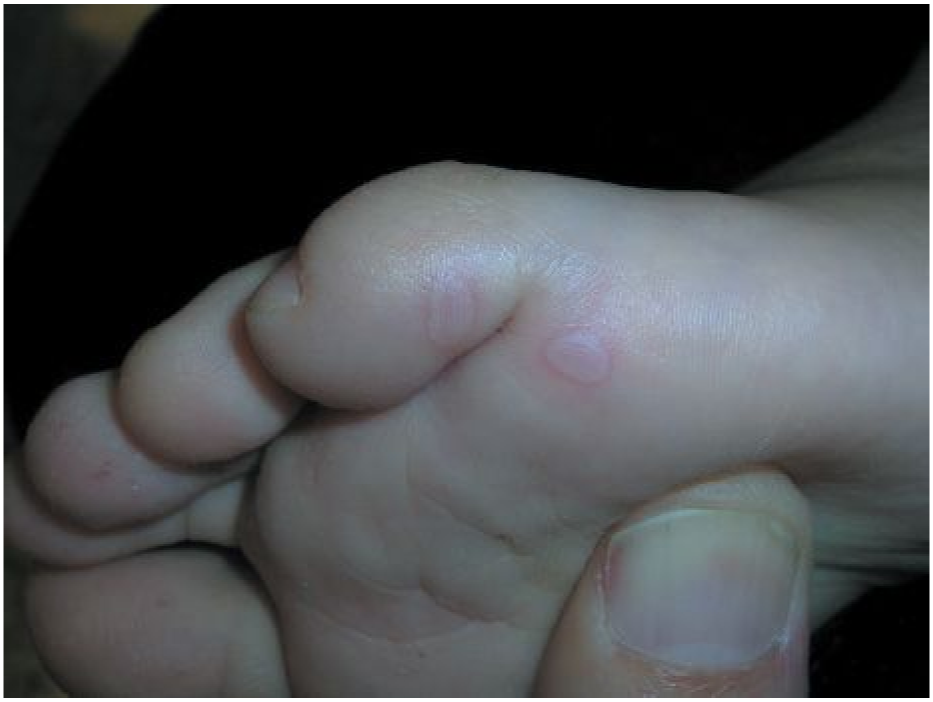

FIGURE 113-2 Foot of the boy in Figure 113-1. Lesions tend to be on palms and soles, fingers, and toes. (*Used with permission from Richard P. Usatine, MD.*)

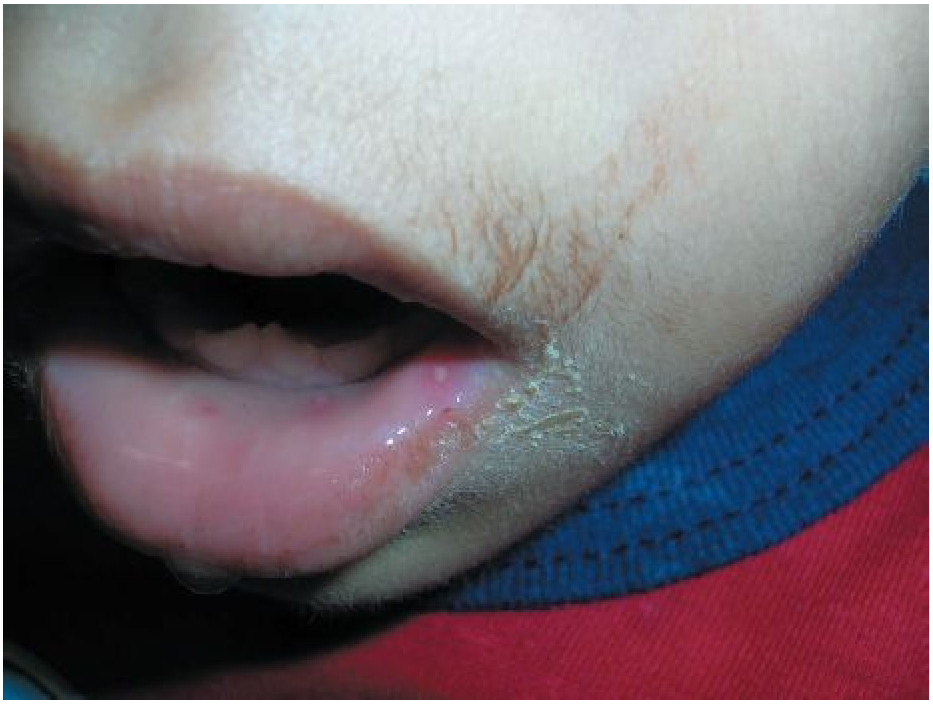

FIGURE 113-3 Mouth lesions in same boy appear as small ulcers on the lips and oral mucosa. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Hand, foot, and mouth disease (HFMD) is a viral illness that may affect humans and some animals, and presents with a distinct clinical presentation. The disease occurs worldwide. In 2011 and 2012, an outbreak of a much more severe and atypical form occurred in the US.

EPIDEMIOLOGY

- Epidemics tend to occur every 3 years worldwide. In temperate climates, the peak incidence is in late summer and early fall.
- HFMD generally has a mild course, but it may be more severe in infants and young children.[1,2]

- There is no racial or gender predilection. Most cases affect children younger than 10 years old.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- HFMD is most commonly caused by members of the enterovirus genus, especially coxsackie viruses. Epidemic infections in the US are usually caused by coxsackievirus A16, and less commonly by other coxsackievirus A strains, coxsackievirus B, or enterovirus 71.[2,3] Sporadic cases occur caused by other coxsackie viruses.
- HFMD is caused by a number of different enteroviruses around the world with different characteristics, but until recently outbreaks of an A6 strain have not been experienced in the US. Most HFMD cases worldwide are due to coxsackievirus A16.[4,5]
- Outbreaks of strains of EV71 enterovirus producing large epidemics of HFMD with significant morbidity and mortality that have occurred recently in east and southeast Asia have not been seen in the US.[5]
- In the fall of 2011 and early winter of 2012, 63 cases of apparent, but more severe HFMD from four US states were reported to the CDC. PCR and gene sequencing detected an A6 strain of coxsackievirus in 74 percent of clinical specimens from 38 cases.[4] Cases of this atypical, severe form of HFMD have now likely been diagnosed throughout much of North America.[4,6,7]
- Coxsackievirus infections are highly contagious. Transmission occurs via aerosolized droplets of nasal and/or oral secretions via the fecal–oral route, or from contact with skin lesions. During epidemics, the virus is spread from child to child and from mother to fetus.
- The incubation period averages 3 to 6 days. Initial viral implantation is in the GI tract mucosa, and it then spreads to lymph nodes within 24 hours. Viremia rapidly ensues, with spread to the oral mucosa and skin. Rarely, aseptic meningitis may occur. Usually by day 7, a neutralizing antibody response develops, and the virus is cleared from the body.

- HFMD may also result in neurologic problems such as a polio-like syndrome, aseptic meningitis, encephalitis, acute cerebellar ataxia, acute transverse myelitis, Guillain-Barré syndrome, and benign intracranial hypertension. Rarely, cardiopulmonary complications such as myocarditis, interstitial pneumonitis, and pulmonary edema may occur.[8,9]
- Infection in the first trimester of pregnancy may lead to spontaneous abortion or intrauterine growth retardation.

RISK FACTORS

- Attendance at child care centers.
- Contact with HFMD.
- Large family.
- Rural residence.

DIAGNOSIS

CLINICAL FEATURES

- A prodrome lasting 12 to 36 hours is usually the first sign of HFMD, and it usually consists of typical general viral infection symptoms with anorexia, abdominal pain, and sore mouth. Lesions are present for 5 to 10 days, and heal spontaneously in 5 to 7 days. Fever is usually mild.
- Atypical, severe HFMD (A6) may be associated with fever as high as 103 to 105 degrees Fahrenheit, produce much more extensive, denser rash in more locations, with greater malaise and likelihood of anorexia, dehydration, and pain.[4]
- Each lesion in typical HFMD begins as a 2- to 10-mm erythematous macule, which develops a gray, oval vesicle that parallels the skin tension

lines in its long axis (**Figures 113-1** and **113-2**). The oral lesions (**Figure 113-3**) begin as erythematous macules, evolve into 2- to 3-mm vesicles on an erythematous base, and then rapidly become ulcerated. The vesicles are painful and may interfere with eating. They are not generally pruritic.

- Atypical (A6) HFMD may produce lesions that are very protean in their character and evolution. Early lesions are usually maculovesicular as with the milder A16 form, but may coalesce (**Figure 113-4**). Others may be vesiculobullous (**Figure 113-5**) and may drain, or simply papular (**Figure 113-6**), or maculopapular and ulcerative (**Figure 113-7**).[4,6,7]

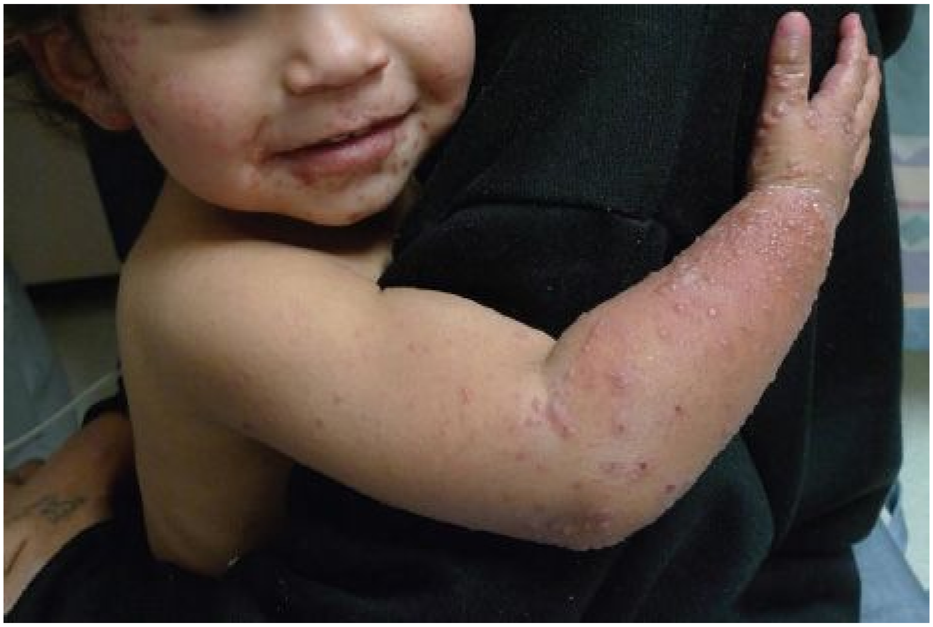

FIGURE 113-4 A one-year-old male with confirmed Coxsackievirus A6 HFMD. His temperature reached 103.8 degrees, and a variety of lesions are visible as well as Koebner phenomenon near the elbow flexure. (*Used with permission from Ann Petru, MD and Julie Kulhanjian, MD.*)

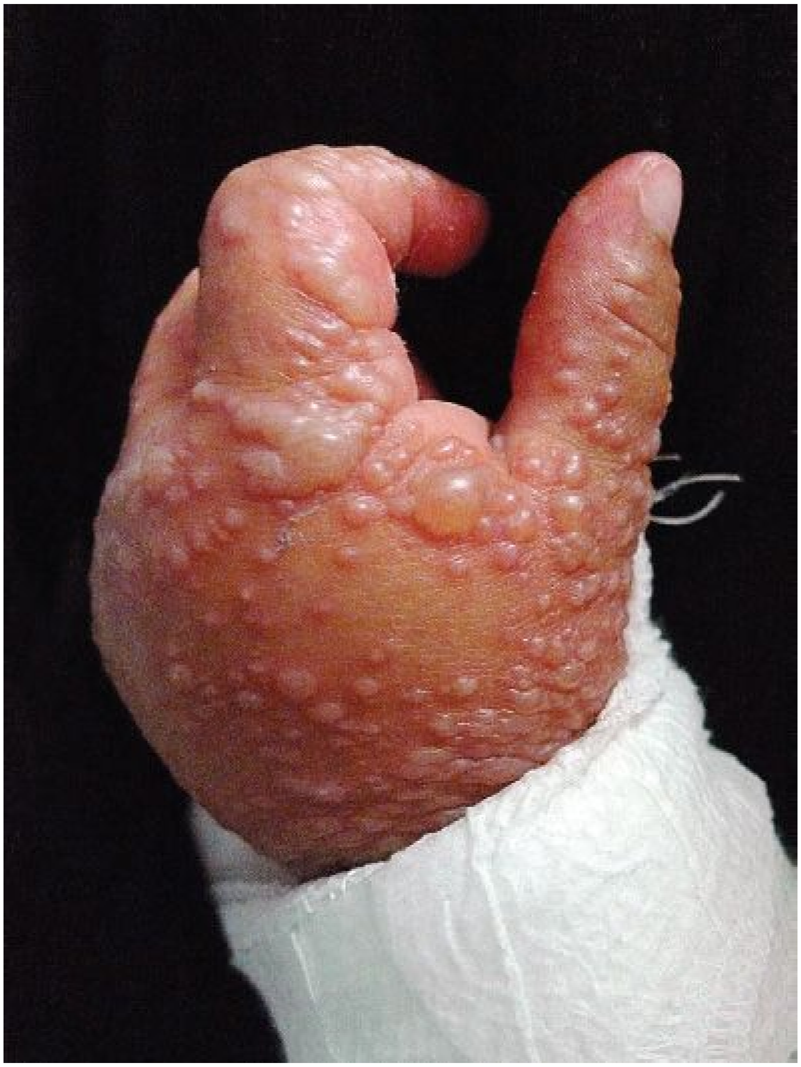

FIGURE 113-5 Vesiculobullous lesions of left hand of child in Figure 113-4. Bullous lesions may rupture. (*Used with permission from Ann Petru, MD and Julie Kulhanjian, MD.*)

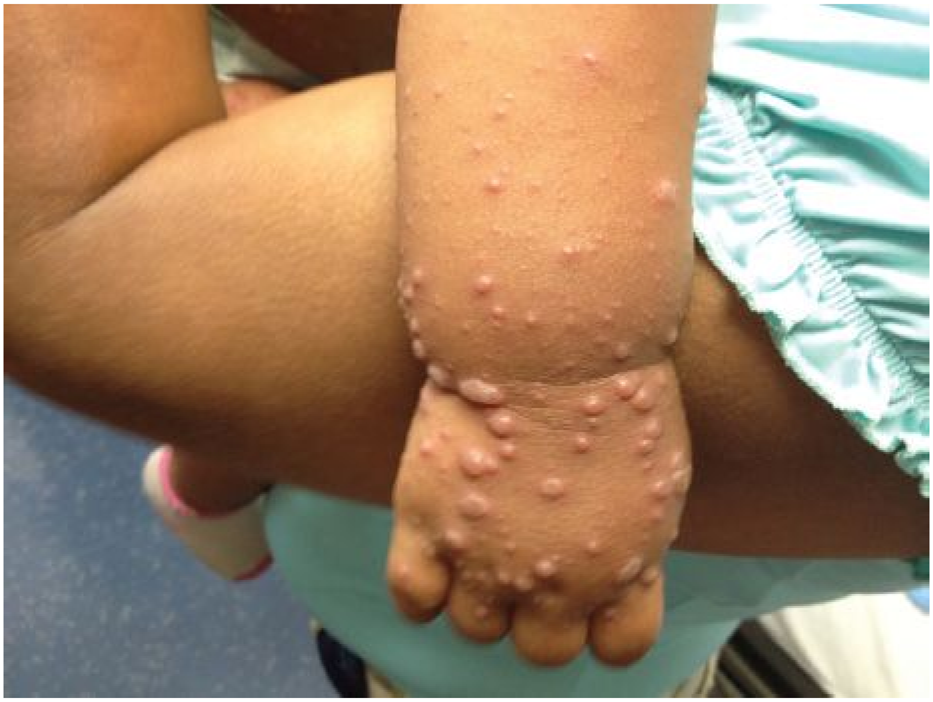

FIGURE 113-6 A 15-month-old female with confirmed A6 infection who demonstrated widespread disease and multiple lesion types. (*Used with permission from Ann Petru, MD.*)

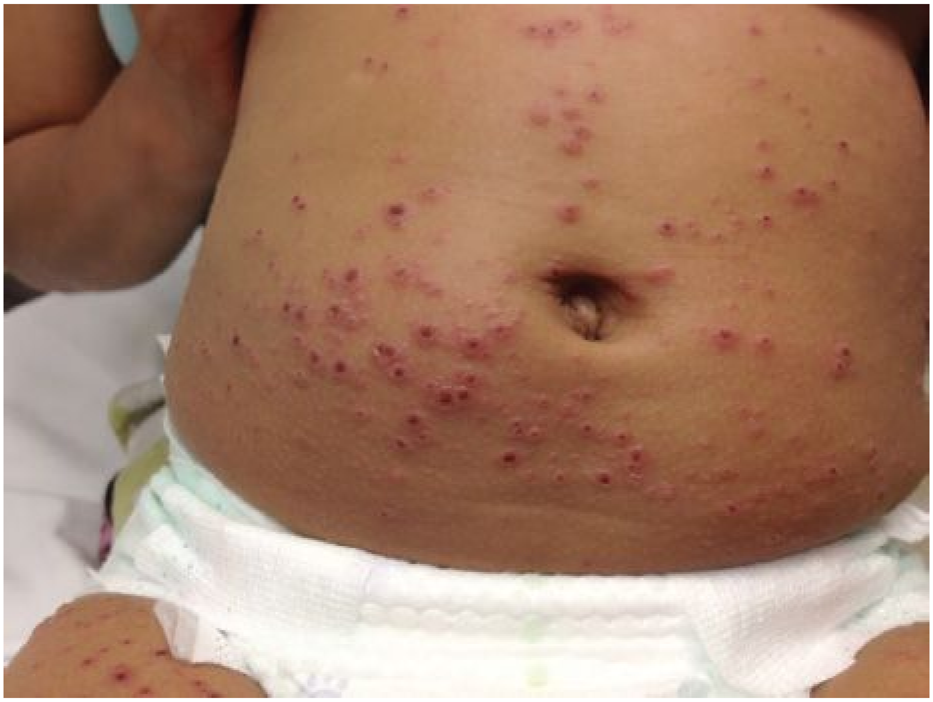

FIGURE 113-7 The abdomen of the child in Figure 113-5 demonstrating two varieties of lesions in the same patient. (*Used with permission from Ann Petru, MD.*)

- Cervical or submandibular lymphadenopathy may be present.

TYPICAL DISTRIBUTION

- Skin lesions of the milder form (A16) develop on the hands, feet, and/or buttocks and oral lesions may involve the palate, buccal mucosa, gingiva, and/or tongue. Lesions on the hands and feet are largely limited to the palmar and plantar surfaces.
- Atypical, severe HFMD (A6) produces a much more extensive rash, and may include the lips and perioral area of the face (**Figure 113-4** and **113-8**), arms, legs, knees, genitalia, trunk (**Figure 113-7**), buttocks (**Figure 113-9**), perianal area, and distinctively the *dorsal* areas of the hands (**Figures 113-5**, **113-6**, and **113-10**) and feet as well as palmar and plantar surfaces. Distribution can be quite variable, however.[4,7]

LABORATORY TESTING

- Laboratory tests are usually not needed for diagnosis.

BIOPSY

Biopsy is not needed.

DIFFERENTIAL DIAGNOSIS

- Aphthous stomatitis presents as single or multiple painful ulcers in the mouth without skin eruptions (see Chapter 40, Aphthous Ulcer).
- Chickenpox presents with body-wide vesicular lesions in multiple crops (see Chapter 108, Chickenpox).
- Erythema multiforme demonstrates body-wide target lesions that also involve the skin of the palms and soles (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Herpes simplex presents with painful recurrent ulcerations of the lips or genitals without simultaneous hand or foot lesions unless there is a herpetic whitlow on the hand (see Chapter 114, Herpes Simplex).
- Eczema herpeticum lesions may very much resemble those of the atypical (severe) form of HFMD, but careful exam usually reveals the typical perioral/intraoral lesions and concurrent hand and foot distribution of HFMD. This new form of HFMD has also been misdiagnosed as varicella (see Chapter 108, Chickenpox), impetigo (see Chapter 99, Impetigo), poison ivy, and atypical Kawasaki disease. Some cases have not manifested intraoral lesions, or lesions on hands or feet.[6,7]

MANAGEMENT

NONPHARMACOLOGIC

- The treatment of HFMD is usually supportive. Usually the mouth lesions are not as painful as in herpes gingivostomatitis. If there is a lot of mouth pain leading to poor oral intake, the following medications may be considered. Topical oral anesthetics such as 2 percent viscous lidocaine by prescription or 20 percent topical benzocaine (Orabase) nonprescription may be used to treat painful oral ulcers. Benzocaine may not be safe in children under 2 years of age due to the risk of methemoglobinemia.[10] SOR Ⓒ
- A solution combining aluminum and magnesium hydroxide (liquid antacid) and 2 percent viscous lidocaine has been reported as helpful when swished and spit out several times a day as needed for pain. This must be limited to patients old enough to reliably spit out the material and avoid anesthetizing critical swallowing surfaces. SOR Ⓒ

MEDICATIONS

- Acetaminophen or NSAIDs/cyclooxygenase (COX)-2 s may be used to manage fever, and analgesics may be used to treat arthralgias. SOR Ⓒ Aspirin should not be used in viral illnesses in children younger than 12 years of age to prevent Reye syndrome. SOR Ⓒ

REFERRAL OR HOSPITALIZATION

- Patients with central nervous system (CNS) manifestations may require hospitalization.
- Those with the new atypical (A6) form are more likely to require hospitalization due to dehydration, severity of symptoms including pain, and diagnostic uncertainty.[5,8]

PREVENTION

- Good hand-washing is critical to reduce the spread of disease, both at home and at daycare facilities experiencing cases. Virus may be shed in stool for at least several weeks.

PROGNOSIS

- HFMD caused by coxsackie viruses is generally a mild self-limited illness that resolves in around 7 to 10 days. HFMD may rarely recur, persist, or cause serious complications.
- The recent atypical (A6) variety outbreak reported by the CDC resulted in a high rate of hospitalization (about 1 in 5 cases), but of the 63 cases reported to the CDC there were no deaths. Lesions tend to heal completely if not complicated. Beau’s lines (Chapter 160, Normal Nail Variants) and onychomadesis (loss of nail) may occur many weeks later, followed by complete healing.[4,7] Illness in both the mild and the “new” atypical form of HFMD is usually followed by complete recovery without scarring. Uncommon CNS involvement has been the cause of most persistent morbidity and deaths associated with HFMD.

PATIENT EDUCATION

- Educate parents of young children to watch for signs of dehydration owing to decreased oral intake secondary to mouth pain.
- To reduce viral spreading, do not rupture blisters.
- The patient may attend school once fever and symptoms subside, no new lesions have appeared, and all lesions have dried or scabbed over.[6]
- The virus that causes hand, foot, and mouth disease may be present in the patient’s stool for 1 month.
- Report any neurologic symptoms to health care providers immediately.

- Good hand washing and contact precautions are critical to preventing spread to others.

114 HERPES SIMPLEX

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 4-year-old girl is brought to her pediatrician’s office because of fever and sores in her mouth for the past 2 days. The child is alert, playful and fully oriented, and her doctor notes that she has crusting on her outer lips (**Figure 114-1A**). The mother pulls back the child’s upper lip to show how her daughter’s gums are inflamed (**Figure 114-1B**). There are small ulcers on the tip of the tongue (**Figure 114-2A**) and when the lower lip is pulled down there are obvious ulcers on the mucosa (**Figure 114-2B**). The doctor easily diagnoses primary herpes gingivostomatitis and determines that the child is drinking fluids but not eating. Her mucous membranes are moist and there are no signs of dehydration. The doctor recommends giving fluids that are nonacidic and somewhat cold (anything that will be tolerated). Oral acyclovir suspension is prescribed three times daily for 7 days. The following day the child the child became afebrile and was tolerating fluids and food better. Within 1 week, she was fully better and able to go back to preschool.

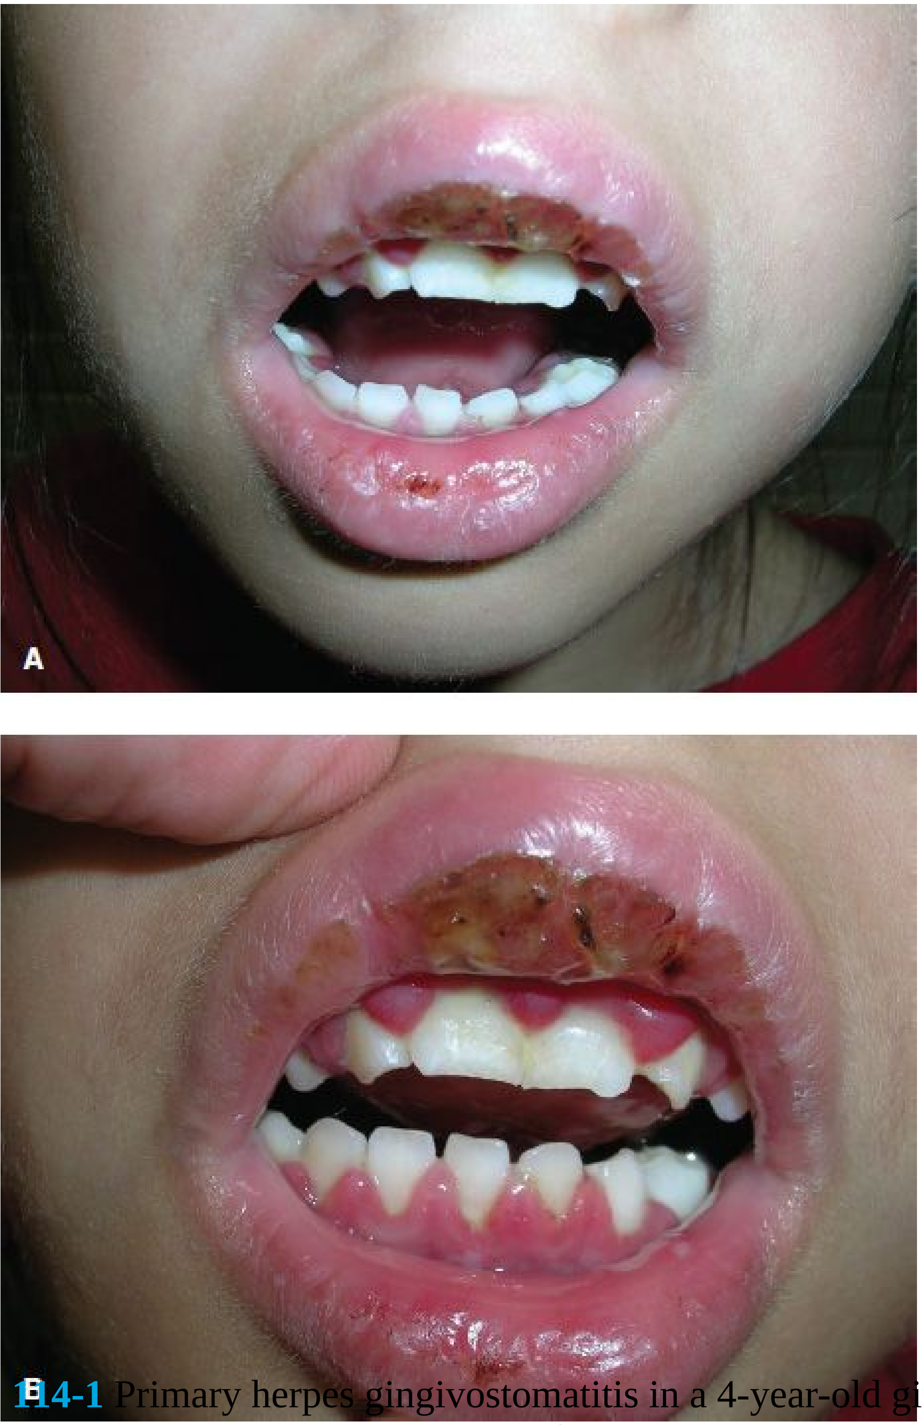

FIGURE 114-1 Primary herpes gingivostomatitis in a 4-year-old girl. **A.** Crusting on the lips. **B.** Gingivitis with significant erythema and swelling of the gums. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Herpes simplex virus (HSV) infection can involve the skin, mucosa, eyes, and central nervous system. HSV establishes a latent state followed by viral reactivation and recurrent local disease. Perinatal transmission of HSV can lead to significant fetal morbidity and mortality.

EPIDEMIOLOGY

HSV affects more than 1/3 of the world's population, with the 2 most common cutaneous manifestations being orolabial herpes (**Figures 114-1** and **114-2**) and genital (**Figures 114-3** and **114-4**).[1]

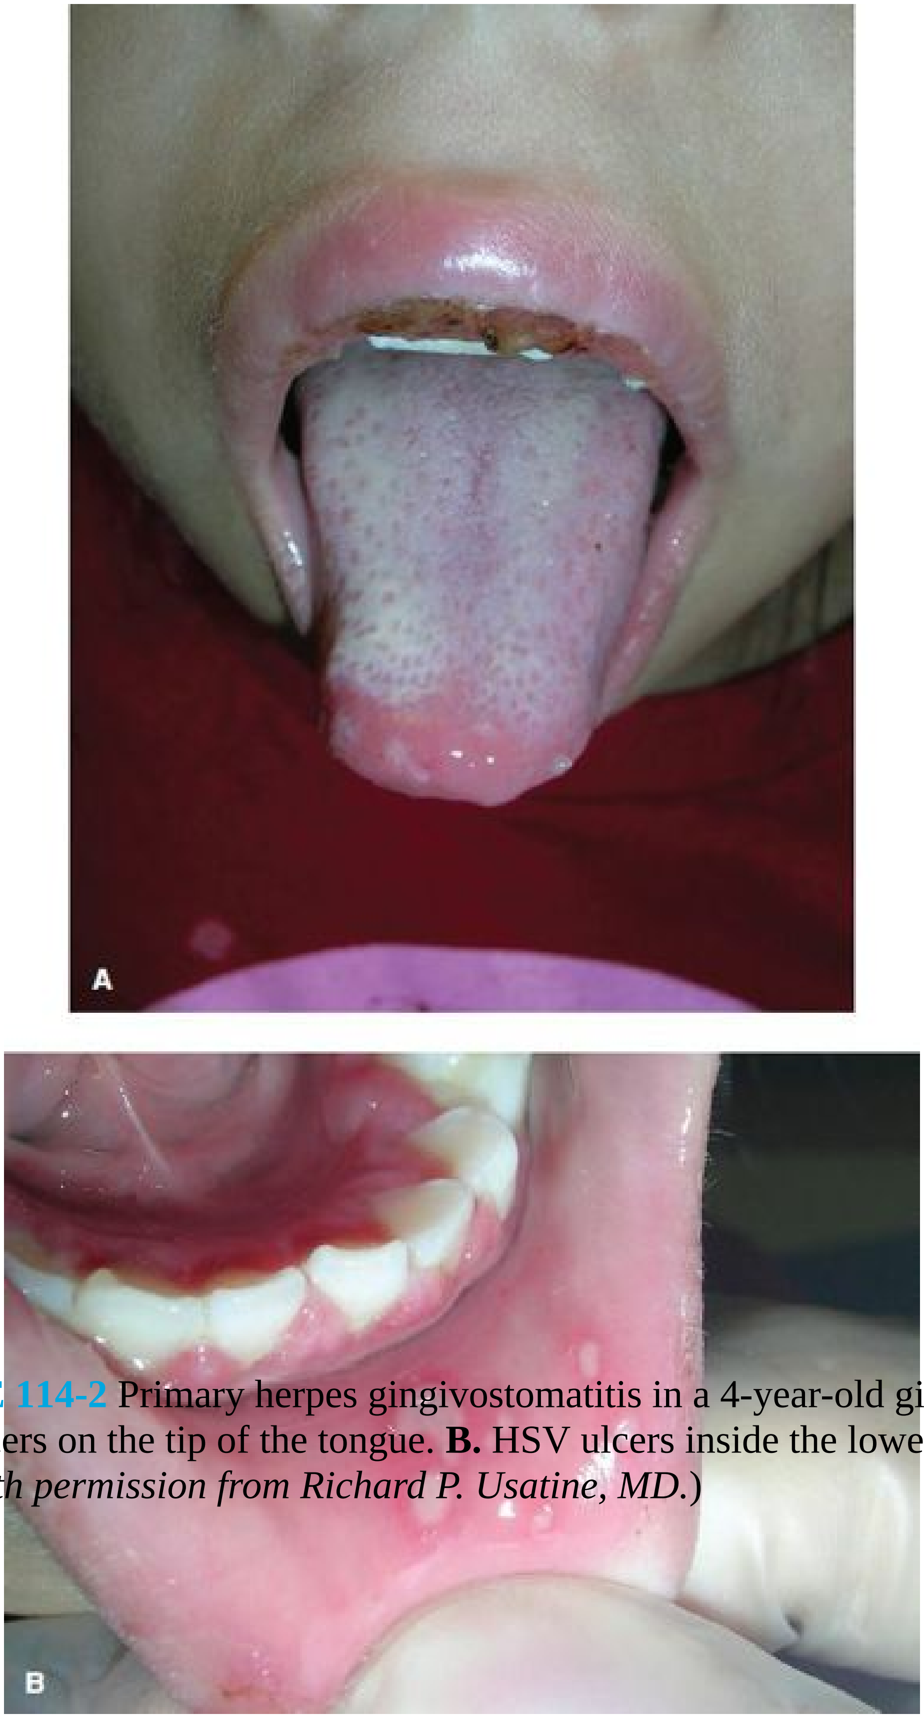

FIGURE 114-2 Primary herpes gingivostomatitis in a 4-year-old girl. **A.** Small ulcers on the tip of the tongue. **B.** HSV ulcers inside the lower lip. (*Used with permission from Richard P. Usatine, MD.*)

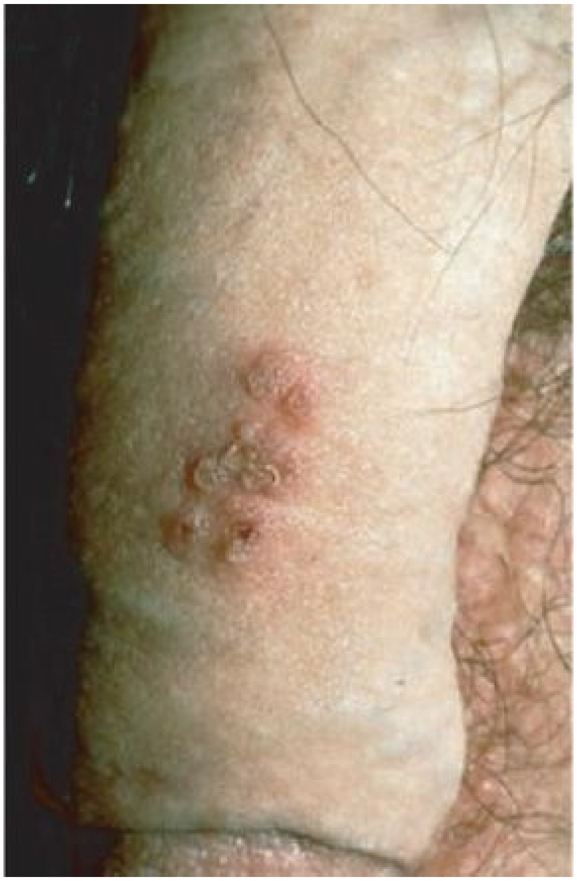

FIGURE 114-3 Herpes simplex on the penis with intact vesicles and visible crusts. (*Used with permission from Jack Rezneck, Sr., MD.*)

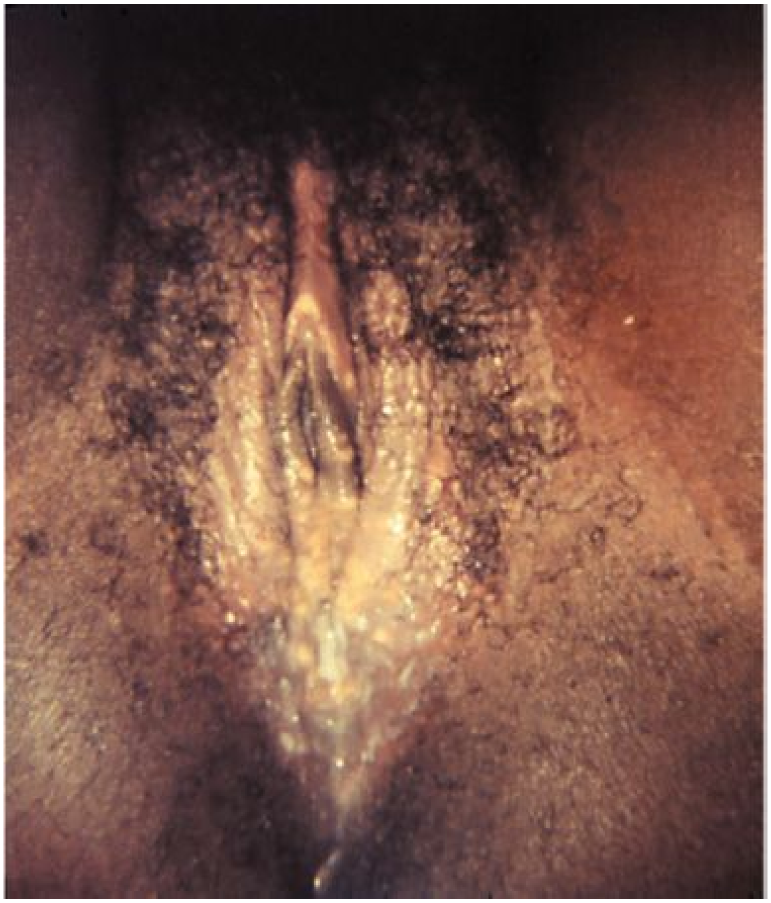

FIGURE 114-4 Vulvar herpes simplex virus at the introitus showing small punched out ulcers. (*Used with permission from the Centers for Disease Control and Prevention and Susan Lindsley*.)

HSV-1 infections are transmitted via saliva and are common in children, although primary herpes gingivostomatitis can be observed at any age. Children are most often infected by five years of age with infection rates ranging from 20 to 40 percent depending upon the geographic location and socioeconomic status of the family.[2] Orolabial herpes is the most prevalent form of herpes infection in children and often affects children younger than 5 years of age. The duration of the untreated illness is 2 to 3 weeks, and oral shedding of virus may continue for as long as 23 days.[1]

Acute herpetic gingivostomatitis (**Figures 114-1** and **114-2**) is a manifestation of primary HSV-1 infection that most often occurs in children aged 6 months to 5 years. Adults may also develop acute gingivostomatitis, but it is less severe and is often associated with a posterior pharyngitis.

Infected saliva from an adult or another child is the mode of infection. The incubation period is 3 to 6 days.[3]

HSV-2 infections generally affect the genitals but may occur in neonates associated with maternal outbreak at delivery, with an incidence of about 1 in 3000 births.[4] Genital HSV-2 infections most commonly occur once sexual activity begins, often in adolescence. HSV-2 genital infections in children can be an indication of sexual abuse.[5]

The Centers for Disease Control and Prevention (CDC) reports that at least 50 million persons in the US have genital HSV-2 infection (**Figures 114-3** and **114-4**).[6] Over the past decade, the percentage of Americans with genital herpes infection in the US has remained stable. Most persons infected with HSV-2 have not been diagnosed with genital herpes.[6]

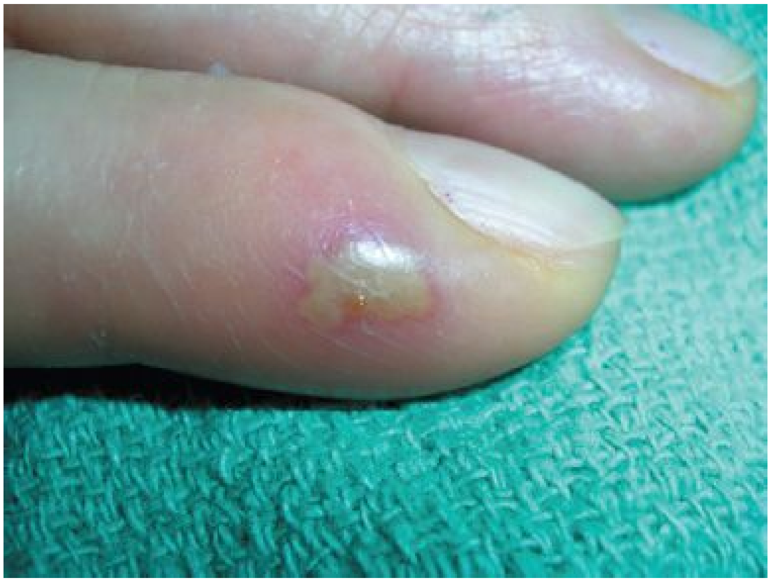

FIGURE 114-5 Herpetic whitlow lesion on distal index finger. (*Used with permission from Richard P. Usatine, MD.*)

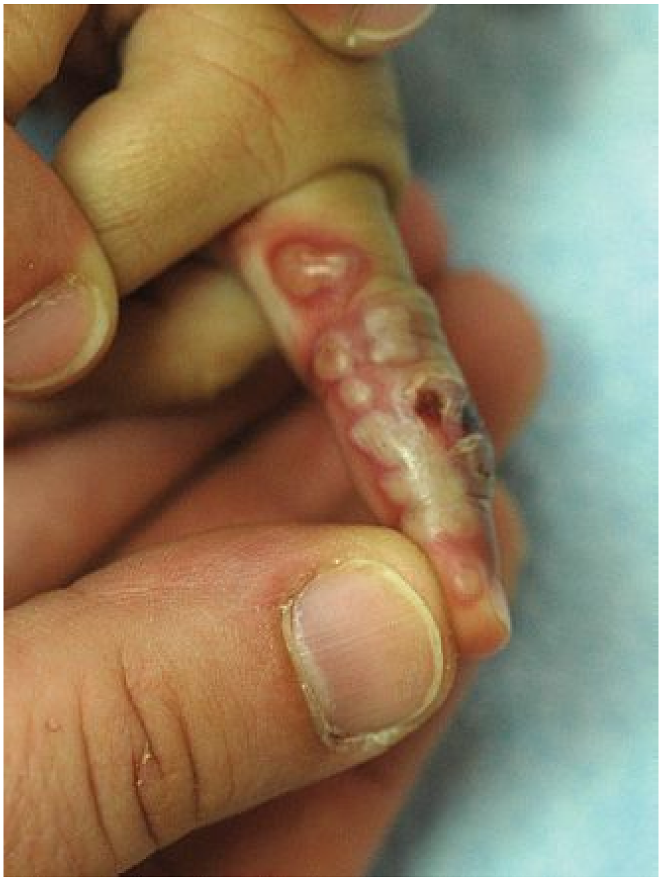

FIGURE 114-6 Herpes whitlow on the left third finger of a 6-month-old child. The mother is demonstrating the lesions on the finger, which are grouped pustules with an erythematous base. The child and mother had a history of recurrent cold sores on the lip and this second primary lesion was most probably from self-innoculation while sucking the finger. A Tzanck prep showed multinucleated giant cells. Viral culture showed HSV1. (*Image used with permission from Robert Brodell, MD.*)

Genital HSV-2 infection is more common in women (approximately 1 out of 5 women 14 to 49 years of age) than in men (approximately 1 out of 9 men 14 to 49 years of age). Transmission from an infected male to his female partner is believed to be more likely than from an infected female to her male partner.[6]

Cross-sectional data from the 2003 to 2004 US National Health and Nutrition Examination Survey (NHANES) shows 24 percent of female adolescents (aged 14 to 19 years) had laboratory evidence of infection with human papillomavirus (HPV, 18%), Chlamydia trachomatis (4%), Trichomonas vaginalis (3%), herpes simplex virus type 2 (HSV-2, 2%), or Neisseria gonorrhoeae. Among girls who reported ever having had sex, 40 percent had laboratory evidence of one of the four STDs, most commonly HPV (30%) and chlamydia (7%).[7]

Herpetic whitlow is an intense painful infection of the hand involving the terminal phalanx of one or more digits (**Figures 114-5** and **114-6**). In the US, the estimated annual incidence is 2.4 cases per 100,000 persons.[8]

ETIOLOGY AND PATHOPHYSIOLOGY

- HSV belongs to the family Herpesviridae and is a double-stranded DNA virus.
- HSV exists as 2 separate types (types 1 and 2), which have affinities for different epithelia.[8] Seventy to ninety percent of HSV-2 infections are genital, whereas 70 to 90 percent of those caused by HSV-1 are oral–labial.
- HSV enters through abraded skin or intact mucous membranes. Once infected, the epithelial cells die, forming vesicles and creating multinucleated giant cells.
- Retrograde transport into sensory ganglia leads to lifelong latent infection.[1] Reactivation of the virus may be triggered by immunodeficiency, trauma, fever, and UV light.
- Genital HSV infection is usually transmitted through sexual contact. When it occurs in a preadolescent, the possibility of abuse must be considered.
- Evidence indicates that 21.9 percent of all persons in the US, 12 years or older, have serologic evidence of HSV-2 infection, which is more commonly associated with genital infections.[4]
- As many as 90 percent of those infected are unaware that they have herpes infection and may unknowingly shed virus and transmit infection.[9]
- Primary genital herpes has an average incubation period of 4 days, followed by a prodrome of itching, burning, or erythema.

- With both types, systemic symptoms are common in primary disease and include fever, headache, malaise, abdominal pain, and myalgia.[10] Recurrences are usually less severe and shorter in duration than the initial outbreak.[1,10]
- Herpetic whitlow occurs as a complication of oral or genital HSV infection and in medical personnel who have contact with oral secretions (**Figures 114-5** and **114-6**).
- Toddlers and preschool children are susceptible to herpetic whitlow if they have herpes labialis and engage in thumb-sucking or finger-sucking behavior (**Figure 114-6**).
- Like all HSV infections, herpetic whitlow usually has a primary infection, which may be followed by subsequent recurrences. The virus migrates to the peripheral ganglia and Schwann cells where it lies dormant. Recurrences observed in 20 to 50 percent of cases are usually milder and shorter in duration.
- Herpes can remain dormant in nerves, including the trigeminal nerve and recur subsequently (**Figures 114-7** to **114-10**).

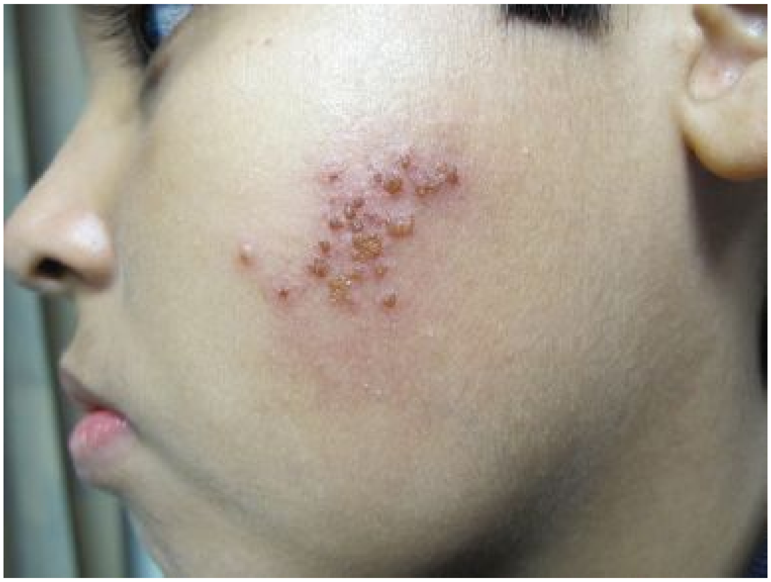

FIGURE 114-7 Recurrent herpes simplex virus on the cheek of a 14-year-old boy. He gets this about once a year since age 8 months. This recurrence started 5 days ago. HSV1 remains dormant in the trigeminal ganglion of V2 between outbreaks. (*Used with permission from Ross Lawler, MD.*)

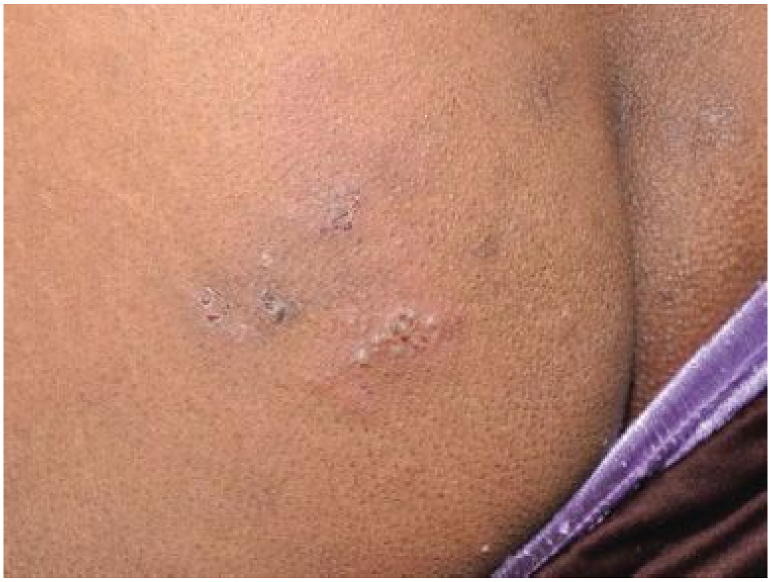

FIGURE 114-8 Recurrent herpes simplex virus on the buttocks of a young woman. Note the vesicles and crusts in a unilateral cluster. (*Used with permission from Richard P. Usatine, MD.*)

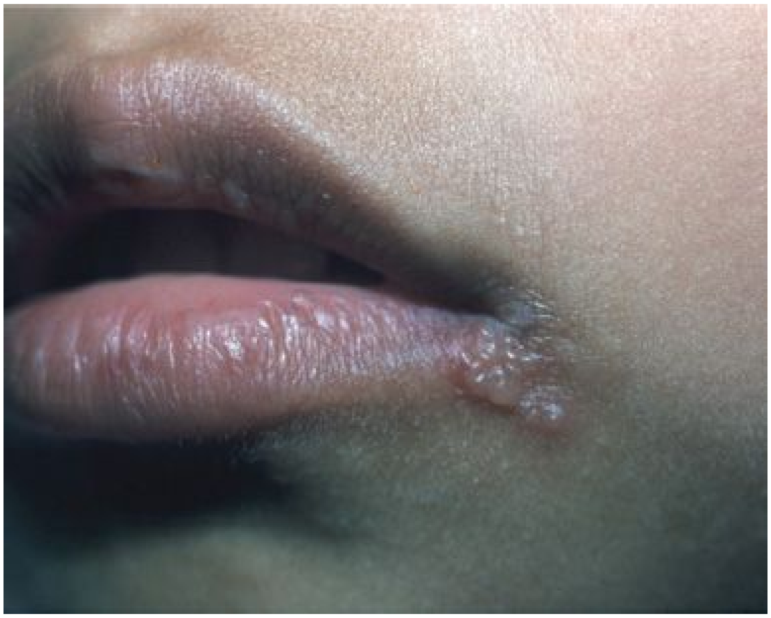

FIGURE 114-9 Close-up of recurrent herpes simplex virus-1 showing vesicles on a red base at the vermillion border in a young girl. (*Used with permission from Richard P. Usatine, MD.*)

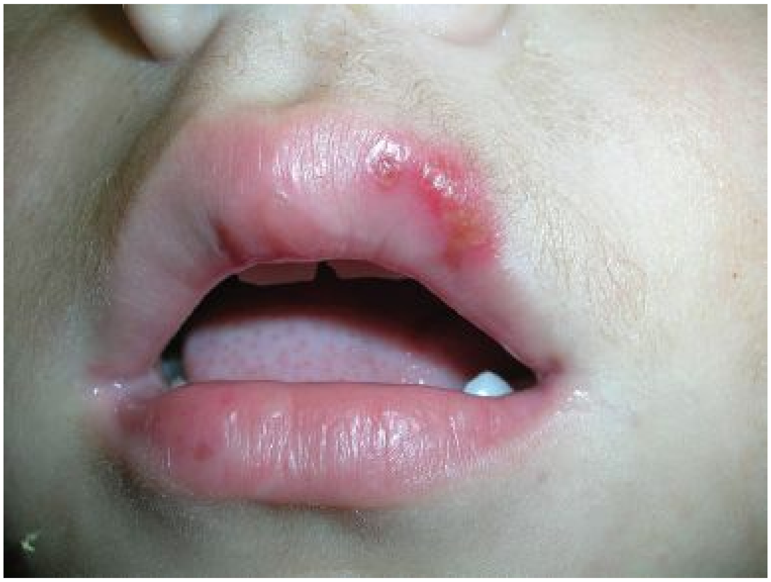

FIGURE 114-10 Orolabial herpes simplex virus in a child showing deroofed blisters (ulcer). (*Used with permission from Richard P. Usatine, MD.*)

- Maternal–fetal transmission of HSV is associated with significant morbidity and mortality. Manifestations of neonatal HSV include localized infection of the skin, eyes, and mouth, central nervous system (CNS) disease, or disseminated multiple organ disease (**Figure 114-11**). The CDC and the American College of Obstetricians and Gynecologists recommend that cesarean delivery should be offered as soon as possible to women who have active HSV lesions or, in those with a history of genital herpes, symptoms of vulvar pain, or burning at the time of delivery.[11]

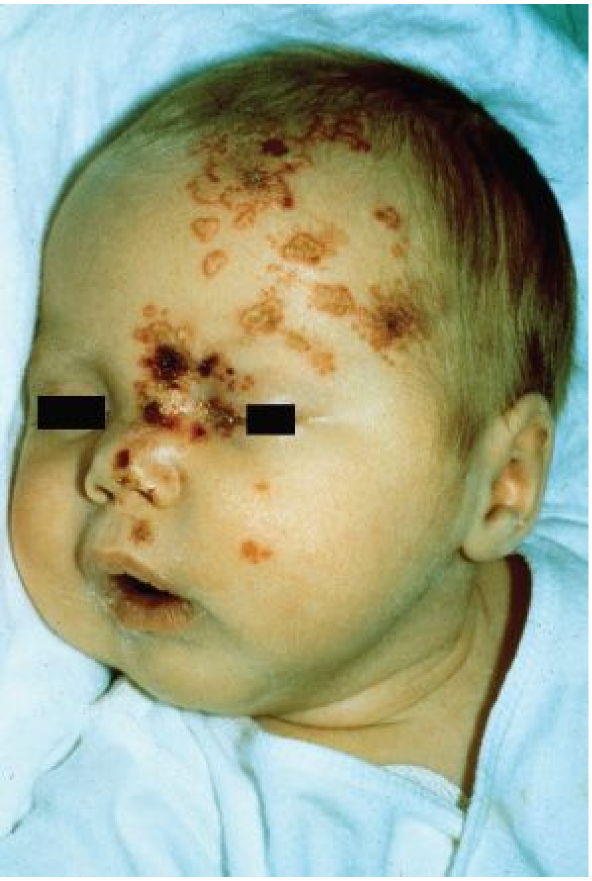

FIGURE 114-11 Neonatal herpes simplex virus-2 infection (culture proven) on the face of an infant most likely acquired during a vaginal birth. The child was hospitalized for intravenous acyclovir and an ophthalmology consult was called due to the skin involvement around the eye. Even though the distribution appears dermatomal this was not a herpes zoster infection. (*Used with permission from Richard P. Usatine, MD.*)

RISK FACTORS

- Multiple sexual partners.
- Female gender.
- Low socioeconomic status.
- HIV infection.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis of HSV infection may be made by clinical appearance. Many patients have systemic symptoms, including fever, headache, malaise, and myalgias.
- Primary herpes gingivostomatitis typically takes the form of painful vesicles and ulcerative erosions on the tongue, palate, gingiva, buccal mucosa, and lips (**Figures 114-1** to **114-2**).
- Acute herpetic gingivostomatitis clinical features include an abrupt onset of high fever (102 to 104°F) gingivitis with markedly swollen, erythematous, friable gums, anorexia, listlessness, vesicular lesions, and/or ulcerated plaques of the oral mucosa, tongue, and lips and later rupture and coalesce, tender regional lymphadenopathy, and perioral skin involvement due to contamination with infected saliva.[5]
- Genital herpes presents with multiple transient, painful vesicles that appear on the penis (**Figures 114-3**), vulva (**Figure 114-4**), buttocks (**Figure 114-8**), perineum, vagina or cervix, and tender inguinal lymphadenopathy.[10] The vesicles break down and become ulcers that develop crusts while these are healing.
- Oral and genital herpes infections can recur with variable frequency depending upon many host factors. The duration is shorter and less painful than in primary infections. The lesions are often single and the vesicles heal completely by 8 to 10 days. Recurrent labial herpes is commonly called a “cold sore” because an upper respiratory infection might trigger the outbreak (**Figures 114-9** and **114-10**).
- UV radiation in the form of sunlight may trigger outbreaks. Another reason to use sun protection when outdoors triggers recurrence of orolabial HSV-1, an effect which is not fully suppressed by acyclovir.

LABORATORY STUDIES

- Infants exposed to HSV during birth should be followed carefully in consultation with a pediatric infectious disease specialist (**Figures 114-11**). Surveillance cultures of mucosal surfaces to detect HSV infection might be considered before the development of clinical signs of neonatal herpes.[6]
- The gold standard of diagnosis is viral isolation by tissue culture and polymerase chain reaction (PCR) testing.[6]
    - The culture sensitivity rate is only 70 to 80 percent and depends upon the stage at which the specimen is collected. The sensitivity is highest at first in the vesicular stage and declines with ulceration and crusting. The tissue culture assay can be positive within 48 hours but may take longer.
    - PCR is extremely sensitive (96%) and specific (99%). PCR testing is generally used for cerebrospinal fluid (CSF) testing in suspected HSV encephalitis or meningitis.[6]
- Older type-specific HSV serologic assays that do not accurately distinguish HSV-1 from HSV-2 antibody are still on the market. Both laboratory-based assays and point-of-care tests that provide results for HSV-2 antibodies from capillary blood or serum with sensitivities of 80 to 98 percent are available. Because nearly all HSV-2 infections are sexually acquired, the presence of type-specific HSV-2 antibody implies anogenital infection. Type-specific HSV serologic assays might be useful in patients with recurrent symptoms and negative HSV cultures and an asymptomatic patient with a partner with genital herpes. Screening for HSV-1 and HSV-2 in the general population is not indicated.[6]
- Direct immunofluorescent staining of vesicular lesions (obtained by unroofing a lesion and removing cells from the base of the lesion) is 80 to 90 percent sensitive and very specific. This can provide a rapid diagnosis.
- The Tzanck test has lower sensitivity rates than viral culture and should not be relied on for diagnosis.[6]
- The CDC does not currently recommend routine type 2 HSV testing in someone with no symptoms suggestive of herpes infection (i.e., for the general population).[11]

- If the herpes was acquired by sexual contact, screening should be performed for other sexually transmitted diseases (STDs), such as syphilis and HIV.
- Biopsy is usually unnecessary unless no infectious etiology is found for a genital lesion and a malignancy is suspected.

DIFFERENTIAL DIAGNOSIS

- Syphilis produces a painless or mildly painful, indurated, clean-based ulcer (chancre) at the site of exposure. It is best to investigate for syphilis or coexisting syphilis in any patient presenting for the first time with a genital ulcer of unproven etiology (see Chapter 181, Syphilis).
- Chancroid produces a painful deep, undermined, purulent ulcer that may be associated with painful inguinal lymphadenitis (see Chapter 75, Mucosal Ulcerative Disorders).
- Drug eruptions produce pruritic papules or blisters without associated viral symptoms (see Chapter 154, Cutaneous Drug Reactions).
- Behçet disease produces ulcerative disease around the mouth and genitals, possibly before onset of sexual activity (**Figure 114-12**; see Chapter 75, Mucosal Ulcerative Disorders).

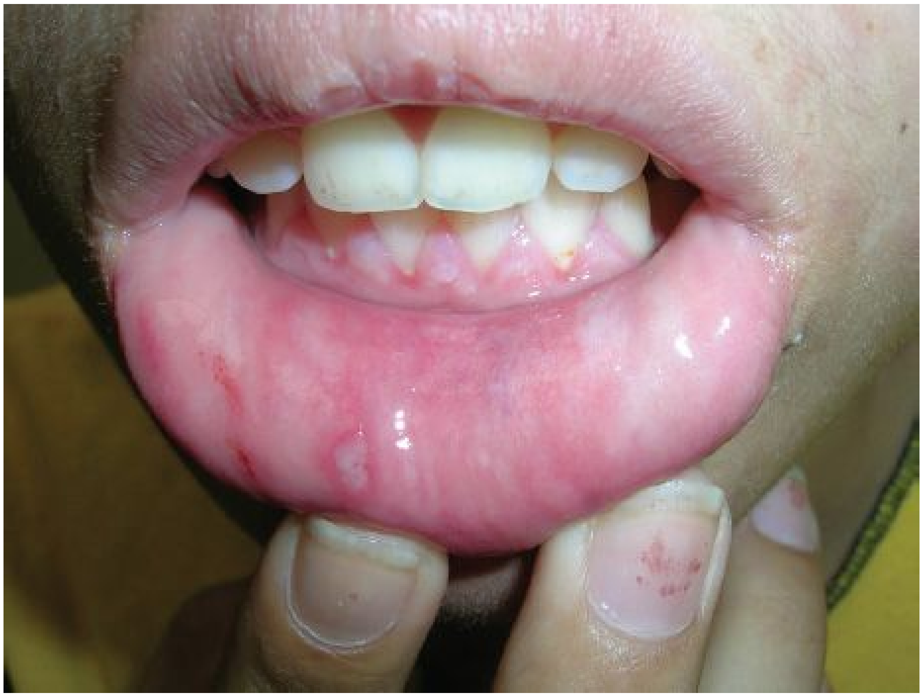

FIGURE 114-12 A 17-year-old girl diagnosed with Behcet’s syndrome with recurrent aphthous stomatitis in the mouth and recurrent genital ulcers prior to the onset of sexual activity. (*Used with permission from Richard P. Usatine, MD.*)

- Acute paronychia which presents as a localized abscess in a nail fold and is the main differential diagnosis in the consideration of herpetic whitlow (see Chapter 164, Paronychia).
- Felon—A red, painful infection, usually bacterial, of the fingertip pulp. It is important to distinguish whitlow from a felon (where the pulp space usually is tensely swollen) as incision and drainage of a felon is needed, but should be avoided in herpetic whitlow because it may lead to an unnecessary secondary bacterial infection.

MANAGEMENT

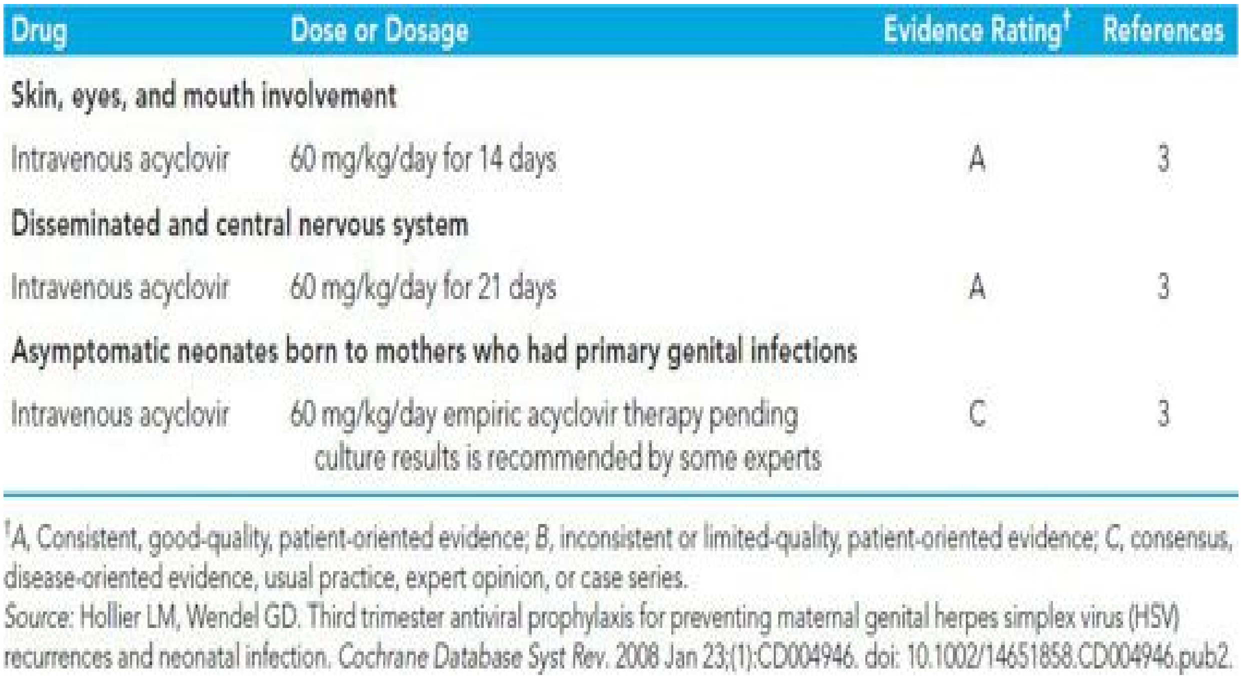
NONPHARMACOLOGIC

- Women with active primary or recurrent genital herpetic lesions at the onset of labor should deliver by cesarean section to lower the chance of neonatal HSV infection.[11] SOR A

MEDICATIONS

- Acyclovir is a guanosine analog that acts as a DNA chain terminator which, when incorporated, ends viral DNA replication. It is indicated for use in children for most herpes related indications Valacyclovir is the *l*-valine ester prodrug of acyclovir that has enhanced absorption after oral administration and high oral bioavailability. Famciclovir is the oral form of penciclovir, a purine analog similar to acyclovir. They must be administered early in the outbreak to be effective, but are safe and extremely well-tolerated.[10] SOR A Only acyclovir is available as an oral formulation and indicated for young children.
- Treatment for neonatal herpes is intravenous acyclovir and is shown in **Table 114-1**.

TABLE 114-1 Treatments for Neonatal Herpes



Drug	Dose or Dosage	Evidence Rating[†]	References
Skin, eyes, and mouth involvement			
Intravenous acyclovir	60 mg/kg/day for 14 days	A	3
Disseminated and central nervous system			
Intravenous acyclovir	60 mg/kg/day for 21 days	A	3
Asymptomatic neonates born to mothers who had primary genital infections			
Intravenous acyclovir	60 mg/kg/day empiric acyclovir therapy pending culture results is recommended by some experts	C	3

Source: Hollier LM, Wendel GD. Third trimester antiviral prophylaxis for preventing maternal genital herpes simplex virus (HSV) recurrences and neonatal infection. *Cochrane Database Syst Rev.* 2008 Jan 23;(1):CD004946. doi: 10.1002/14651858.CD004946.pub2.

- All infants who have neonatal herpes should be promptly evaluated and treated with systemic acyclovir 20 mg/kg IV every 8 hours for 21 days for disseminated and CNS disease or for 14 days for disease limited to the skin and mucous membranes.[6] SOR Ⓑ

Genital herpes:

- Antiviral therapy is recommended for an initial genital herpes outbreak. Although systemic antiviral drugs can partially control the signs and symptoms of herpes episodes, they do not eradicate latent virus.
- Acyclovir, famciclovir, and valacyclovir are equally effective for episodic treatment of genital herpes, but famciclovir appears somewhat less effective for suppression of viral shedding.[6] Only acyclovir is indicated for use in children. SOR Ⓑ
- Effective episodic treatment of herpes requires initiation of therapy during the prodrome period or within 1 day of lesion onset. Providing the patient with a prescription for the medication with instructions to initiate treatment immediately when symptoms begin improves efficacy.[6] SOR Ⓑ
- HSV strains resistant to acyclovir have been detected in immunocompromised patients so that other antivirals (e.g., foscarnet) need to be considered in these patients. SOR Ⓒ
- Topical medication for HSV infection is generally not effective and not recommended. Topical penciclovir applied every 2 hours for 4 days, reduces clinical healing time by approximately 1 day.[1,6]
- All patients with a first episode of genital herpes should receive antiviral therapy as even with mild clinical manifestations initially, they can develop severe or prolonged symptoms.
- Toxicity of these 3 antiviral drugs is rare, but in patients who are dehydrated or who have poor renal function, the drug can crystallize in the renal tubules, leading to a reversible creatinine elevation or, rarely, acute tubular necrosis. Adverse effects, usually mild, include nausea, vomiting, rash, and headache. Lethargy, tremulousness, seizures, and delirium have been reported rarely in studies of renally impaired patients.[12]

Oral herpes:

- Oral acyclovir treatment for primary herpes gingivostomatitis in children, started within the first three days of onset, shortens the duration of all clinical manifestations and the period of infectivity.[13] SOR B In this RCT, acyclovir suspension was given (15 mg/kg) five times a day for seven days, or placebo. Children receiving acyclovir (age 1 to 6) had oral lesions for a shorter period than children receiving placebo (median 4 versus 10 days) and earlier disappearance of the following signs and symptoms: fever (1 versus 3 days); extraoral lesions (lesions around the mouth but outside the oral cavity) (0 versus 5.5 days); eating difficulties (4 versus 7 days); and drinking difficulties (3 versus 6 days). Viral shedding was significantly shorter in the group treated with acyclovir (1 versus 5 days).

Dosing of oral acyclovir is based on age and weight:

- 3 months to 2 years old: 15 mg/kg/day IV or oral divided 3 to 5 times per day for 5 to 7 days.
- Over 2 years old: 400 mg orally divided q8h for 7 to 10 days (or 15 mg/kg/day).
- The oral lesions in primary herpes gingivostomatitis can lead to poor oral intake especially in children (**Figures 114-13**). To prevent dehydration, the following medications may be considered. Topical oral anesthetics such as 2 percent viscous lidocaine by prescription or 20 percent topical benzocaine OTC may be used to treat painful oral ulcers. SOR C A solution combining aluminum and magnesium hydroxide (liquid antacid) and 2 percent viscous lidocaine has been reported as helpful when swished and spit out several times a day as needed for pain. SOR C

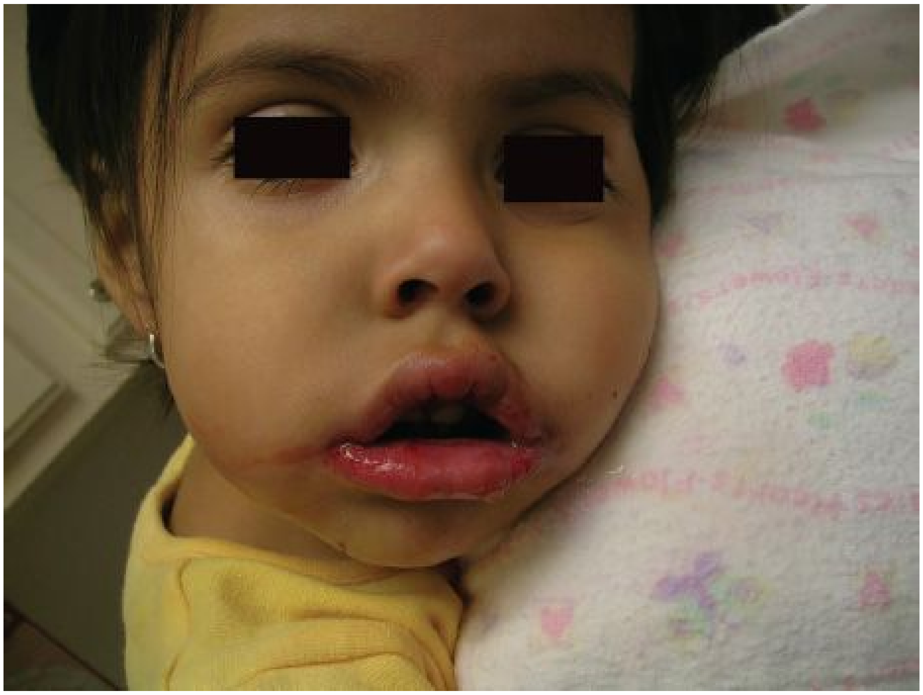

FIGURE 114-13 Primary herpes gingivostomatitis in a toddler. Her lips are swollen and she is drooling because it is painful to swallow. She is febrile and clearly not feeling well at all. (*Used with permission from Richard P. Usatine, MD.*)

- Docosanol cream (Abreva) is available without prescription for recurrent oral herpes. One randomized controlled trial (RCT) of 743 patients with herpes labialis showed a faster healing time in patients treated with docosanol 10 percent cream compared with placebo cream (4.1 versus 4.8 days), as well as reduced duration of pain symptoms (2.2 versus 2.7 days).[14] More than 90 percent of patients in both groups healed completely within 10 days.[14] Treatment with docosanol cream, when applied 5 times per day and within 12 hours of episode onset, is safe and somewhat effective.[15]

PREVENTION

- Barrier protection using latex condoms is recommended to minimize exposure to genital HSV infections (see the following section called

“Patient Education”). In a large analysis using prospective data, condoms did offer moderate protection against HSV-2 acquisition in men and women.[16] SOR Ⓐ

- Suppressive therapy with antiviral drugs reduces the frequency of genital herpes recurrences by 70 to 80 percent in patients with frequent recurrences.[6] SOR Ⓐ Traditionally this is reserved for use in patients who have more than 4 to 6 outbreaks per year (see **Table 114-1**).
- Short-term prophylactic therapy with acyclovir for orolabial HSV may be used in patients who anticipate intense exposure to UV light.

FOLLOW-UP

- The patient should return for follow-up if pain is uncontrolled or superinfection is suspected. The patient should be periodically evaluated for the need for suppressive therapy based on the number of recurrences per year.
- Acute herpetic gingivostomatitis generally lasts 5 to 7 days, and the symptoms subside in 2 weeks. Viral shedding from the saliva may continue for 3 weeks or more.[5]

PATIENT EDUCATION

Inform women with recurrent genital herpes simplex virus that the risk of neonatal herpes is low. There is insufficient evidence to determine if maternal antiviral prophylaxis reduces the incidence of neonatal herpes. Antenatal antiviral prophylaxis reduces viral shedding and recurrences at delivery and reduces the need for cesarean delivery for genital herpes.[3]

Measures to prevent genital HSV infection:

- Abstain from sexual activity or limit number of sexual partners to prevent exposure to the disease.

- Use condoms to protect against transmission, but this is not foolproof as ulcers can occur on areas not covered by condoms.
- Prevent autoinoculation by patting dry affected areas, not rubbing with towel.
- Studies show that patients may shed virus when they are otherwise asymptomatic.
- A link between HSV genital ulcer disease and sexual transmission of HIV has been established. Safer sex practices should be strongly encouraged to prevent transmission of HSV to others and acquiring HIV by the patient.

115 MOLLUSCUM CONTAGIOSUM

E.J. Mayeaux, Jr., MD
Stephen Taylor, MD
Kevin Carlisle, MD

PATIENT STORY

An 8-year-old girl is brought to the office because of an outbreak of bumps on her face for the past 3 months (**Figure 115-1**). Occasionally she scratches them, but she is otherwise asymptomatic. The mother and child are unhappy with the appearance of the molluscum contagiosum and chose to try topical imiquimod 5 percent cream. Fortunately, her health insurance covered this expensive treatment. A topical treatment was chosen to avoid the risk of hypopigmentation that can occur in dark-skinned individuals with cryotherapy.

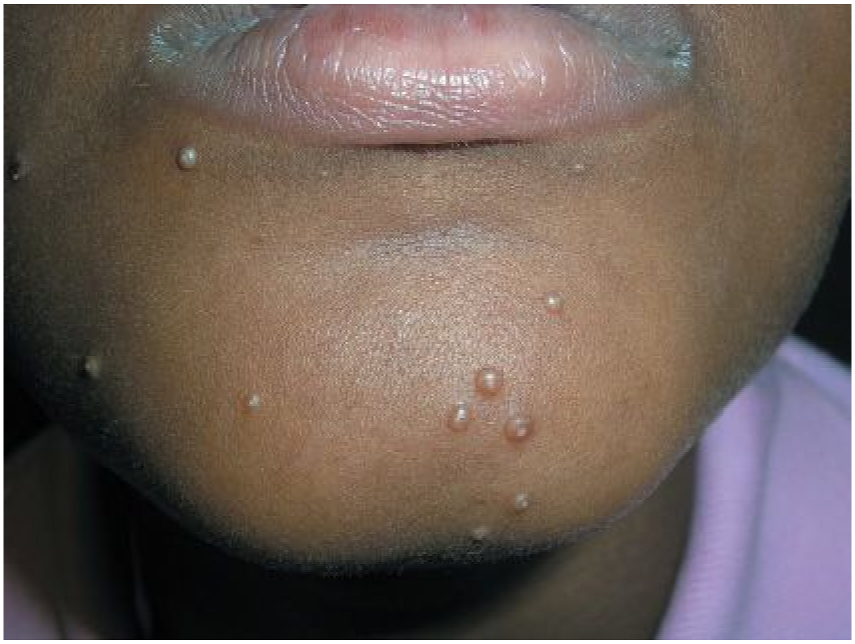

FIGURE 115-1 Molluscum contagiosum on the face of an 8-year-old girl. (*Used with permission from Richard P. Usatine, MD.*)

An 11-year-old girl was also seen with molluscum on her face. The child and her mother decided to try cryotherapy as her treatment. She very bravely tolerated the treatment with liquid nitrogen in a Cryogun (**Figure 115-2**). The molluscum disappeared without scarring or hypopigmentation after 2 treatments.

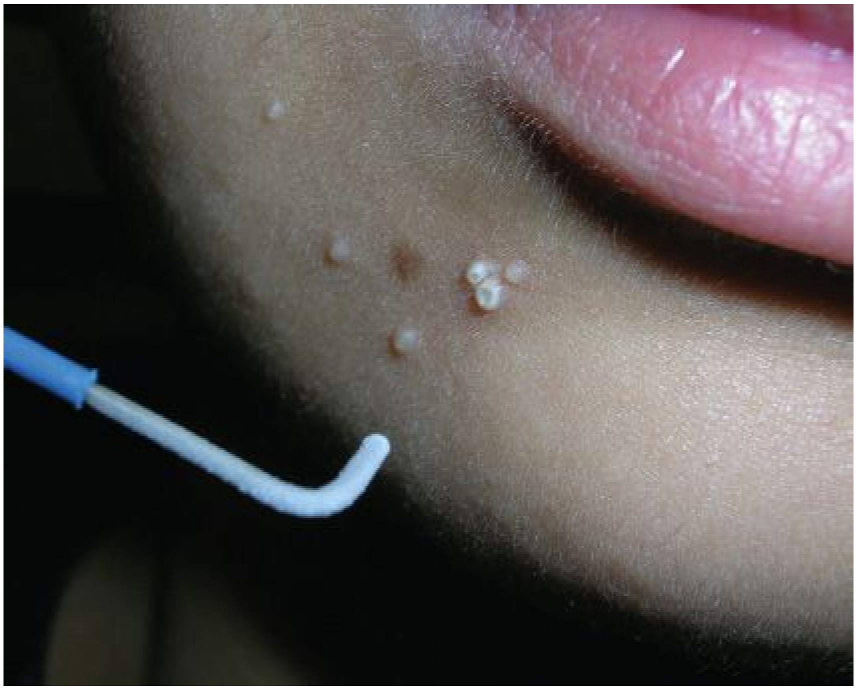

FIGURE 115-2 Cryotherapy of molluscum on the face of an 11-year-old girl. The central umbilication is easily seen in the 2 papules that were just frozen. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Molluscum contagiosum is a viral skin infection that produces pearly papules that often have a central umbilication. It is seen most commonly in children, but can also be transmitted sexually among adults.

EPIDEMIOLOGY

- Molluscum contagiosum infection has been reported worldwide. An Australian seroepidemiology study found a seropositivity rate of 23 percent.[1]

- Up to 5 percent of children in the US have clinical evidence of molluscum contagiosum infection.[2] It is a common, nonsexually transmitted condition in children (see **Figures 115-1** to **115-4**).

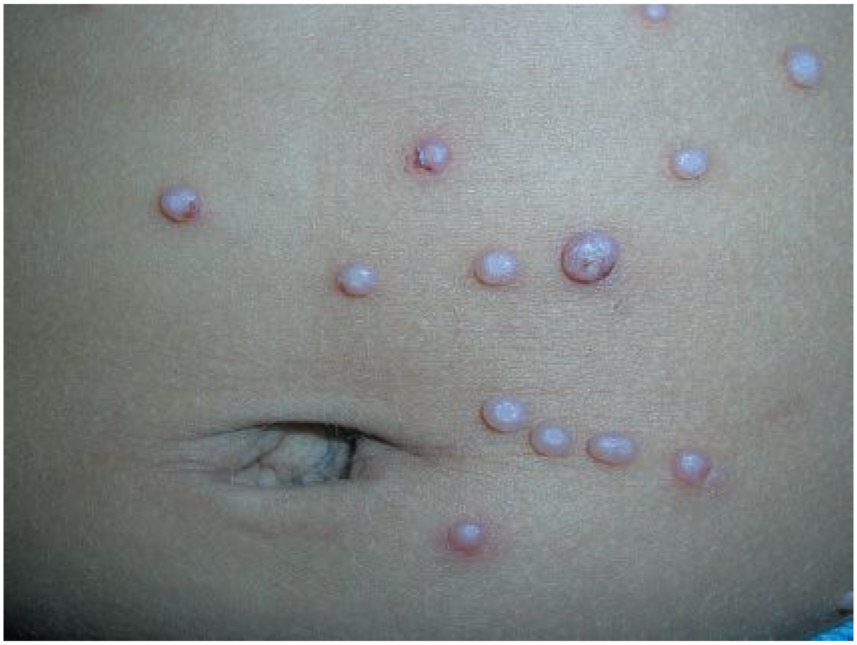

FIGURE 115-3 A group of molluscum contagiosum lesions on the abdomen of a 4-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

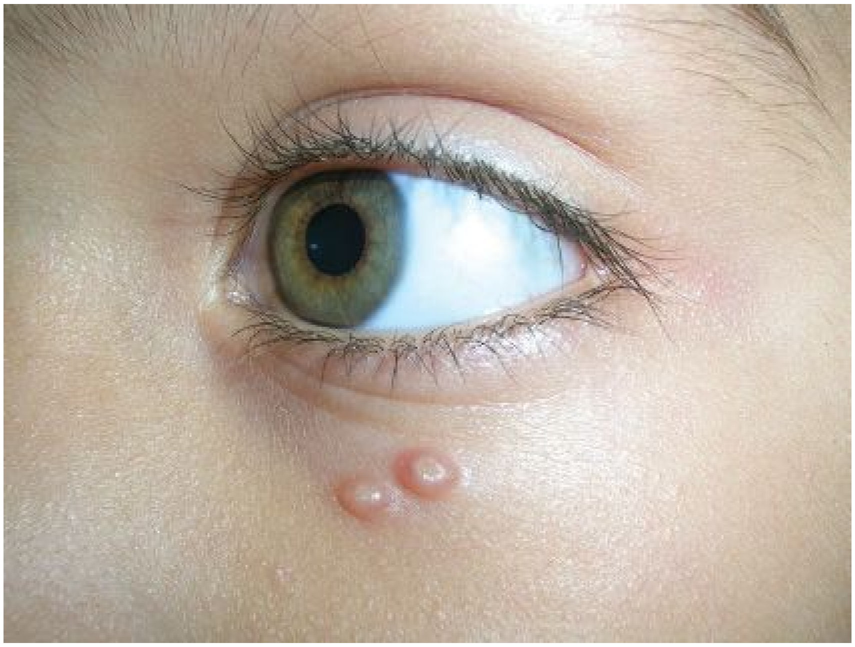

FIGURE 115-4 Molluscum contagiosum under the eye of a young girl with central umbilication. (*Used with permission from Richard P. Usatine, MD.*)

- The number of cases in US adults increased in the 1980s probably as a result of the HIV/AIDS epidemic. Since the introduction of highly active antiretroviral therapy (HAART), the number of molluscum contagiosum cases in HIV/AIDS patients has decreased substantially.[3] However, the prevalence of molluscum contagiosum in patients who are HIV-positive may still be as high as 5 to 18 percent (**Figure 115-5**).[4,5]

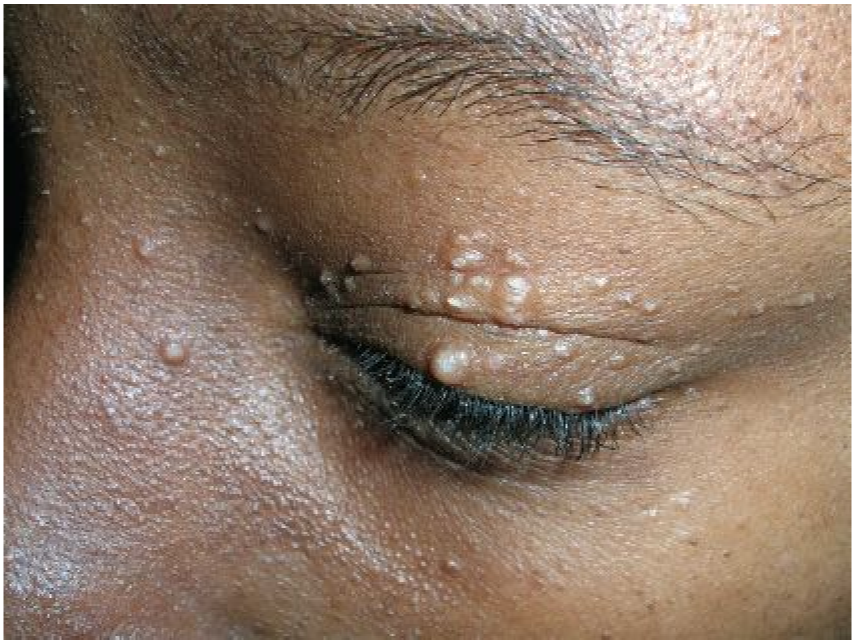

FIGURE 115-5 Extensive molluscum contagiosum on the face of a young girl who has perinatally-acquired HIV infection. (*Used with permission from Richard P. Usatine, MD.*)

ETIOLOGY AND PATHOPHYSIOLOGY

- Molluscum contagiosum is a benign condition that is often transmitted through close contact in children and through sexual contact in adolescents.

- It is a large DNA virus of the Poxviridae family of poxvirus. It is related to the orthopoxviruses (variola, vaccinia, smallpox, and monkeypox viruses).
- Molluscum replicates in the cytoplasm of epithelial cells. It causes a chronic localized skin infection consisting of dome-shaped pearly papules on the skin. Like most of the viruses in the poxvirus family, molluscum is spread by direct skin-to-skin contact. It can also spread by autoinoculation when scratching, touching, or treating lesions. Any single lesion is usually present for approximately 2 months, but autoinoculation often causes continuous crops of lesions.

RISK FACTORS

- Common childhood disease.
- Molluscum contagiosum may be more common in patients with atopic dermatitis (**Figure 115-6**).[2]

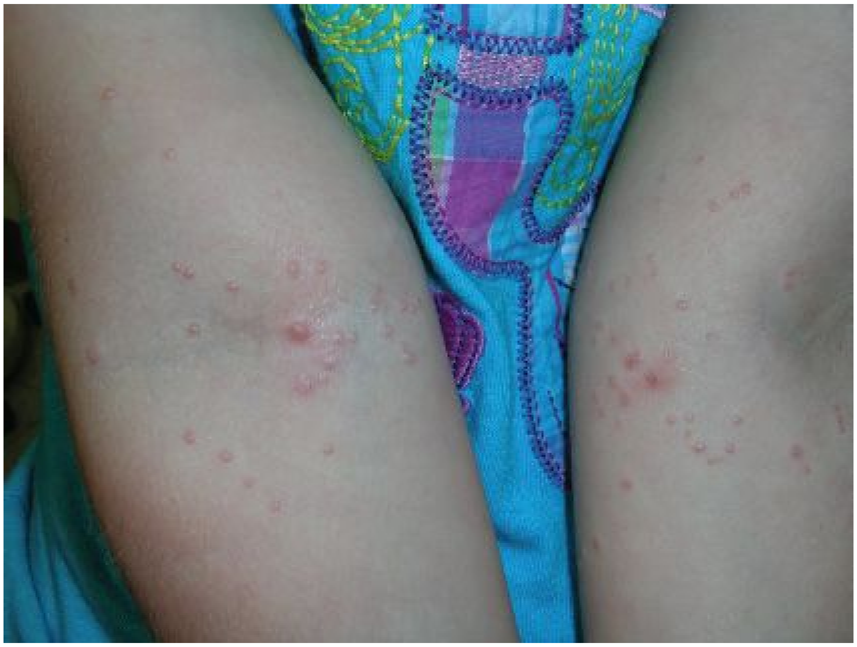

FIGURE 115-6 Molluscum contagiosum in the antecubital fossa of a 6-year-old girl with atopic dermatitis. (*Used with permission from Richard P.*

Usatine, MD.)

- The disease also may be spread by participation in contact sports.[2]
- It is also associated with immunodeficient states such as in HIV infection (**Figure 115-5**) and with immunosuppressive drug treatment.

DIAGNOSIS

CLINICAL FEATURES

- Firm, multiple, 2- to 5-mm dome-shaped papules with a characteristic shiny surface and umbilicated center (**Figure 115-7**). Not all the papules have a central umbilication, so it helps to take a moment and look for a papule that has this characteristic morphology. If all features point to molluscum and no single lesion has central umbilication, do not rule out molluscum as the diagnosis.

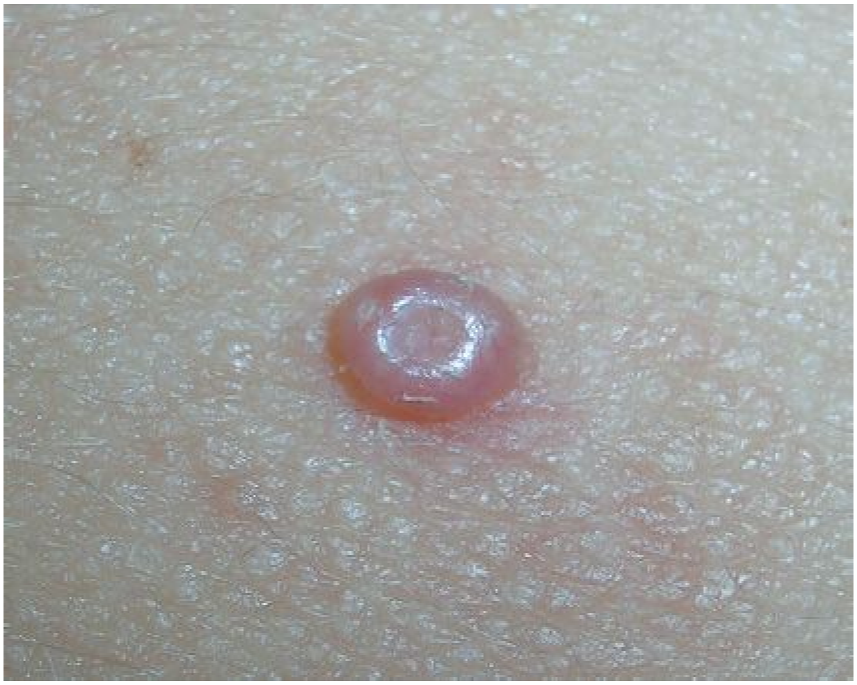

FIGURE 115-7 Close-up of a molluscum lesion on the back of a child showing a dome-shaped pearly papule with a characteristic umbilicated center. (*Used with permission from Richard P. Usatine, MD.*)

- The lesions range in color from pearly white to flesh-colored, to pink or yellow.
- Pruritus may be present or absent.

TYPICAL DISTRIBUTION

- The lesions may appear anywhere on the body except the palms and soles. The number of lesions may be greater in an HIV-infected individual. In children, the lesions are often on the trunk or face, but occasionally are found around the genitalia, inguinal area, buttocks, or inner thighs.
- If a child is found to have molluscum contagiosum in the genital area, a history and physical exam should be directed at looking for other clues that might indicate sexual abuse (see Chapter 8, Child Sexual Abuse). Not all cases of molluscum in this area will be secondary to sexual abuse (**Figure 115-8**).

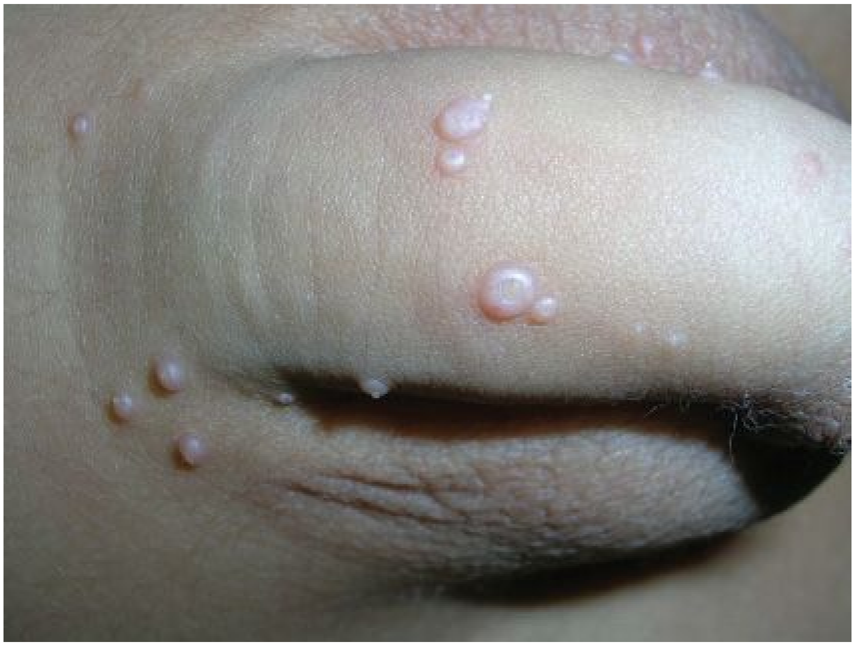

FIGURE 115-8 Molluscum contagiosum on and around the penis of a young boy. There was no evidence for sexual abuse. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY TESTING

- Laboratory testing is not typically indicated.
- Sexually active adolescents with genital lesions should be evaluated for other sexually transmitted diseases, including for HIV infection.

BIOPSY

- If confirmation is needed, smears of the caseous material expressed from the lesions can be examined directly under the microscope looking for molluscum bodies (enlarged keratinocytes that are engorged with viral inclusion bodies). Hematoxylin and eosin (H&E) staining from a shave biopsy usually reveals keratinocytes that contain eosinophilic cytoplasmic inclusion bodies.[5]

DIFFERENTIAL DIAGNOSIS

- Scabies is caused by *Sarcoptes scabiei* mite and can be transmitted through close or sexual contact. Early lesions are flesh-colored to red papules that produce significant itching. The itching and excoriations are greater than seen with molluscum. Scabies lesions also usually appear in the finger webs and ventral wrist fold (see Chapter 128, Scabies).
- Dermatofibromas—Firm to hard nodules ranging in color from flesh to black that typically dimple downward when compressed laterally. Usually not seen in crops as in molluscum. These nodules are deeper in the dermis and do not appear stuck on like molluscum.
- Genital warts may be flat and grossly resemble molluscum but they lack the characteristic shiny surface and central umbilication (see Chapter 118,

Genital Warts).

MANAGEMENT

NONPHARMACOLOGIC

- Treatment of nongenital lesions is usually not medically necessary as the infection is usually self-limited and spontaneously resolves after a few months. Treatment may be performed in an attempt to decrease autoinoculation. Patients and parents of children often want treatment for cosmetic reasons and when watchful waiting fails.
- A 2009 Cochrane Database systematic review investigated the efficacy of treatments for nongenital molluscum contagiosum in healthy individuals and found insufficient evidence to conclude that any treatment was definitively effective.[6] SOR Ⓐ
- In the HIV-infected patient, molluscum may resolve after control of HIV disease with HAART.[3] SOR Ⓑ
- Immunocompromised patients should have a full body skin examination to ensure all lesions are identified. Treatment is still optional but should proceed in patients whose parents desire intervention.

MEDICATIONS

- Podophyllotoxin 0.5 percent (Condylox) is an antimitotic agent that is indicated for the treatment of genital warts. The efficacy of podophyllotoxin was established in a randomized trial of patients 10 to 26 years of age who had lesions located on the thighs or genitalia. SOR Ⓑ Local erythema, burning, pruritus, inflammation, and erosions can occur with the use of this agent. The safety and efficacy of this drug has not been established in young children.[7]

- Topical imiquimod 5 percent (Aldara) cream has been shown (not FDA approved) to be better than vehicle alone to treat molluscum.[8,9] SOR B It can be well tolerated, although application site irritation can be uncomfortable and lead to discontinuation of therapy. It has been shown not to have systemic or toxic effects in children.[9] In one study, 23 children ranging in age from 1 to 9 years with molluscum contagiosum infection were randomized to either imiquimod cream 5 percent (12 patients) or vehicle (11 patients).
- Parents applied the study drug to the patient's lesions 3 times a week for 12 weeks. Complete clearance at week 12 was noted in 33.3 percent (4/12) of imiquimod patients and in 9.1 percent (1/11) of vehicle patients.[10]
- Tretinoin cream 0.1 percent or gel 0.025 percent applied daily are commonly used but not FDA-approved for this indication.[11] SOR B
- Cantharidin was studied in 300 children for molluscum where parents reported 90 percent of children experienced lesion clearing and 8 percent experience lesion improvement (**Figure 115-9**). Furthermore, 95 percent of parents stated they would use cantharidin therapy again.[12] Local erythema, burning, pruritus, and inflammation were reported side effects.

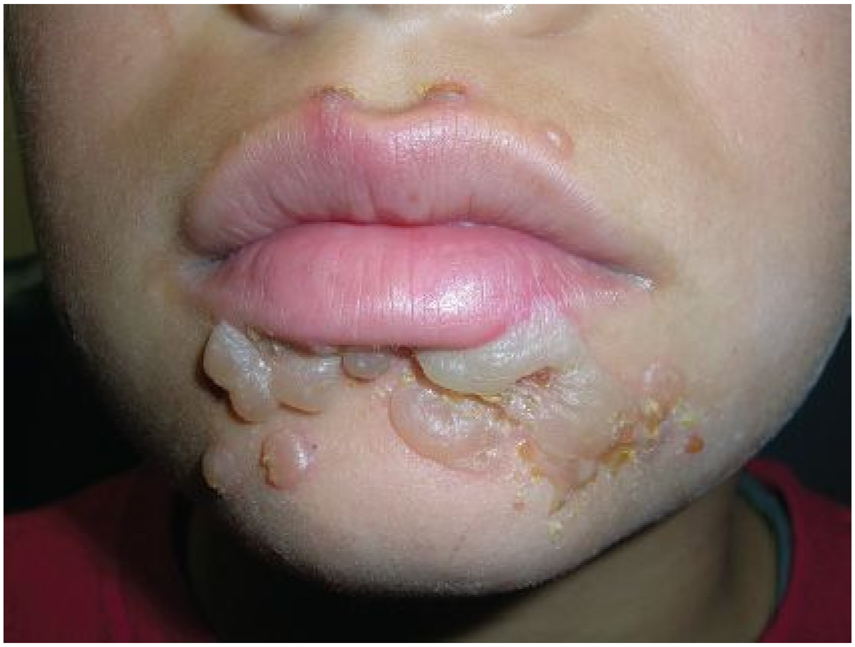

FIGURE 115-9 Blisters that formed the next day after treating molluscum contagiosum with cantharidin. The blisters are not always so large but are supposed to form as the cantharidin is derived from the blister beetle and these blisters help to eradicate the molluscum. (*Used with permission from Richard P. Usatine, MD.*)

- Trichloroacetic acid[13] are topical chemicals that can be applied by the physician in the office. SOR Ⓑ

SURGICAL

- Curettage and cryotherapy are physical methods used to eradicate molluscum.[14,15] SOR Ⓑ However, many children will fear treatment with a curette or with any form of cryotherapy particularly if multiple lesions are present.

COMPLEMENTARY/ALTERNATIVE THERAPY

- ZymaDermis a nonprescription, topical, homeopathic agent that is marketed for the treatment of molluscum contagiosum, but no published studies have evaluated its efficacy or safety.
- Potassium hydroxide has been used for molluscum but has not proved to be statistically significant when compared to placebo.[16]
- Pulsed dye lasers have shown to be safe and effective in case reports and small uncontrolled studies. One prospective study of 19 children between 2 and 13 concluded that all patients tolerated the 585 nm laser well and 84.3 percent had complete lesion resolution with one treatment.[17]

PREVENTION

- Molluscum contagiosum is a common childhood disease.

- Limiting sexual exposure or number of sexual contact may help prevent exposure.
- Genital lesions should be treated to prevent spread by sexual contact.

PROGNOSIS

- In immunocompetent patients, lesions usually spontaneously resolve within several months. In a minority of cases, disease persists for a few years.[18]

FOLLOW-UP

- Have patients watch for complications that may include irritation, inflammation, and secondary infections. Lesions on eyelids may be associated with follicular or papillary conjunctivitis, so eye irritation should prompt a visit to an eye care specialist.

PATIENT EDUCATION

- Instruct patients to avoid scratching to prevent autoinoculation.

116 COMMON WARTS

E.J. Mayeaux, Jr., MD
Anthony Todd Flowers, MD

PATIENT STORY

An 11-year-old girl presents with warts on her fingers that have not responded to nonprescription wart medications (**Figure 116-1**). It causes her and her mother some social embarrassment and they would like to be rid of them. Her mother is also worried that it is affecting her daughter's nails. The girl was able to tolerate the discomfort of liquid nitrogen treatment and wanted all her warts treated. The mother was instructed to purchase 40 percent salicylic acid to continue treatment of any residual warts at home.

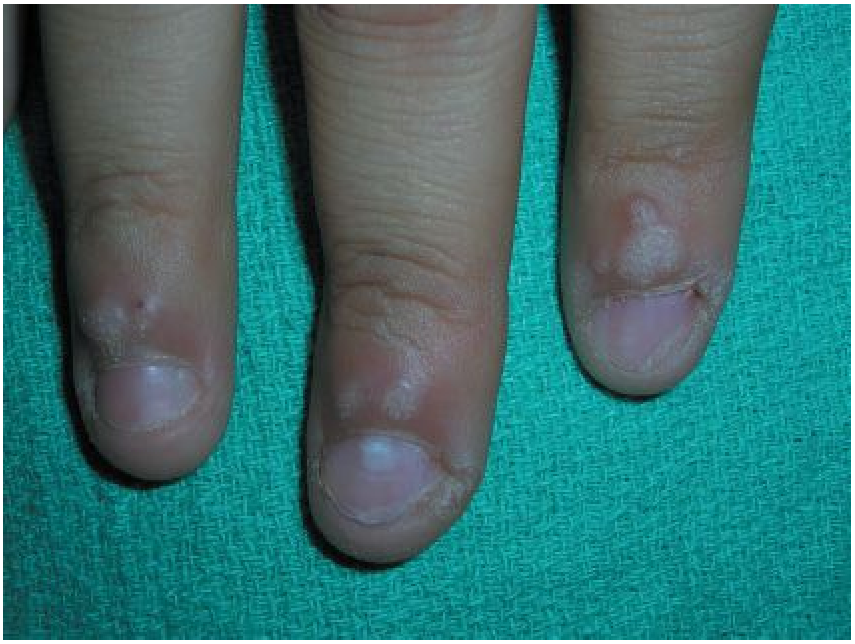

FIGURE 116-1 Common warts on the fingers of an 11-year-old girl. These periungual warts are particularly difficult to eradicate. (*Used with*

permission from Richard P. Usatine, MD.)

INTRODUCTION

Human papillomaviruses (HPVs) are DNA viruses that infect skin and mucous membranes. Infection is usually confined to the epidermis and does not result in disseminated systemic infection. The most common clinical manifestation of these viruses is warts (verrucae). There are more than 100 distinct HPV subtypes based on DNA testing. Some tend to infect specific body sites or types of epithelium. Some HPV types have a potential to cause malignant change but transformation is rare on keratinized skin.

SYNONYMS

Verrucae, verruca vulgaris, common warts.

EPIDEMIOLOGY

- Nongenital cutaneous warts are widespread worldwide and are more common in children, with a peak incidence in the teenage years and a sharp decline thereafter.[1] Warts are the third most common reason for a pediatric general dermatology clinic visit accounting for about 16 percent of such visits.[2]
- They are most commonly caused by HPV types 1–5, 7, 27, and 29.[1]
- Common warts account for approximately 70 percent of nongenital cutaneous warts.[3]
- Common warts occur most commonly in children and young adults (**Figures 116-1** and **116-2**).[4]

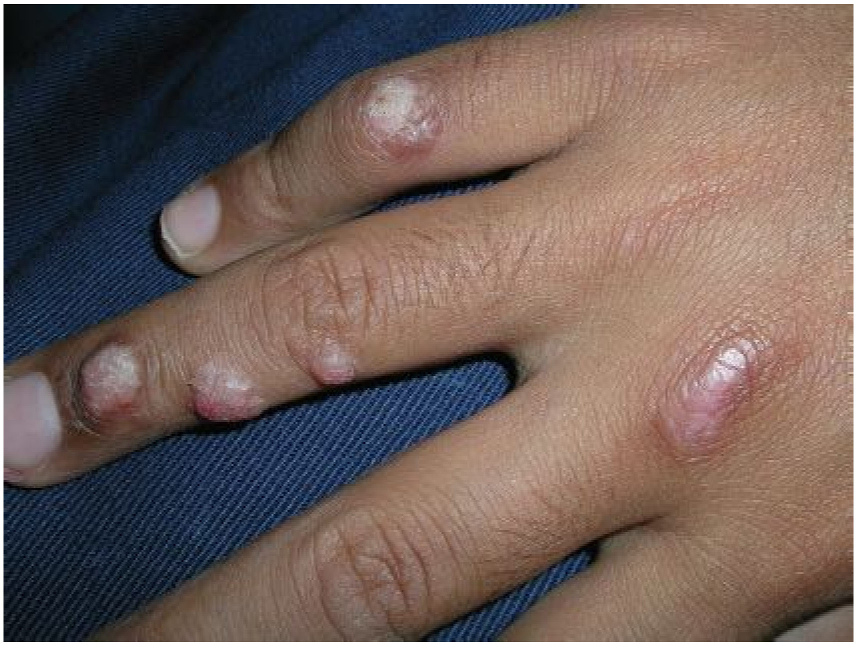

FIGURE 116-2 Common warts on the hand of a 9-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Infection with HPV occurs by skin-to-skin contact. It starts with a break in the integrity of the epithelium caused by maceration or trauma that allows the virus to infect the basal layers.
- Warts may infect the skin on opposing digits causing “kissing warts” (**Figure 116-3**).

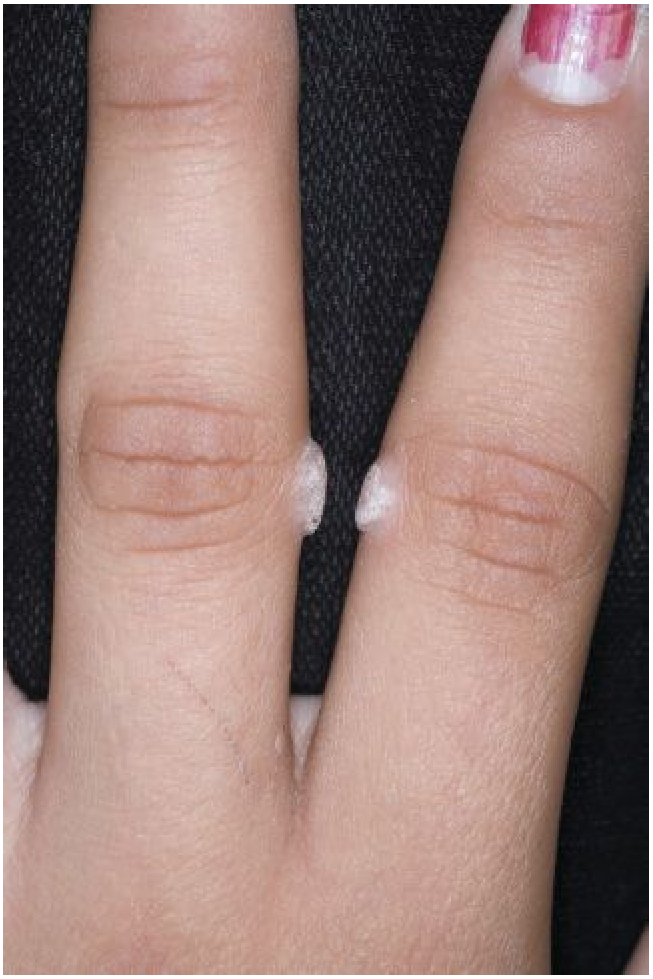

FIGURE 116-3 Warts may infect the skin on opposing digits causing “kissing warts.” (*Used with permission from Richard P. Usatine, MD*.)

- Individuals with subclinical infection may serve as a reservoir for HPVs.
- An incubation period following inoculation lasts for approximately 2 to 6 months.

RISK FACTORS[1]

- Young age.
- Disruption to the normal epithelial barrier.

- More common among meat handlers.
- Atopic dermatitis.
- Nail biters more commonly have multiple periungual warts.
- Conditions that decrease cell-mediated immunity such as HIV (**Figure 116-4**) and immunosuppressant drugs.

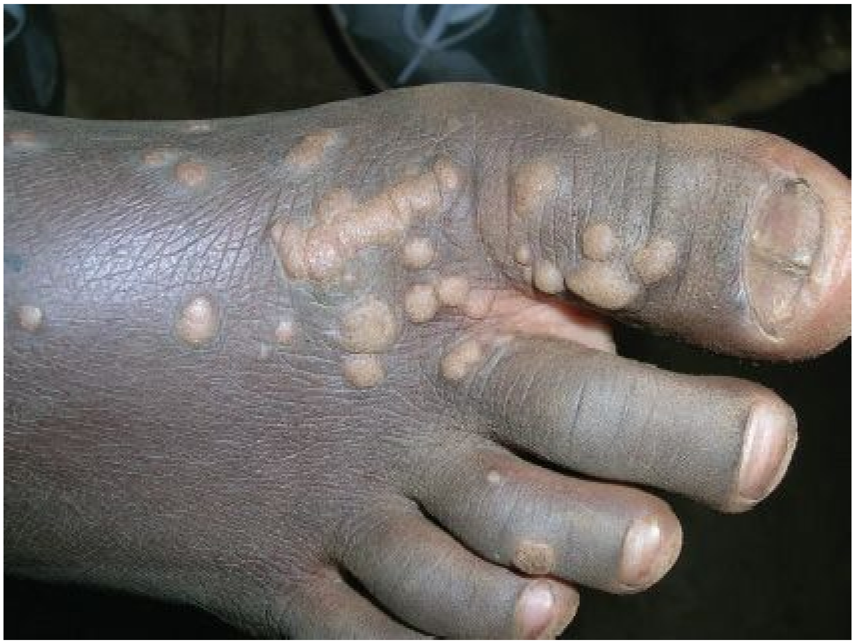

FIGURE 116-4 Large cluster of warts on the foot of a child in Africa suspected of being HIV-positive. (*Used with permission from Richard P. Usatine, MD.*)

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis of warts is based upon clinical appearance. Warts will obscure normal skin markings (**Figure 116-5**).

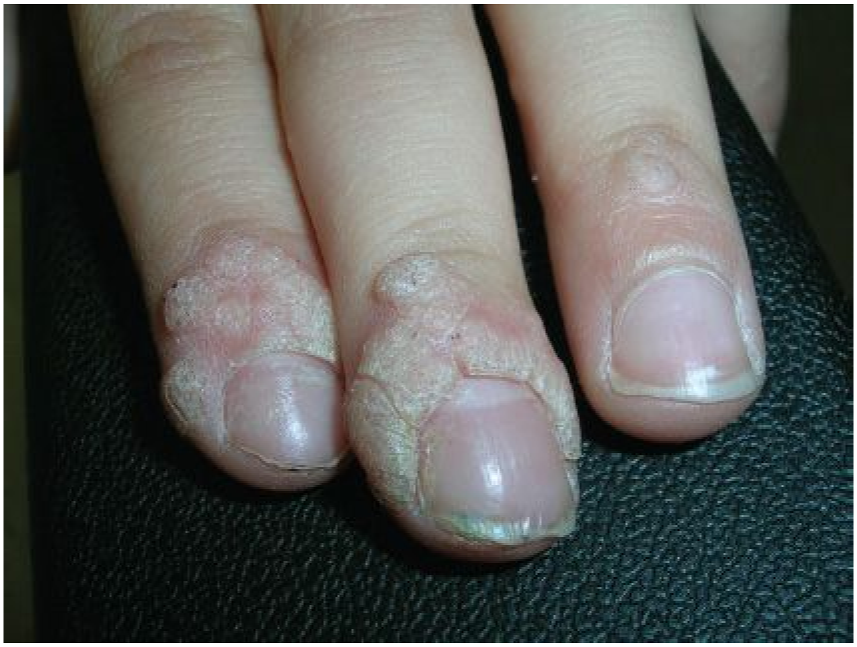

FIGURE 116-5 Periungual warts on the fingers of a child. Warts will obscure normal skin markings. (*Used with permission from Richard P. Usatine, MD.*)

- Common warts are well-demarcated, rough, hard papules with irregular papillary surface. They are usually asymptomatic unless located on a pressure point.
- Warts may form cylindrical of filiform projections (**Figures 116-6** and **116-7**).

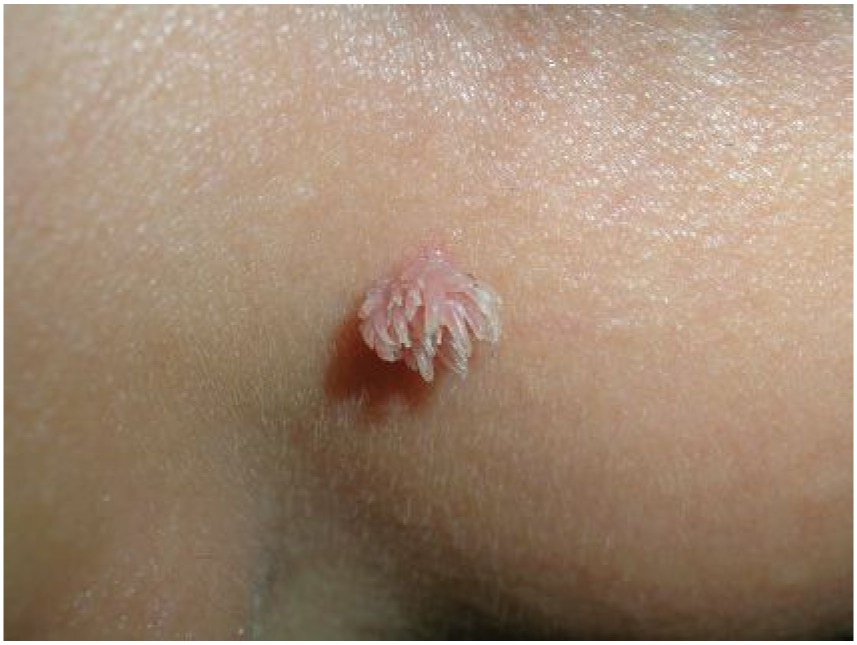

FIGURE 116-6 Filiform warts are identified by their multiple projections as opposed to a unified papule. This wart was on the cheek of a young girl. (*Used with permission from Richard P. Usatine, MD.*)

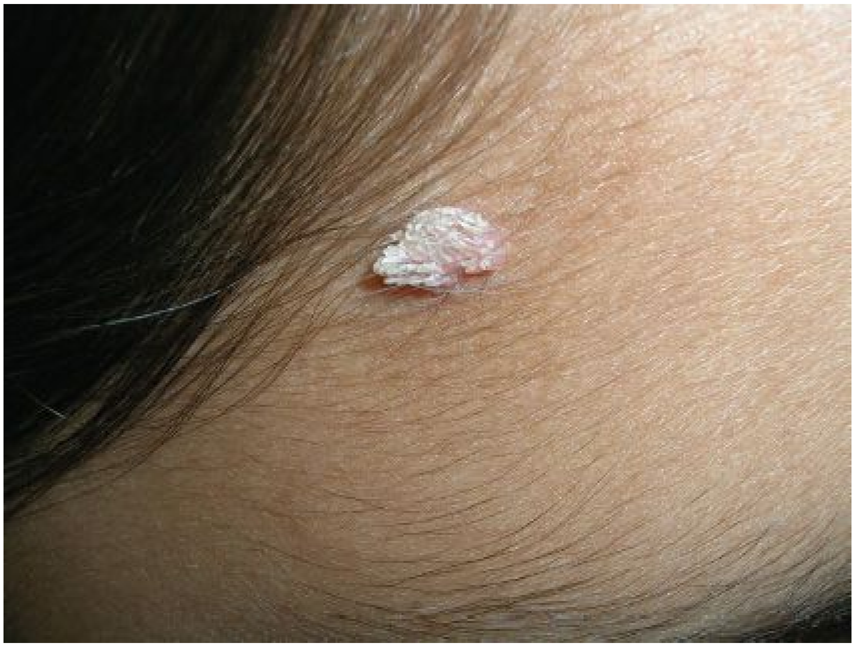

FIGURE 116-7 Filiform wart on the face of a young girl. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

- Common anatomic locations include the dorsum of the hand, between the fingers, flexor surfaces, and adjacent to the nails (periungual; **Figures 116-1**, **116-2**, and **116-5**).

LABORATORY TESTING

- HPV testing is not useful for this condition.[5] In a 2011 study, response to cryotherapy did not correlate HPV type.[6]
- HIV testing may be useful if the warts are severe and there are risk factors present (**Figure 116-4**).

BIOPSY

- Paring the surface with a surgical blade may expose punctate hemorrhagic capillaries, or black dots, which are thrombosed capillaries. If the diagnosis is in doubt, a shave biopsy is indicated to confirm the diagnosis.

DIFFERENTIAL DIAGNOSIS

- Molluscum contagiosum can appear similar to the common wart when the central umbilication is not easily visible. However, molluscum papules are usually more rounded and appear to be more stuck-on to the top of the skin (see Chapter 115, Molluscum Contagiosum).
- Acrochordon (skin tags) are pedunculated flesh-colored papules that are more common in obese persons. They lack the surface roughness of common warts. Filiform warts also may be pedunculated, but typically have a characteristic filiform appearance.

MANAGEMENT

NONPHARMACOLOGIC

- Because spontaneous regression occurs in 2/3 of warts within 2 years, observation without treatment is always an option. In 17 trials, the average reported cure rate was 30 percent within 10 weeks.[7] Observational studies show that 1/2 of cutaneous warts resolve spontaneously within 1 year, and about 2/3 within 2 years.[8]
- Treatment does not decrease transmissibility of the virus.[9]
- Distraction may help with pediatric acceptance and tolerance of treatment procedures. A 2012 study of patients aged 2 to 6 years who underwent cryotherapy for cutaneous viral warts found that the use of a portable video player significantly reduced preprocedural anxiety levels in patients undergoing cryotherapy for cutaneous viral warts.[10]

MEDICATIONS

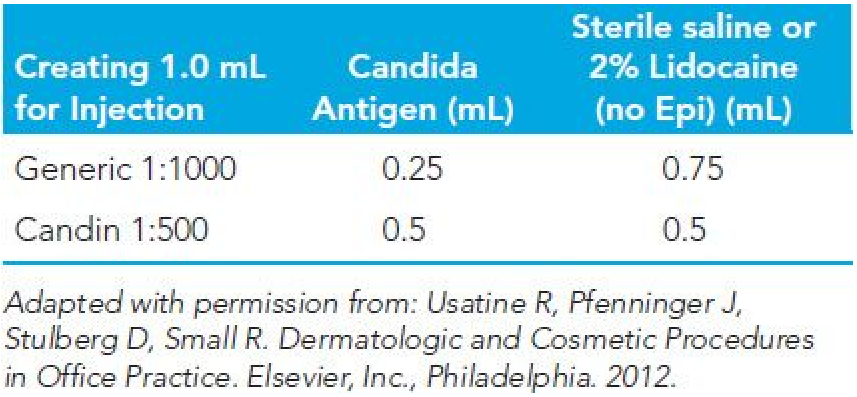
- Therapies for common warts do not specifically treat the HPV virus. They work by destruction of virus-containing skin while preserving uninvolved tissue. This usually exposes the blood and its immune cells to the virus, which may promote an immune response against the virus.
- The least-painful methods should be used first in children. SOR Ⓒ
- A Cochrane review found that there is a considerable lack of evidence on which to base the rational use of the local treatments for common warts.[7] The trials are highly variable in method and quality. There is evidence that simple topical treatments containing salicylic acid have a therapeutic effect.[7] SOR Ⓐ There is less evidence for the efficacy of cryotherapy and no convincing evidence that it is any more effective than simple topical treatments. A 2011 meta-analysis of randomized trials for treatments for warts found that salicylic acid was superior to placebo (risk ratio for cure

1.60, 95 percent CI 1.15-2.24) but data were insufficient to draw conclusions on the efficacy of other therapies studied.[11]

- Seventeen percent salicylic acid is a useful first-line agent, especially for thick or multiple warts.[7] SOR Ⓐ It is safe in children. Combined results from five randomized controlled trials (RCTs) showed a 73 percent cure rate with 6 to 12 weeks of salicylic acid treatment, compared with a 48 percent cure rate with placebo (number needed to treat [NNT] = 4).[7] A number of preparations are available without a prescription. Topical 17 percent salicylic acid is applied overnight and is now the most commonly used form for this type of wart. Soak the wart area with warm water for 5 minutes, and then gently file down any thick skin with a pumice stone or emery board. The salicylic acid product should be applied to the wart. Repeat the first 2 steps daily with liquid or gel preparations, or every other day with the patch. Tape may be used to cover the wart after application of salicylic acid liquid. Repeat treatment until the wart has cleared or for up to 12 weeks. Discontinue the treatment if severe redness or pain occurs in the treated area. Do not use salicylic acid on the face because of an increased risk of hypopigmentation.[1]
- Forty percent salicylic acid plasters (Mediplast) are available over the counter for larger and thicker warts. The plasters are cut to fit and then applied a few millimeters beyond the wart for 48 hours. Then the patch is removed, the wart pared down with a nail file, pumice stone, or scalpel, and the process repeated as needed.
- Imiquimod 5 percent is an expensive topical immunomodulator that is indicated for treatment of anogenital warts but is also used on nongenital warts.[12–14] SOR Ⓑ It is nonscarring and painless, although local irritation is common. Debriding heavily keratinized warts may enhance penetration of the medication. The cream is applied in a thin layer to the lesions three times a week (every other night) and covered with a adhesive bandage or tape. The medication is removed with soap and water in the morning. It can also be used as adjunctive therapy. A lower concentration of imiquimod (3.75% cream) is also available, but data for common warts is lacking.
- Intralesional injections with *Candida* antigen induces a localized, cell-mediated and HPV-specific response that may target the injected wart as

well as more distant warts (**Figure 116-8**). This method has moderate effectiveness (60% cure rates) for treatment of recalcitrant warts in patients with a positive skin antigen pretest.[1] SOR Ⓑ The *Candida* antigen must be diluted before used (**Table 116-1**). Inject 0.1 to 0.3 mL into the largest warts using a 30-gauge needle and up to 1 mL per treatment. Warn the patient to expect itching in the area, burning, or peeling. Repeat every 4 weeks, up to 3 treatments or until warts are gone.

TABLE 116-1 Candida Dilutions



Creating 1.0 mL for Injection	Candida Antigen (mL)	Sterile saline or 2% Lidocaine (no Epi) (mL)
Generic 1:1000	0.25	0.75
Candin 1:500	0.5	0.5

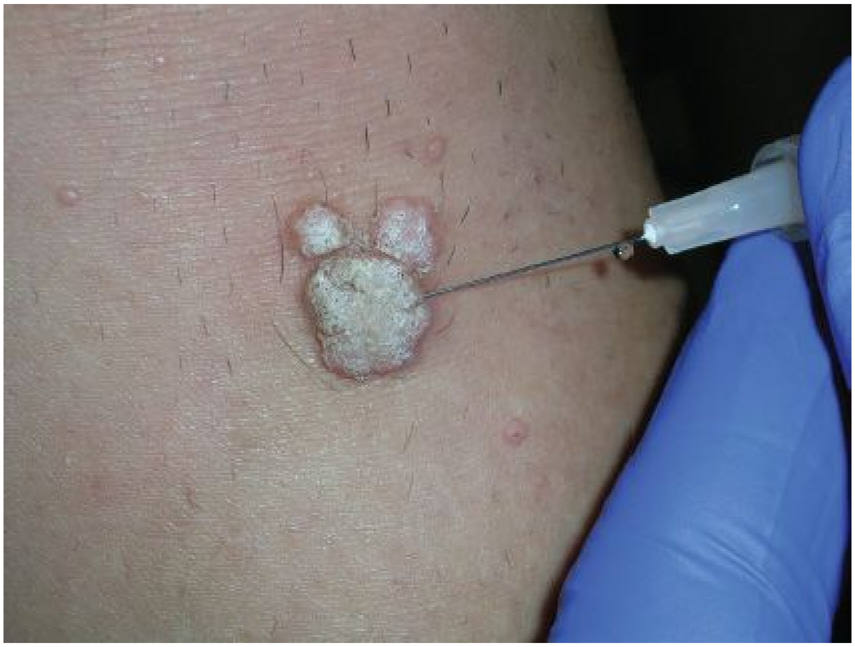

FIGURE 116-8 Candida antigen is being injected into a cluster of warts on the knee of a teenage boy. His warts had not responded to multiple

therapies, including topical salicylic acid and cryotherapy. (*Used with permission from Richard P. Usatine, MD.*)

- Photodynamic therapy with aminolevulinic acid plus topical salicylic acid is a moderately effective option for treatment of recalcitrant warts.[1] SOR Ⓑ Although it is likely to be beneficial, it is expensive and often requires referral.
- Cantharidin 0.7 percent is an extract of the blister beetle that is applied to the wart, after which blistering occurs on the following day. It may be used in resistant cases. It is also useful in young children because application is painless in the office. However, painful blisters often occur within a day after application. Be careful not to overtreat with cantharidin because the blistering can be quit severe. Carefully apply to multiple lesions using the wooden end of a cotton-tipped applicator (**Figure 116-9**). SOR Ⓒ

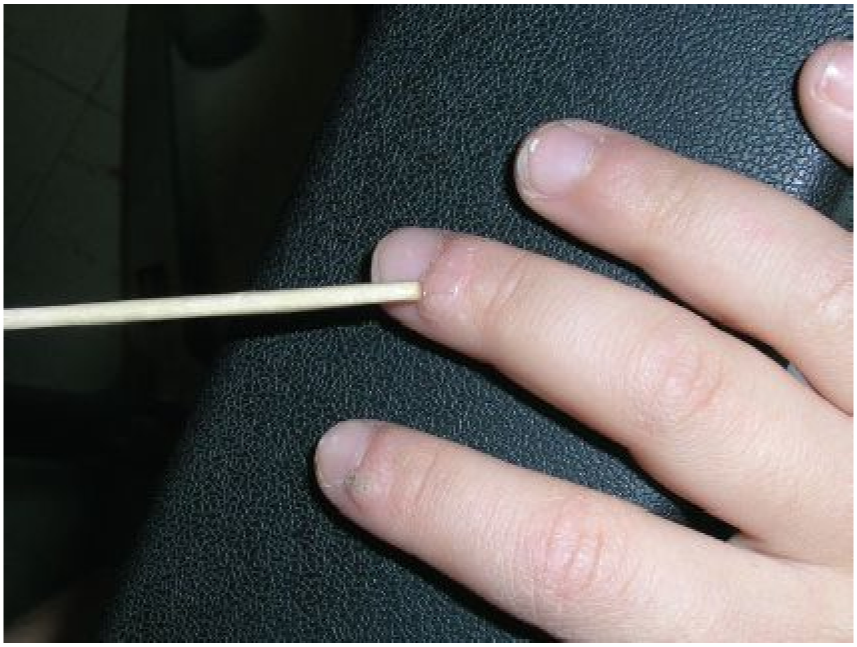

FIGURE 116-9 Cantharidin is being applied to periungual warts on the fingers of a 5-year-old child. Note the use of the wooden stick end of a cotton-tipped applicator. If the cotton tip is used, the cantharidin stays within the cotton and the application is insufficient. (*Used with permission from Richard P. Usatine, MD.*)

- Contact immunotherapy using dinitrochlorobenzene, squaric acid dibutylester, and diphenylcyclopropenone may be applied to the skin to sensitize the patient and then to the lesion to induce an immune response. SOR Ⓒ
- Intralesional injection with bleomycin can be considered for treatment of recalcitrant warts, although the effectiveness is unproven.[1] SOR Ⓑ
- Early open-label, uncontrolled studies indicate cimetidine might be useful in treating warts. However, three placebo-controlled, double-blind studies and two open-label comparative trials demonstrate that its efficacy is equal to placebo.[15] SOR Ⓐ

SURGERY

- Cryotherapy, most commonly with liquid nitrogen, is useful but is somewhat painful for younger children.[7] SOR Ⓑ Chemical cryogens are now available over the counter but are not as cold or effective as liquid nitrogen. Most trials comparing cryotherapy with salicylic acid found similar effectiveness, with overall cure rates of 50 to 70 percent after three or four treatments.[1] Aggressive cryotherapy (10 to 30 seconds) is more effective than less-aggressive cryotherapy, but may increase complications.[1] SOR Ⓑ Anesthesia is usually unnecessary but may be achieved with 1 percent lidocaine or EMLA (eutectic mixture of local anesthetics) cream. Liquid nitrogen is applied for 10 to 20 seconds via a Cryogun or a cotton swab so that the freeze ball extends 2 mm beyond the lesion (**Figure 116-10**). Two freeze cycles may improve resolution, but it is better to underfreeze than overfreeze as overfreezing may lead to permanent scarring or hypopigmentation. Best results of cryotherapy can be achieved when the patient is treated every 2 or 3 weeks. There is no therapeutic benefit beyond 3 months.[1] SOR Ⓑ Because HPV can survive in liquid nitrogen, cotton swabs and residual liquid nitrogen should be properly discarded to avoid spreading the virus to other patients or contaminating the liquid nitrogen reservoir.[16] After cryotherapy, the skin shows erythema and may progress to hemorrhagic blistering. Healing occurs in approximately a week and hypopigmentation may occur. Ring warts may result from an inadequate margin of treatment of a common wart (**Figure 116-11**). Common adverse effects of cryotherapy include pain, blistering, and hypo- or hyperpigmentation. Cryotherapy must be used cautiously where nerves are located superficially (such as on the fingers) to prevent pain and neuropathy. Overfreezing in the periungual region can result in permanent nail dystrophy.

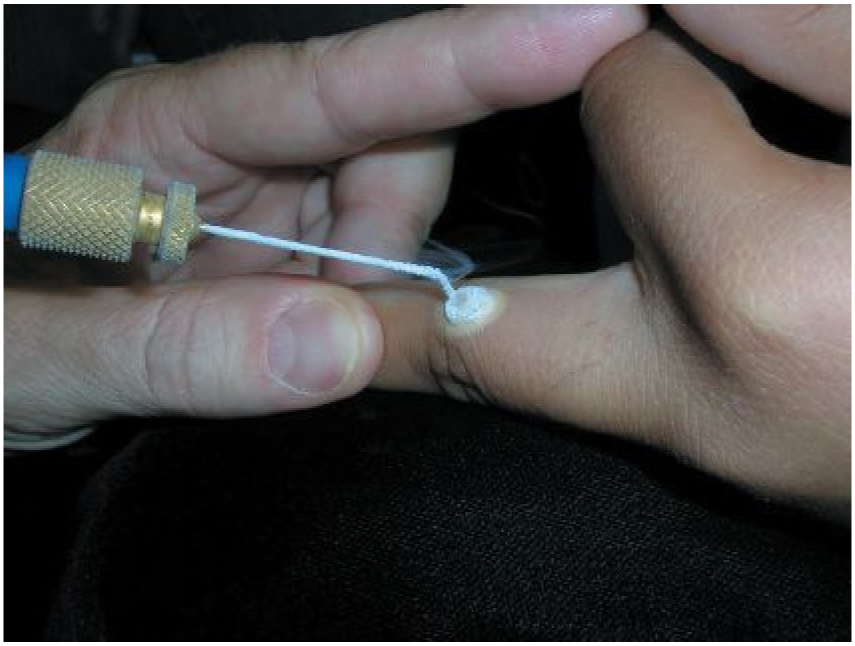

FIGURE 116-10 Cryotherapy showing an adequate free zone (halo) around the wart. (*Used with permission from Richard P. Usatine, MD.*)

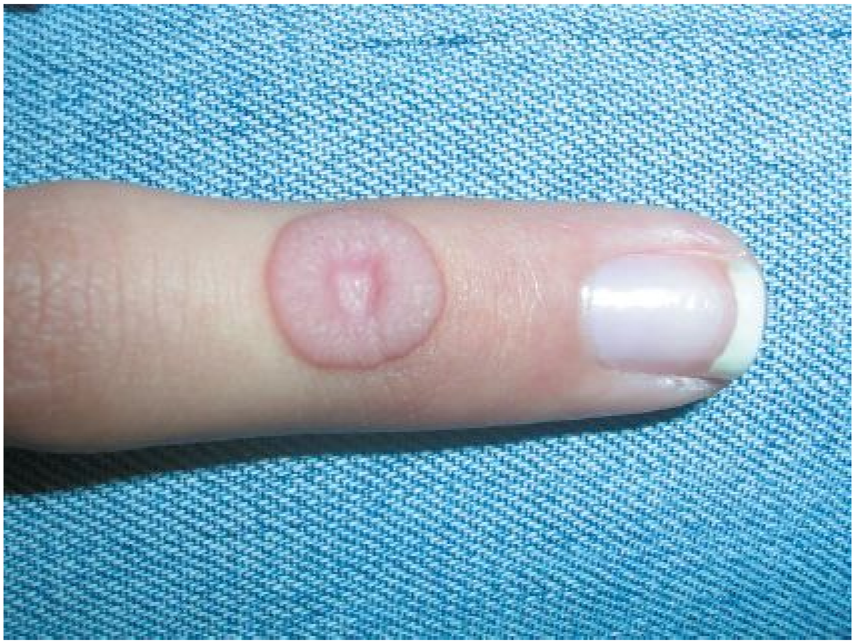

FIGURE 116-11 Ring wart that resulted from inadequate cryotherapy of a common wart. (*Used with permission from Richard P. Usatine, MD.*)

- Simple excision may be used for small or filiform warts (**Figures 116-6** and **116-7**). The area is injected using lidocaine with epinephrine and the wart is excised with sharp scissors or a scalpel blade. SOR Ⓒ
- Pulsed-dye laser can be considered for treatment of recalcitrant warts, although the effectiveness is unproven.[1] SOR Ⓑ

COMPLIMENTARY/ALTERNATIVE THERAPY

- Although preliminary studies were promising, duct tape is of uncertain efficacy for wart treatment.[1] A randomized controlled trial in adults showed it to be no better than moleskin and both groups only had a 21 to 22 percent success rate.[17] SOR Ⓑ

PREVENTION

- Tools used for paring down warts, such as nail files and pumice stones, should not be used on normal skin or by other people.
- Hair-bearing areas with warts should be shaved with depilatories, electric razors, or not at all to help limit spread of warts.

PROGNOSIS

- Sixty to 70 percent of cutaneous warts resolve in 3 to 24 months without treatment.[18,19]

- New warts may appear while others are regressing. This is not a treatment failure but part of the natural disease process with HPV.

FOLLOW-UP

- Schedule patients for return visits after treatment to limit loss of follow-up and to assess therapy.
- Follow-up visits can be left to the patient’s discretion when self-applied therapy is being used.

PATIENT EDUCATION

- Therapy often takes weeks to months, so patience and perseverance are essential for successful therapy.

117 FLAT WARTS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 16-year-old girl presents with multiple flat lesions on her forehead (**Figure 117-1**). It started with just a few lesions but has spread over the past 3 months. She is diagnosed with flat warts and topical imiquimod is prescribed as the initial treatment.

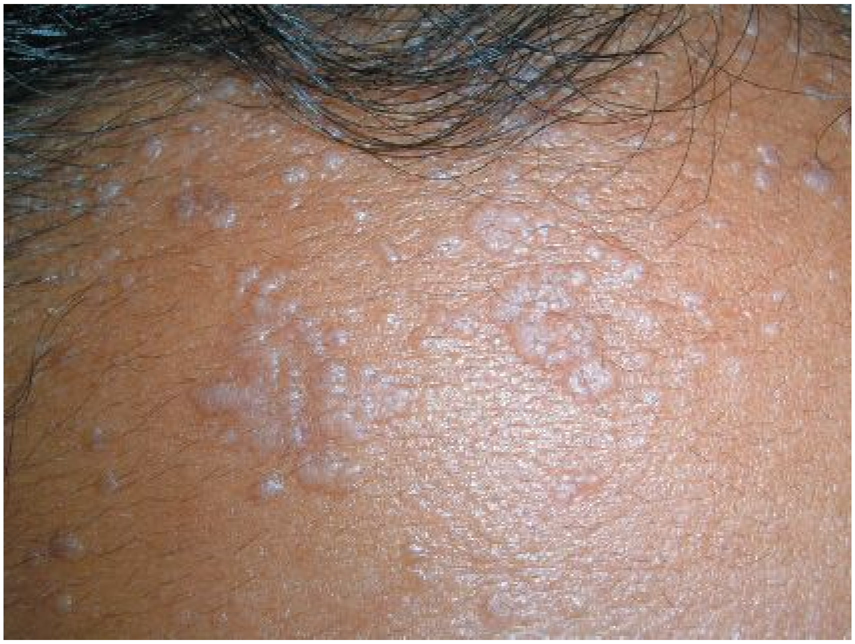

FIGURE 117-1 Flat warts on a patient's forehead. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Flat warts are characterized as flat or slightly elevated flesh-colored papules. They may be smooth or slightly hyperkeratotic. They range in size from 1 to 5 mm or more, and numbers range from a few to hundreds of lesions, which may become grouped or confluent. They occur most commonly on the face, hands, and shins. They may appear in a linear distribution as a result of scratching, shaving, or trauma (Koebner phenomenon) (**Figures 117-2** and **117-3**).

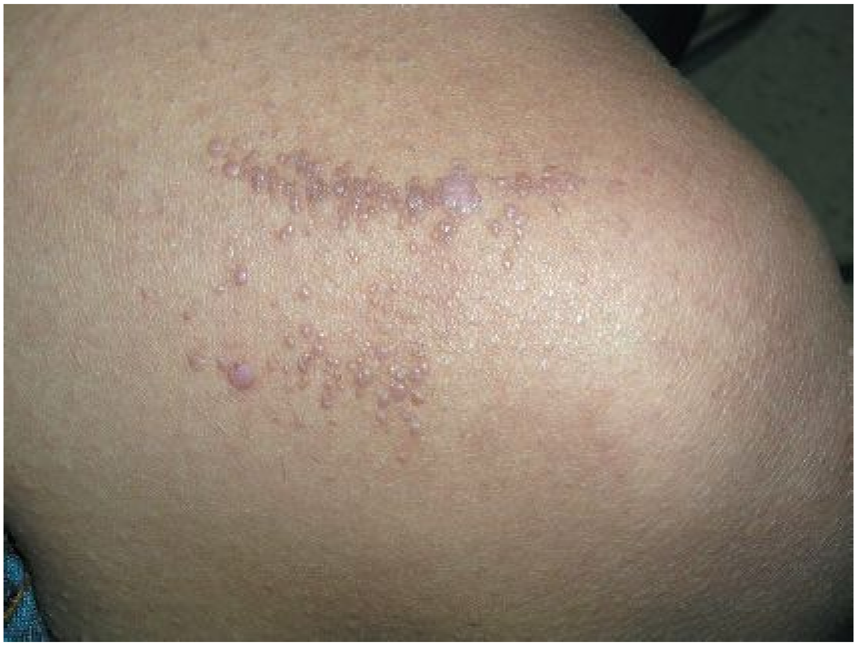

FIGURE 117-2 Flat warts just above the knee of a young woman. Notice the linear distribution probably resulting from spread by shaving (Koebner phenomenon). (*Used with permission from Richard P. Usatine, MD*.)

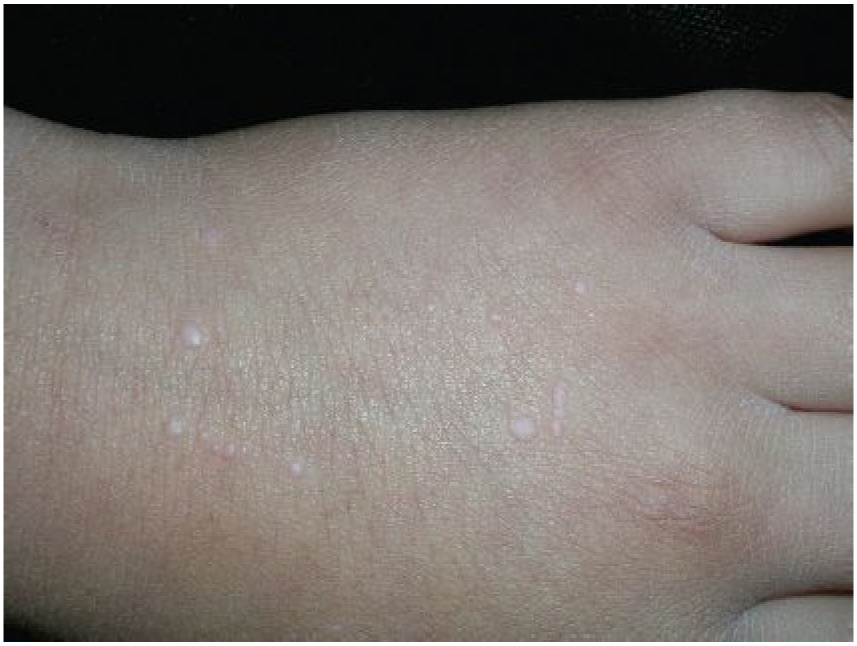

FIGURE 117-3 Flat warts on the hand of a child. Note the linear distribution, which is probably the result of scratching or minor trauma (Koebner phenomenon). (*Used with permission from Richard P. Usatine, MD*.)

SYNONYMS

Plane warts, verruca plana, verruca plana juvenilis, plane warts.

EPIDEMIOLOGY

- Flat warts (verruca plana) are most commonly found in children and young adults (**Figures 117-1** to **117-3**).
- Flat warts are the least common variety of wart, but are generally numerous on an individual.[1]

- Flat warts are usually caused by human papillomavirus (HPV) types 3, 10, 28, and 29.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Like all warts, flat warts are caused by HPV.[2]
- Flat warts may spread in a linear pattern secondary to spread by scratching or trauma, such as shaving (**Figure 117-2** and **117-3**).
- Flat warts present a special treatment problem because they persist for a long time, they are generally located in cosmetically important areas, and they are resistant to therapy.

RISK FACTORS

- Shaving next to infected areas (**Figures 117-2** and **117-3**).
- HIV infection or other types of immunosuppression.

DIAGNOSIS

CLINICAL FEATURES

- Multiple small, flat-topped papules that may be pink, light brown, or light yellow colored. They may be polygonal in shape (**Figure 117-4**).

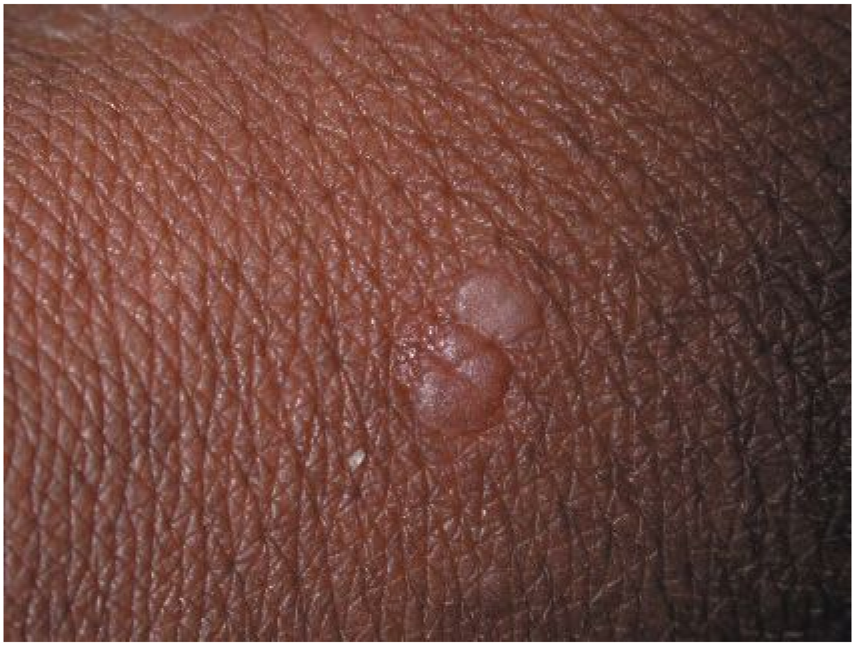

FIGURE 117-4 Close-up of a flat wart. Note typical small, flat-topped papule. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

- Flat warts typically appear on the forehead (**Figure 117-1**), around the mouth (**Figure 117-5**), the backs of the hands (**Figure 117-3**), and shaved areas, such as the lower face and neck in men (**Figure 117-3**) and the lower legs in women (**Figures 117-2** and **117-6**).

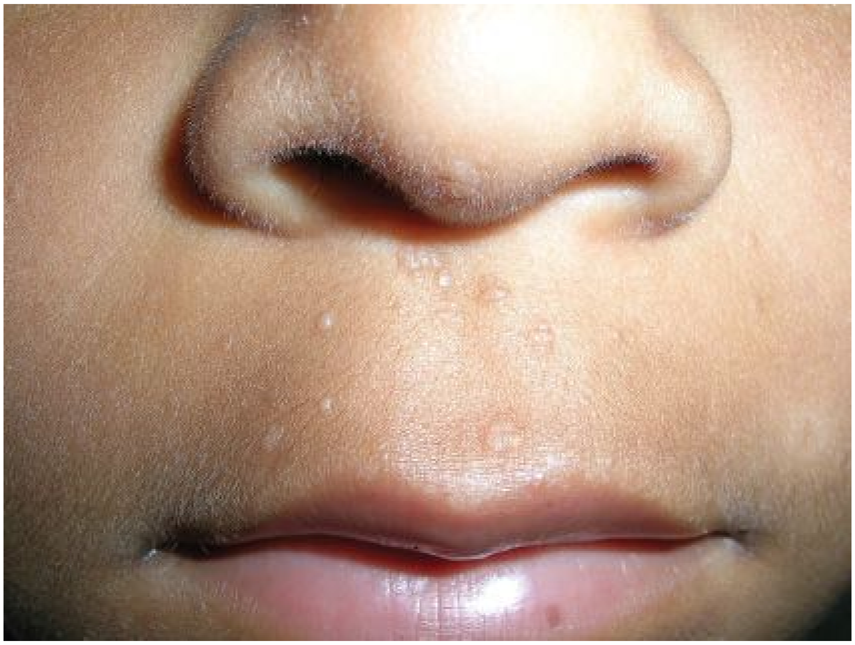

FIGURE 117-5 Flat warts on the upper lip and nose of a young girl. (*Used with permission from Richard P. Usatine, MD.*)

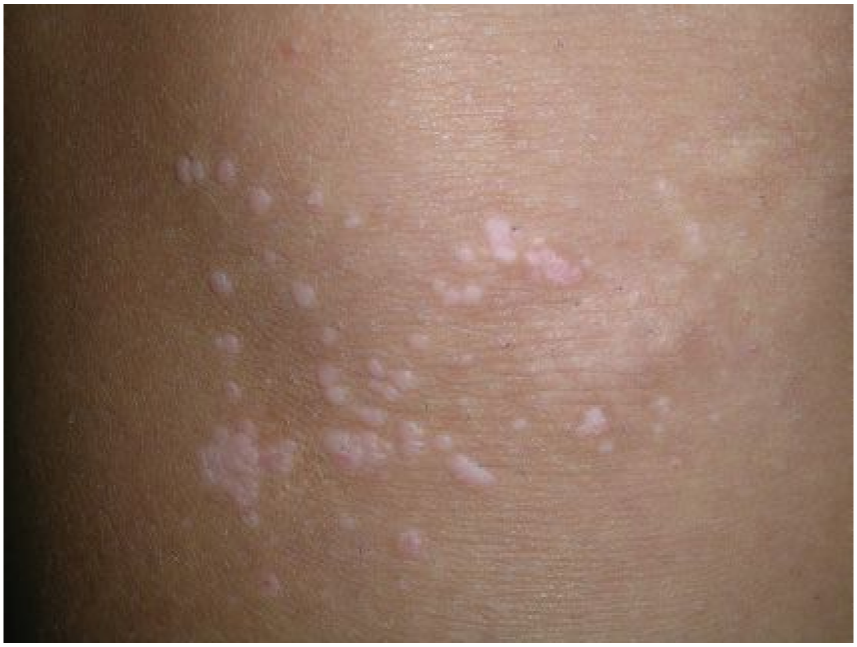

FIGURE 117-6 Flat warts on the leg of a teenager. (*Used with permission from Richard P. Usatine, MD.*)

LABORATORY TESTING

- HPV testing is not useful for this condition.[3]

BIOPSY

- Although usually not necessary, a shave biopsy can confirm the diagnosis if the diagnose is in question.

DIFFERENTIAL DIAGNOSIS

- Lichen planus produces flat-topped papules that may be confused with flat warts. Look for characteristic signs of lichen planus such as the symmetric distribution, purplish coloration, and oral lacy lesions. (Wickham striae are white, fine, reticular scale seen on the lesions.) The distribution of lichen planus is different, with the most common sites being the ankles, wrists, and back (see Chapter 138, Lichen Planus). Lichen planus rarely occurs in children.
- Seborrheic keratoses are often more darkly pigmented and have a stuck-on appearance; “horn cysts” may be visible on close examination. These are also rare in children.

MANAGEMENT

NONPHARMACOLOGIC

- Regression of these lesions may occur, which usually is heralded by inflammation.
- There are no current therapies for HPV that are virus specific.

- Distraction may help with pediatric acceptance and tolerance of treatment procedures. A 2012 study of patients aged 2 to 6 years who underwent cryotherapy for cutaneous viral warts found that the use of a portable video player significantly reduced preprocedural anxiety levels i undergoing cryotherapy for cutaneous viral warts.[4]

MEDICATIONS

- Topical salicylic acid treatments by topical liquid or patch are the most effective treatment for all types of warts with a success rate average of 73 percent from five pooled placebo-controlled trials.[5] Number needed to treat (NNT) = 4. SOR Ⓐ Salicylic acid may be more acceptable on the legs than the face.[2] Often, 17 percent salicylic acid topicals are applied overnight daily until the warts resolve.
- Fluorouracil (Efudex 5% cream, Fluoroplex 1%) may be used to treat flat warts in adults only.[6,7] SOR Ⓑ It is not indicated for use in children.
- Imiquimod 5 percent cream is an expensive topical immunomodulator that has shown some efficacy in treating flat warts.[8,9] It is nonscarring and painless to apply. There are rare reports of systemic side effects. The cream is applied to the lesions 3 times a week (every other day). The cream may be applied to the affected area, not strictly to the lesion itself.[10] It can be used on all external HPV-infected sites, but not on occluded mucous membranes. Therapy can be temporarily halted if symptoms become problematic. Imiquimod has the advantage of having almost no risk of scarring.[8,9] SOR Ⓑ A lower concentration of imiquimod (3.75% cream) is also available, but data for its use with flat or common warts is lacking. It is not indicated for use in children although there are data for its use in adolescents.
- Tretinoin cream, 0.025 percent, 0.05 percent, or 0.1 percent, applied at bedtime over the entire involved area is one accepted treatment. The frequency of application is then adjusted so as to produce a mild, fine scaling and erythema. Sun protection is important. Treatment may be required for weeks or months and may not be effective. No published

studies were found to support this treatment. SOR Ⓒ Safety and efficacy in children under age 12 years is not established.

- Intralesional injections with *Candida* antigen induces a localized, cell-mediated, and HPV-specific response that may target the injected wart as well as more distant warts. This method has moderate effectiveness (60% cure rates) for treatment of recalcitrant warts (**Figure 117-3**).[2] The *Candida* antigen must be diluted before used (see **Table 116-1**). Inject 0.1 to 0.3 mL into the largest warts using a 30-gauge needle and up to 1 mL per treatment. Warn the patient to expect itching in the area, burning, or peeling. Repeat every 4 weeks, up to three treatments or until warts are gone.[11] SOR Ⓑ
- Cantharidin 0.7 percent is an extract of the blister beetle that is applied to the wart after which blistering occurs. It may be used in resistant cases.[12] It is also useful in young children because application is painless in the office. However, painful blisters often occur within a day after application. Be careful not to overtreat with cantharidin because the blistering can be quite severe. Carefully apply to multiple lesions using the wooden end of one or two cotton-tipped applicators. SOR Ⓒ

SURGICAL

- Cryotherapy, most commonly with liquid nitrogen, is useful but is somewhat painful for younger children.[7] SOR Ⓑ Chemical cryogens are now available over the counter but are not as cold or effective as liquid nitrogen. Most trials comparing cryotherapy with salicylic acid found similar effectiveness.[2] Liquid nitrogen is applied for 5 to 10 seconds via a Cryogun or a cotton swab so that the freeze ball extends 1 to 2 mm beyond the lesion. Because flat warts are thinner than common warts, the freeze times needed are shorter. Two freeze cycles may improve resolution, but it is better to underfreeze than overfreeze since overfreezing may lead to permanent scarring or hypopigmentation. Best results of cryotherapy can be achieved when the patient is treated every 2 or 3 weeks. There is no therapeutic benefit beyond 3 months.[2] SOR Ⓑ Because HPV can survive in liquid nitrogen, cotton swabs and residual liquid nitrogen should be properly discarded to avoid spreading the virus to other patients or contaminating the liquid nitrogen reservoir.[13] After cryotherapy, the skin shows erythema and may progress to hemorrhagic blistering. Healing occurs in approximately a week and hypopigmentation may occur. Common adverse effects of cryotherapy include pain, blistering, and hypo- or hyperpigmentation.

- Pulsed-dye laser can be considered for treatment of recalcitrant warts, although the effectiveness is unproven.[2] SOR B

PREVENTION

- Hair-bearing areas with warts should be shaved with depilatories, electric razors, or not at all to help limit spread of warts.

FOLLOW-UP

- Schedule patients for a return visit in 2 to 3 weeks after therapy to assess efficacy.

PATIENT EDUCATION

- To help avoid spreading warts, patients should avoid touching or scratching the lesions.
- Razors that are used in areas where warts are located should not be used on normal skin or by other people to prevent spread.

118 GENITAL WARTS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 16-year-old boy presents with growths in the genital area for about 1 month (**Figure 118-1**). He has never had a sexually transmitted disease (STD) or vaccination against human papillomavirus (HPV) infection. He has had multiple sexual partners. The patient is told that he has genital warts which are an STD caused by HPV. The treatment options are discussed and he chooses to have cryotherapy with liquid nitrogen. A urine test for gonorrhea and *Chlamydia* is performed and the patient is tested for syphilis and HIV. Fortunately, all the additional tests are negative. Further patient education is performed and follow-up is arranged.

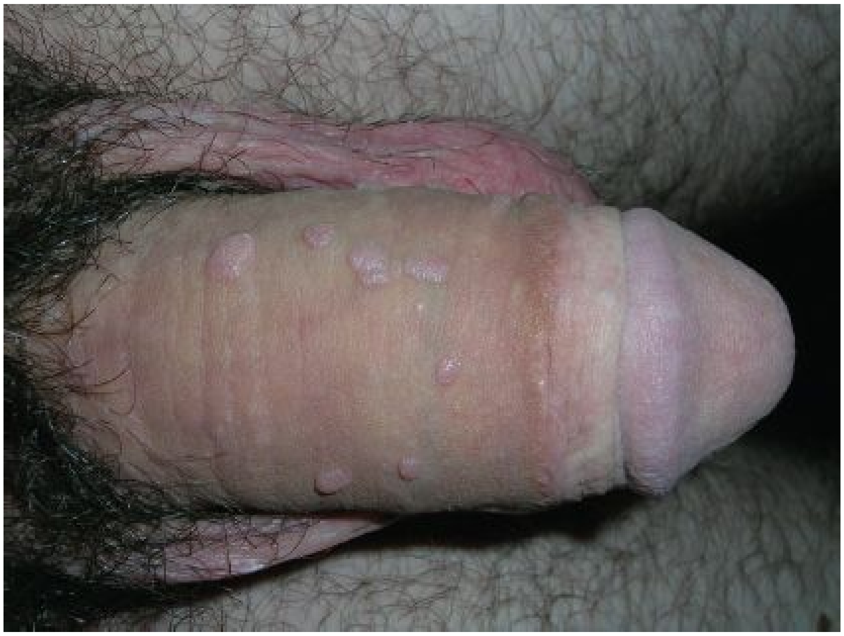

FIGURE 118-1 Condyloma acuminata in 16-year-old circumcised boy not practicing safe sex. He has isolated lesions on the shaft of the penis. He was treated with cryotherapy using liquid nitrogen. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

More than 100 types of HPV exist, with more than 40 that can infect the human genital area. Most HPV infections are asymptomatic, unrecognized, or subclinical. Low-risk HPV types (e.g., HPV types 6 and 11) cause genital warts, although coinfection with HPV types associated with squamous intraepithelial neoplasia can occur. Asymptomatic genital HPV infection is common in sexually active persons and usually self-limited.[1]

SYNONYMS

Condyloma acuminata.

EPIDEMIOLOGY

- Anogenital warts are the most common viral STD in the US. There are approximately 1 million new cases of genital warts per year in the US.[2]
- Most infections are transient and cleared within 2 years.[2]
- Some infections persist and recur and cause much distress for the patients.

ETIOLOGY AND PATHOPHYSIOLOGY

- Genital warts are caused by HPV infection in males (**Figure 118-1**) and females (**Figure 118-2**). HPV encompasses a family of primarily sexually transmitted double-stranded DNA viruses. The incubation period after exposure ranges from 3 weeks to 8 months.

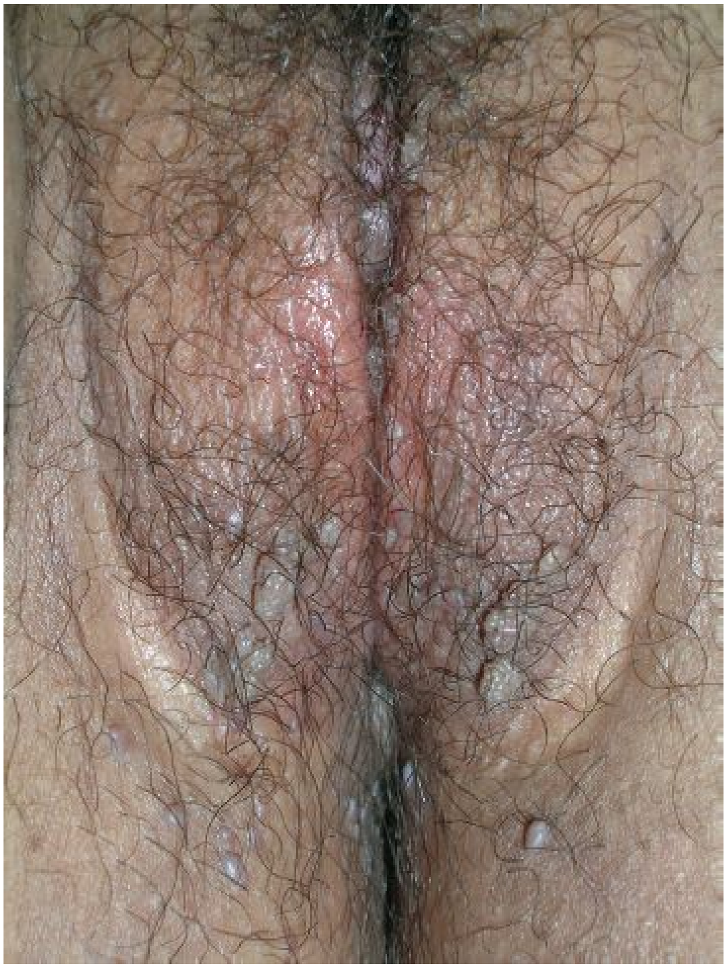

FIGURE 118-2 Multiple vulvar exophytic condyloma in an 18-year-old woman. She had never had a sexually transmitted disease (STD) or vaccination against human papillomavirus (HPV) but admitted to 2 new sexual partners in the prior 6 months. (*Used with permission from Richard P. Usatine, MD.*)

- HPV can be transmitted both sexually and non-sexually.[3] Cutaneous HPV types can persist over a long time in healthy skin.[4] HPV DNA detection in amniotic fluid, fetal membranes, cord blood and placental trophoblastic cells all suggest some HPV infection may occur in utero (prenatal transmission).[3]

- The first systematic review on vertical transmission of HPV included 2,113 newborns found the pooled mother-to-child HPV transmission was 6.5 percent. Transmission was higher after vaginal delivery than after caesarean section (18.3% vs 8%) (RR = 1.8; 95% CI 1.3–2.4).[5]
- Most of the mucosal HPV infections in infants are incidental, persistent infections in oral and genital mucosa being found in less than 10 and 2 percent respectively.[3] Condyloma acuminata in children younger than two to three years of age are more likely the result of maternal-child transmission, but may be due to sexual or nonsexual transmission (**Figure 118-3**).

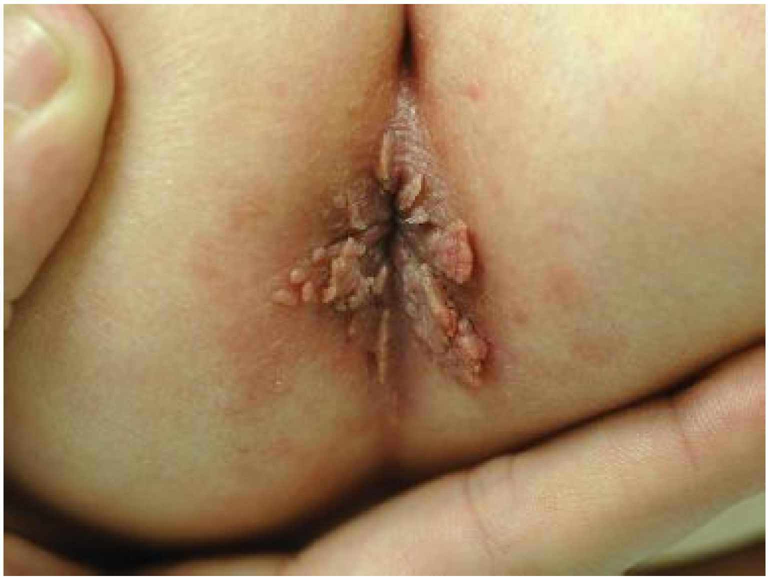

FIGURE 118-3 Perianal condyloma in a 2-year-old girl for 2 months. The child was brought in by her mother who did have warts on her hands. The mother claims that the child is always with her immediate family, never in day care, and no one in the family had genital warts. The clinician did not suspect child abuse, did not file a report and treated the condyloma topically. (*Image used with permission from Robert Brodell, MD.*)

- In one study, 73 children with anogenital warts were examined for sexual abuse during a 2-year period. Approximately 25 percent of these children were younger than age 1 year, and another 50 percent were between the ages of 1 and 3 years. No evidence of sexual abuse was detected in 66 children. The authors concluded that nonsexual transmission is common, particularly in children under 3 years of age.[6]

- HPV testing of mothers does not exclude sexual abuse and is not generally performed.
- Evaluation for potential sexual abuse should be considered, especially in older children, and evaluation by appropriately experienced professionals considered.

RISK FACTORS

- Sexual intercourse and oral sex.
- Other types of sexual activity including digital–anal, oral–anal, and digital–vaginal contact.
- Immunosuppression, especially HIV.

DIAGNOSIS

CLINICAL FEATURES

- Diagnosis of genital warts is usually clinical based on visual inspection.[1]
- Genital warts are usually asymptomatic, and typically present as flesh-colored, exophytic lesions on the genitalia, including the penis, vulva, vagina, scrotum, perineum, and perianal skin.
- External warts can appear as small bumps, or they may be flat, verrucous, or pedunculated (**Figures 118-4** to **188-6**).

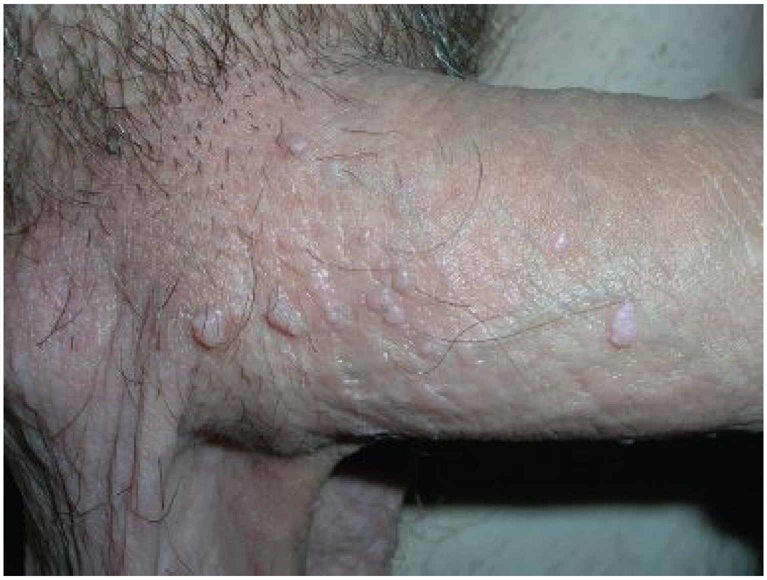

FIGURE 118-4 Smooth-topped condyloma on the well-keratinized skin of a circumcised teen. (*Used with permission from Richard P. Usatine, MD*.)

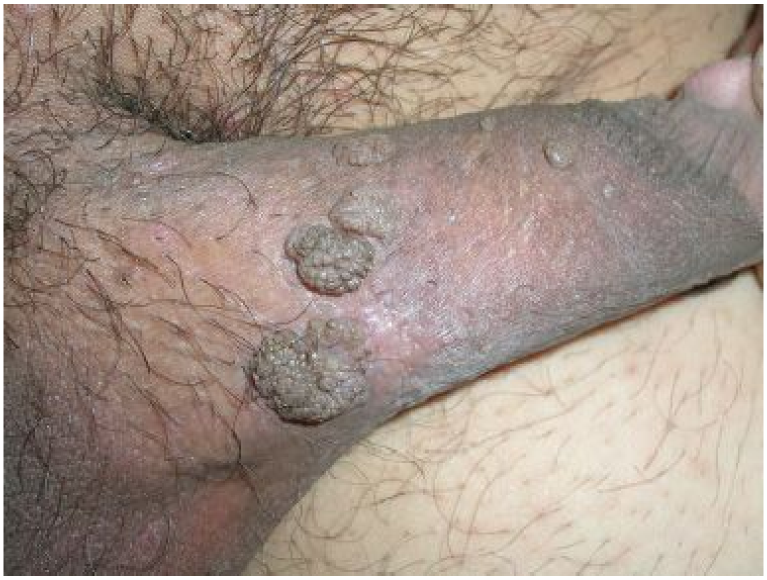

FIGURE 118-5 Condyloma can take on a cauliflower appearance even on the well-keratinized skin of a circumcised male. (*Used with permission from Richard P. Usatine, MD*.)

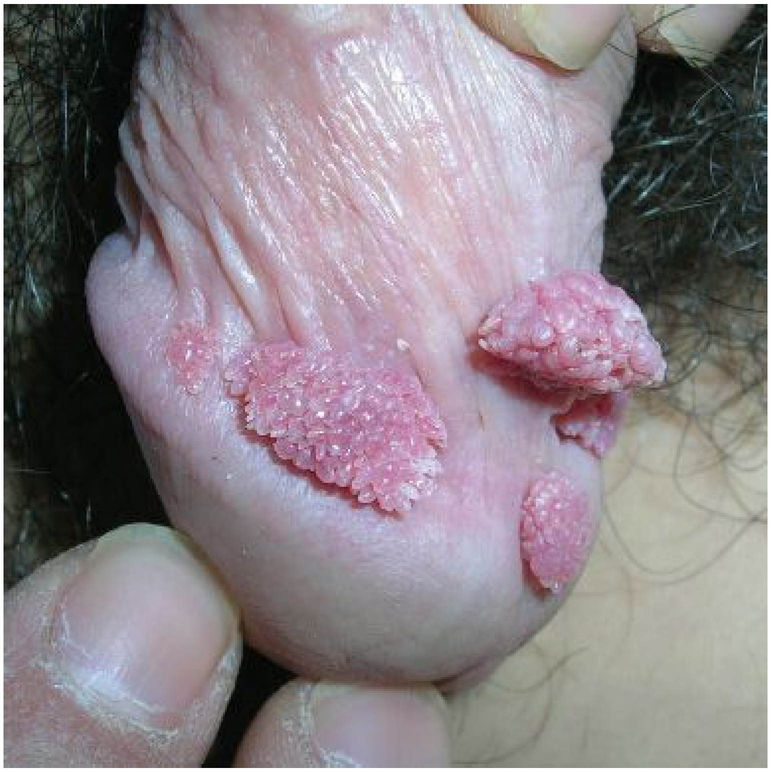

FIGURE 118-6 Condyloma acuminata demonstrating a cauliflower appearance with typical papillary surface seen when the foreskin is retracted in an uncircumcised young man. Note that the top wart is pedunculated with a narrow base. (*Used with permission from Richard P. Usatine, MD.*)

- Less commonly, warts can appear as reddish or brown, smooth, raised papules, or as dome-shaped lesions on keratinized skin.

TYPICAL DISTRIBUTION

- In women, the most common sites of infection are the vulva (**Figure 118-2**), perianal area, and the vagina.
- In men, the most common sites of infection are the penis (**Figures 118-1**, and **118-4** to **118-6** and scrotum.
- Perianal warts can occur in men or women who have a history of anal intercourse, and in those who do not have any such history (**Figure 118-7**).[1]

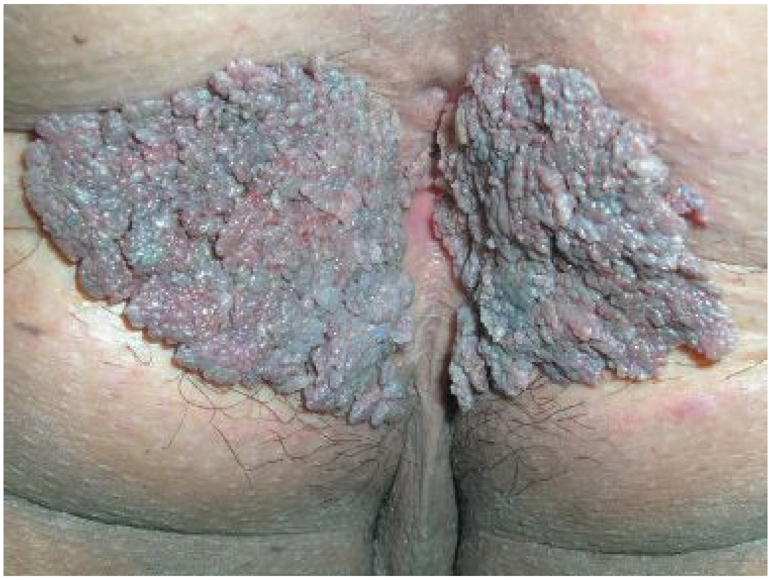

FIGURE 118-7 Extensive perianal warts in a 17-year-old boy who denies sexual abuse and anal intercourse. Patient failed imiquimod therapy and was referred to surgery. (*Used with permission from Richard P. Usatine, MD*.)

- Condyloma acuminata may be seen on the abdomen or upper thighs in conjunction with genital warts (**Figure 118-8**).

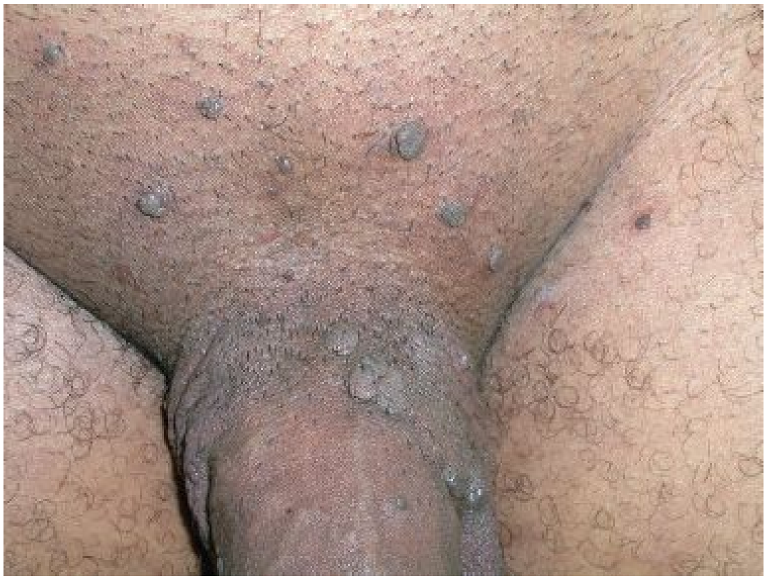

FIGURE 118-8 Condyloma that started on the penis and spread up the abdomen and on to the thighs. Note how these warts are hyperpigmented in this black teenager. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY TESTING

- A screen for syphilis and a HIV test should be ordered as well. Genital warts are a sexually transmitted disease and patients who have one STD should be screened for others (**Figure 118-9**).

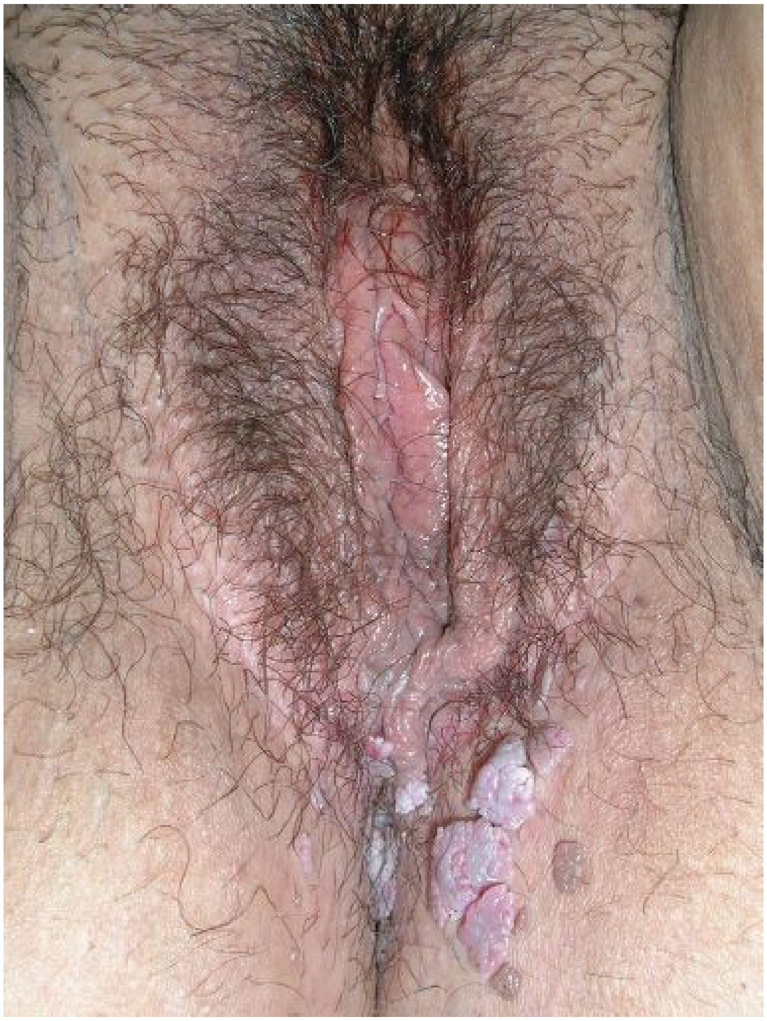

FIGURE 118-9 This teenager tested positive for syphilis at the time she presented with condyloma acuminata. While her RPR was positive these warts were more likely to be HPV related rather than the condyloma lata of secondary syphilis. The patient was treated with IM benzathine penicillin and cryotherapy. (*Used with permission from Richard P. Usatine, MD.*)

- HPV viral typing is not recommended because test results would not alter clinical management of the condition. The application of 3 to 5 percent acetic acid to detect mucosal changes attributed to HPV infection is no longer recommended.[1]

BIOPSY

- Diagnosis may be confirmed by shave or punch biopsy if necessary.[1] Biopsy is indicated if:
  - The diagnosis is uncertain.
  - The patient has a poor response to appropriate therapy.
  - Warts are atypical in appearance (unusually pigmented, indurated, fixed, or ulcerated).
  - The patient has compromised immunity and squamous cell carcinoma is suspected (one type of HPV-related malignancy).

DIFFERENTIAL DIAGNOSIS

- Pearly penile papules, which are small papules around the edge of the glans penis (**Figure 118-10**), may be confused with genital warts.

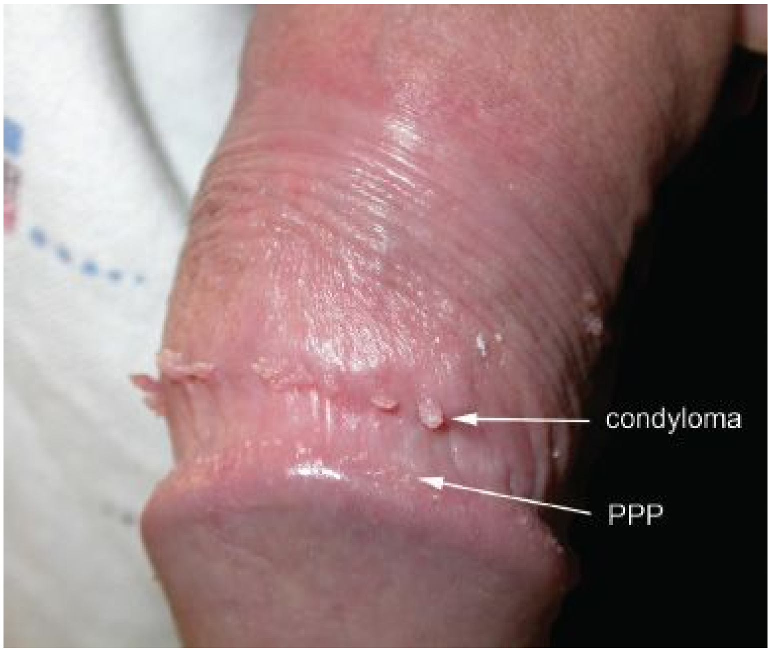

FIGURE 118-10 Condyloma coexisting with pearly penile papules (PPPs), which are a normal variant on the edge of the corona. (*Used with permission from Richard P. Usatine, MD.*)

- Molluscum contagiosum—Waxy umbilicated papules around the genitals and lower abdomen (see Chapter 115, Molluscum Contagiosum).
- Condyloma lata is caused by secondary syphilis infection; lesions appear flat and velvety (see Chapter 181, Syphilis). A full work-up for other STDs, including syphilis, should be done for any patient with genital warts (**Figure 118-9**).
- Micropapillomatosis of the vulva is a normal variant and appears as distinct individual papillary projections from the labia in a symmetrical pattern.

MANAGEMENT

- The primary reason for treating genital warts is the amelioration of symptoms and ultimately removal of the warts.[1]
- The choice of therapy is based on the number, size, site, and morphology of lesions, as well as patient preference, treatment cost, convenience, adverse effects, and physician experience.
- Although available therapies for genital warts are likely to reduce HPV infectivity, they probably do not eradicate transmission.[1]

MEDICATIONS AND SURGICAL METHODS

- Treatments for external genital warts include topical medications, cryotherapy (**Figure 118-11**), and surgical methods, and are shown in **Table 118-1**.

TABLE 118-1 Treatments for External Genital Warts

Treatment	Possible Adverse Effects	Clearance (%)	Recurrence (%)
Patient-Applied Therapy			
Imiquimod (Aldara) is applied at bedtime for 3 days, then rest 4 days; alternatively, apply every other day for 3 applications; may repeat weekly cycles for up to 16 weeks[8] SOR Ⓐ	Erythema, irritation, ulceration, pain, and pigmentary changes; minimal systemic absorption	30 to 50	15
Sinecatechins 15 percent ointment—Apply a 0.5-cm strand of ointment to each wart 3 times daily[6] SOR Ⓐ	Erythema, pruritus/burning, pain, ulceration, edema, induration, and vesicular rash	53 to 57	3.7
Podofilox (Condylox) is applied twice daily for 3 days, then rest 4 days; may repeat for 4 cycles[7] SOR Ⓐ	Burning, pain, inflammation; low risk for systemic toxicity unless applied to occluded membranes	45 to 80	5 to 30
Provider-Applied Therapy			
Cryotherapy performed with liquid nitrogen or a cryoprobe[6] SOR Ⓑ	Pain or blisters at application site, scarring	60 to 90	20 to 40
Podophyllin resin is applied to each wart and allowed to dry, and is repeated weekly as needed[6,10] SOR Ⓐ	Local irritation, erythema, burning, and soreness at application site; neurotoxic and oncogenic if absorbed	30 to 80	20 to 65
Surgical treatment for warts involves removal to the dermal–epidermal junction; options include scissor excision, shave excision, laser vaporization, and loop electrosurgical excision procedure (LEEP) excision[9] SOR Ⓑ	Pain, bleeding, scarring; risk for burning and allergic reaction from local anesthetic; laser and LEEP have risk for spreading HPV in plume	35 to 70	5 to 50
Trichloroacetic acid (TCA) and bichloracetic acid (BCA) are applied to each wart and allowed to dry; repeated weekly[6] SOR Ⓑ	Local pain and irritation; no systemic side effects	50 to 80	35

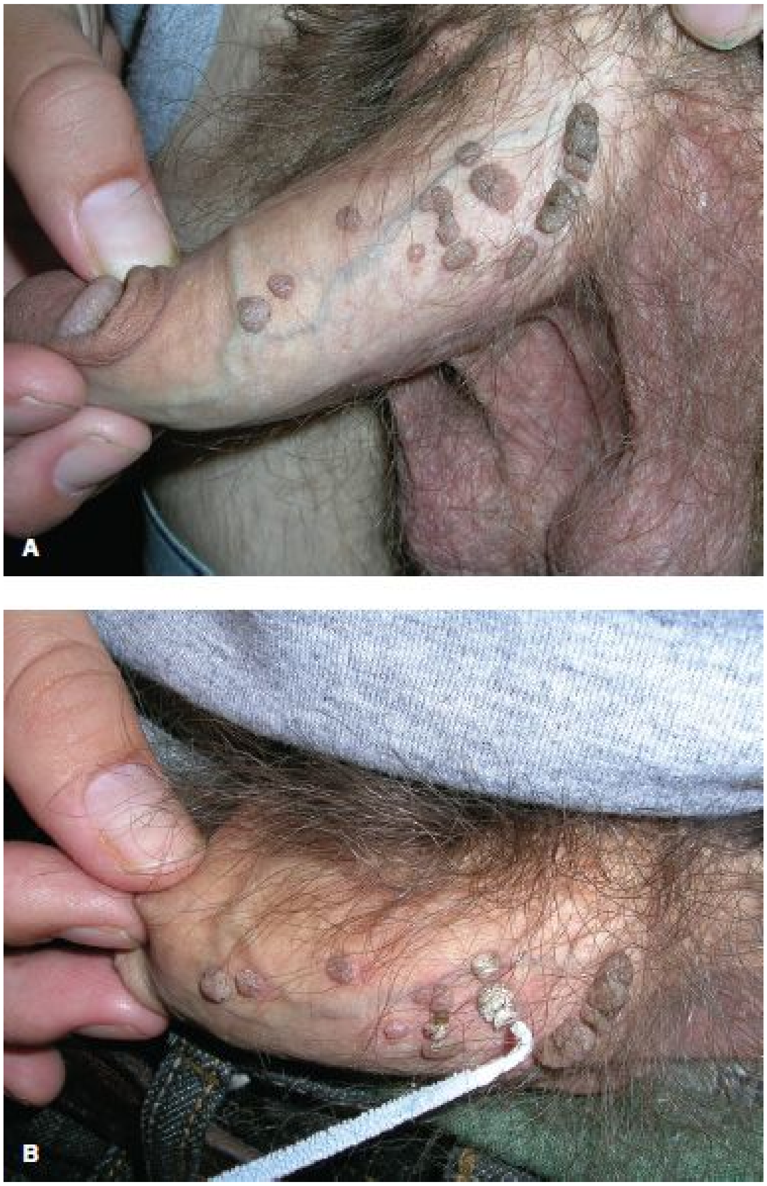

FIGURE 118-11 A. Condyloma on the penile shaft of a sexually active teenager not practicing safe sex. B. Cryotherapy of the condyloma using a liquid nitrogen spray technique and a bent-tipped applicator. (*Used with permission from Richard P. Usatine, MD*.)

- For children under 12 years of age, there are no US Food and Drug Administration-approved treatments for genital warts.[11]
- Cryotherapy is best applied with a bent-tipped spray applicator that allows for precise application with a less painful attenuated flow (**Figure 118-11**).[12] Application may be repeated every 2 weeks if necessary.

- Treatment with 5 percent fluorouracil cream (Efudex) is no longer recommended because of severe local side effects and teratogenicity.[1]
- In younger children, cryotherapy is often not well tolerated because of associated pain. Some authors suggest applying topical anesthetics prior to cryotherapy. However, a double-blind, randomized, controlled trial using eutectic lidocaine/prilocaine 5 percent cream for local anesthesia before cryotherapy of nongenital warts in children ages 6 to 18 did not significantly decrease the pain associated with the procedure.[13] SOR A
- Podophyllotoxin 0.5 percent gel and imiquimod 5 percent cream has been safely used in children as young as age 1 year.[14,15] SOR B

REFERRAL OR HOSPITALIZATION

- Consider consultation for patients with very large or recalcitrant lesions.

PREVENTION

- A bivalent vaccine (Cervarix) containing HPV types 16 and 18, and a quadrivalent vaccine (Gardasil) vaccine containing HPV types 6, 11, 16, and 18 are licensed in the US. The quadrivalent HPV vaccine protects against the HPV types that cause 90 percent of genital warts (i.e., types 6 and 11) in males and females when given prophylactically. Both vaccines offer protection against the HPV types that cause 70 percent of cervical cancers (i.e., types 16 and 18). In the US, the quadrivalent (Gardasil) HPV vaccine can also be used in males and females ages 9 to 26 years to prevent genital warts.[7]

PROGNOSIS

- Many genital warts will eventually resolve without treatment. Resolution can usually be hastened with therapy (**Table 118-1**).

FOLLOW-UP

- Patients should be offered a follow-up evaluation 2 to 3 months after treatment to check for new lesions.[1] SOR Ⓒ

PATIENT EDUCATION

- HPV is transmitted mainly by skin-to-skin contact. Although condoms may decrease the levels of transmission, they are imperfect barriers at best as they can fail, and they do not cover the scrotum or vulva, where infection may reside.

119 PLANTAR WARTS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 15-year-old boy presents with painful growths on his right heel for approximately 6 months (**Figure 119-1**). It is painful to walk on and he would like it treated. He was diagnosed with multiple large plantar warts called *mosaic warts*. The lesions were treated with gentle paring with a #15 blade scalpel and liquid nitrogen therapy over a number of sessions. He and his mom were instructed on how to use salicylic acid plasters on the remaining warts.

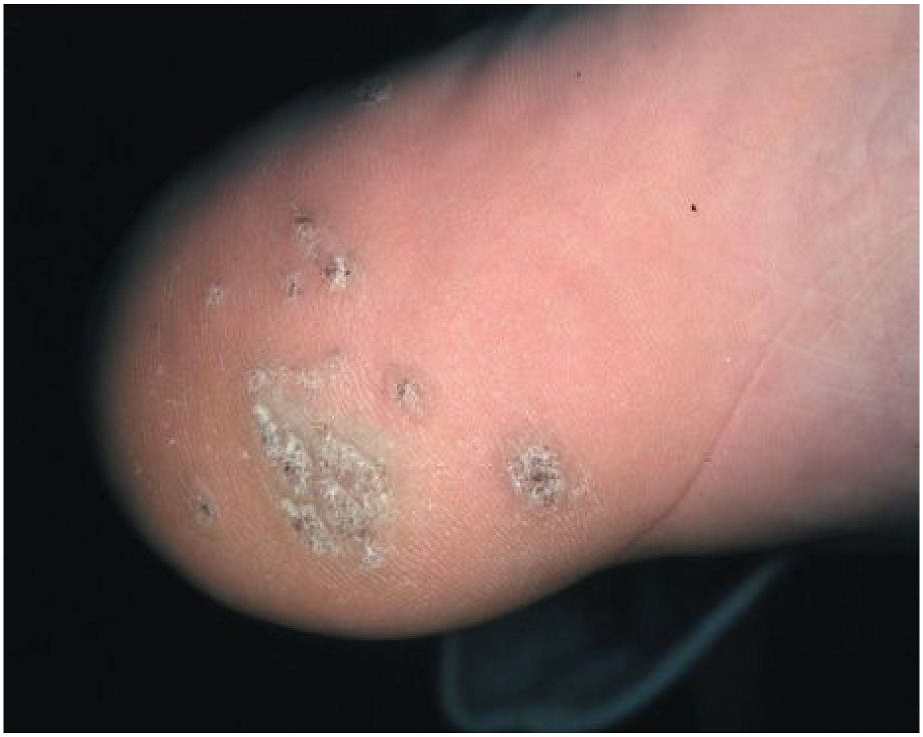

FIGURE 119-1 Plantar warts. Note small black dots in the warts that represent thrombosed vessels. Large plantar warts such as these are called

mosaic warts. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Plantar warts (verruca plantaris) are human papilloma virus (HPV) lesions that occur on the soles of the feet (**Figures 119-1** to **119-5**) and palms of the hands (**Figure 119-6**).

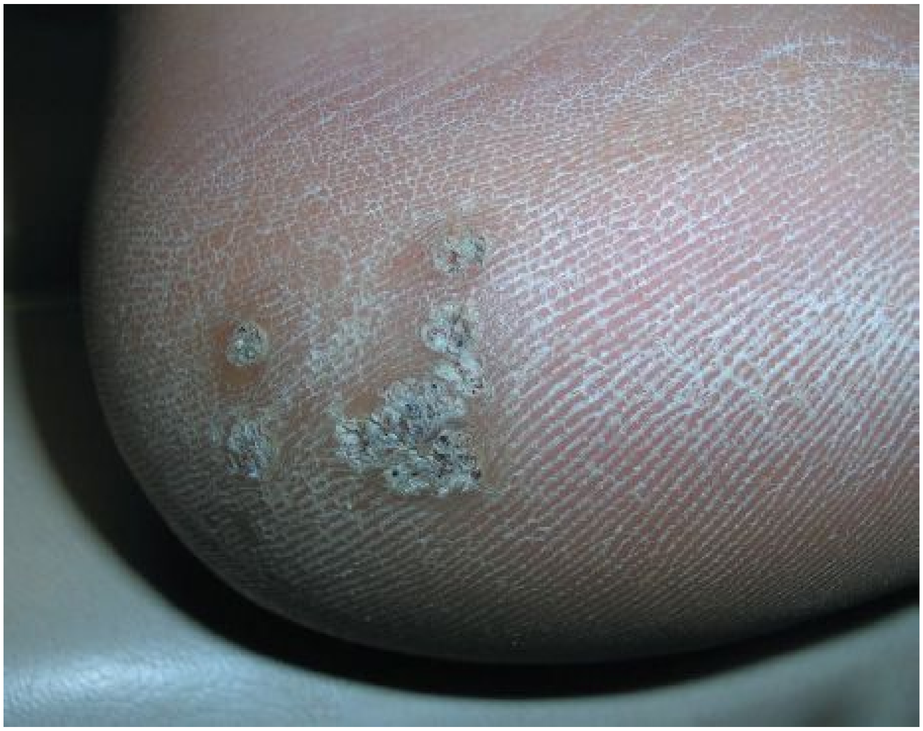

FIGURE 119-2 Close-up of plantar wart on the side of the heel. Note the disruption of skin lines and black dots. (*Used with permission from Richard P. Usatine, MD.*)

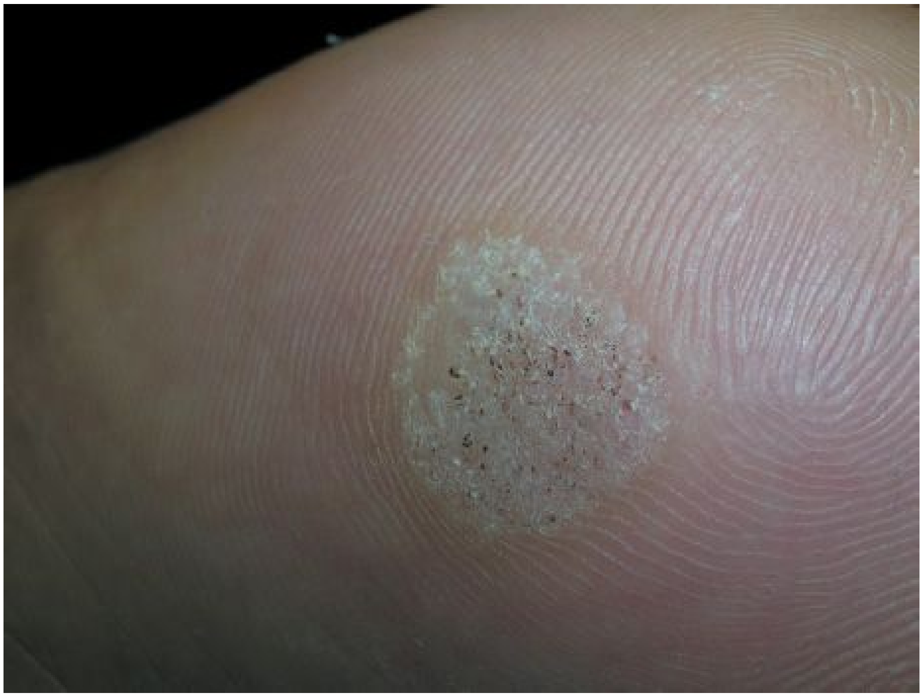

FIGURE 119-3 Close-up of a plantar wart demonstrating disruption of normal skin lines. Corns and callus do not disrupt normal skin lines. The black dots are thrombosed vessels, which are frequently seen in plantar warts. (*Used with permission from Richard P. Usatine, MD.*)

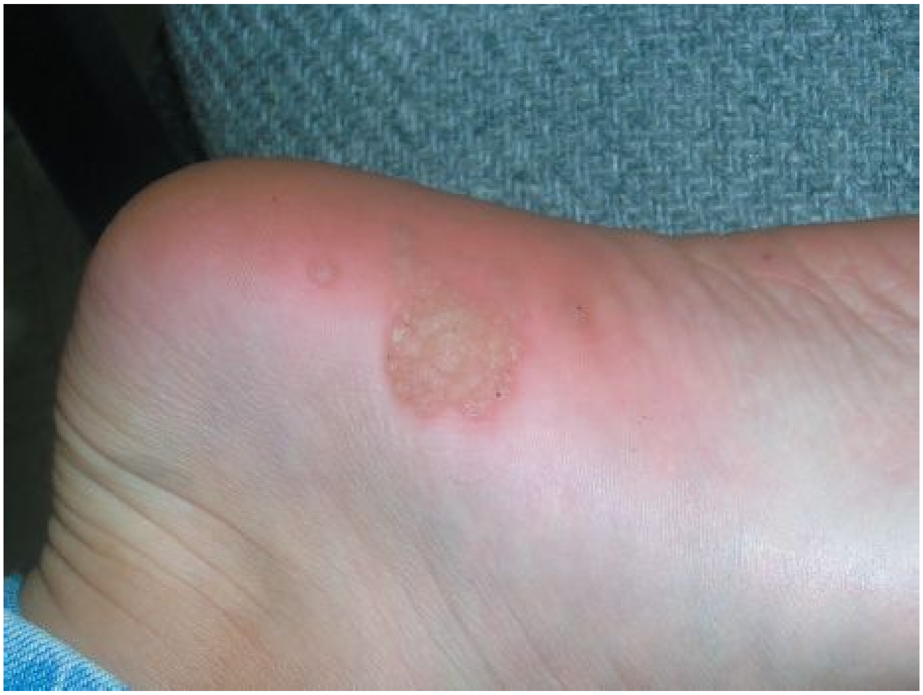

FIGURE 119-4 A mosaic wart is formed when several plantar warts become confluent. (*Used with permission from Richard P. Usatine, MD*.)

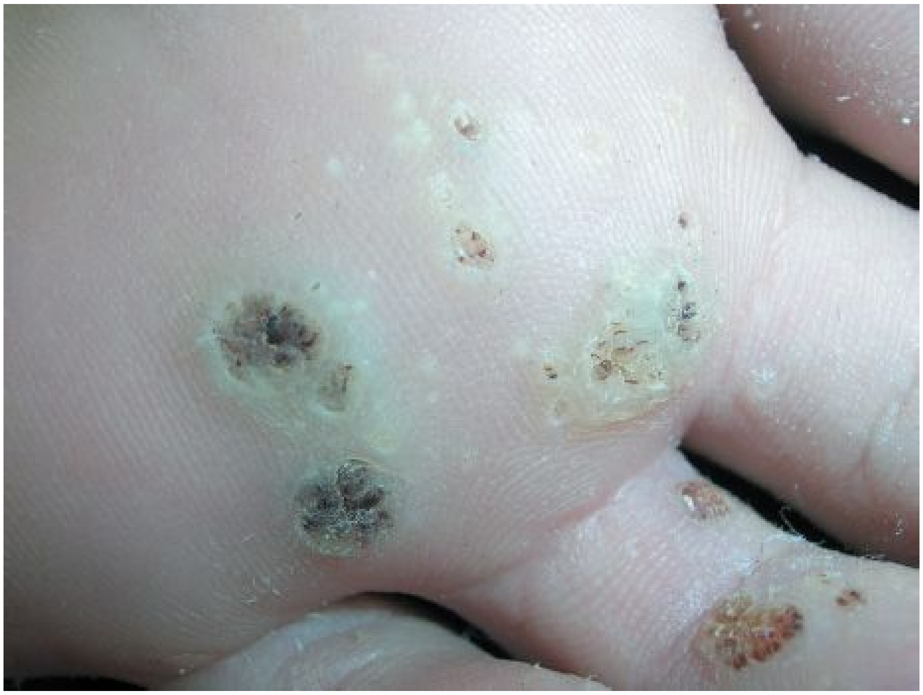

FIGURE 119-5 Multiple plantar warts on the ball of the foot and toes. The thrombosed vessels within the warts appear as black dots. (*Used with permission from Richard P. Usatine, MD*.)

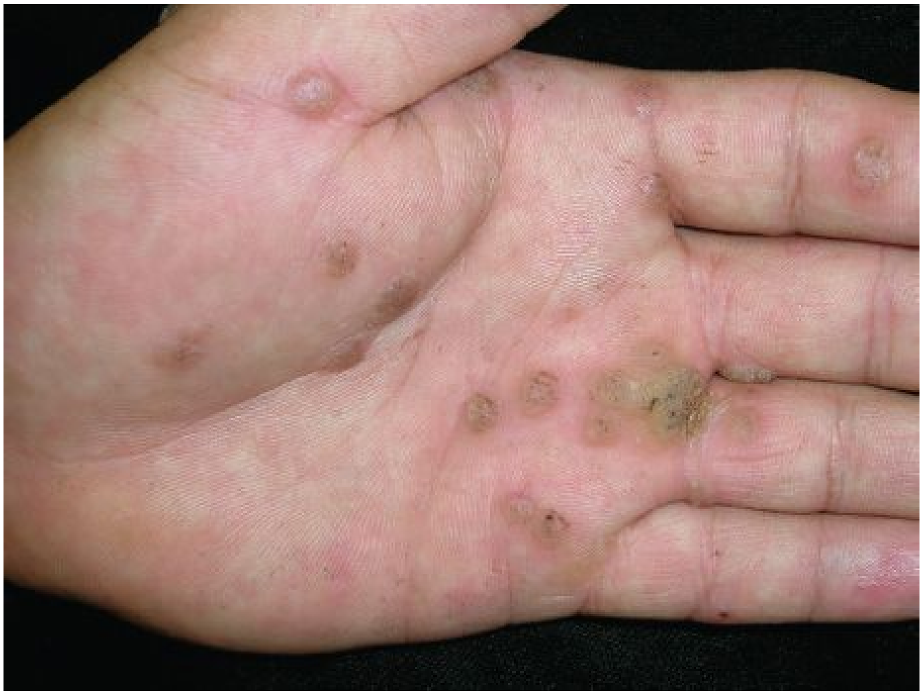

FIGURE 119-6 Multiple plantar warts on the palms of an HIV-positive young man. (*Used with permission from Richard P. Usatine, MD.*)

SYNONYMS

Palmoplantar warts, myrmecia.

EPIDEMIOLOGY

- Plantar warts affect mostly adolescents and young adults, affecting up to 10 percent of people in these age groups.[1]
- Prevalence studies demonstrate a wide range of values, from 0.84 percent in the US[2] to 3.3 to 4.7 percent in the United Kingdom,[3] to 24 percent in 16- to 18-year-olds in Australia.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Plantar warts are caused by HPV.
- They usually occur at points of maximum pressure, such as on the heels (**Figures 119-1** to **119-4**) or over the heads of the metatarsal bones (**Figure 119-5** and **119-6**), but may appear anywhere on the plantar surface including the tips of the fingers (**Figure 119-7**).

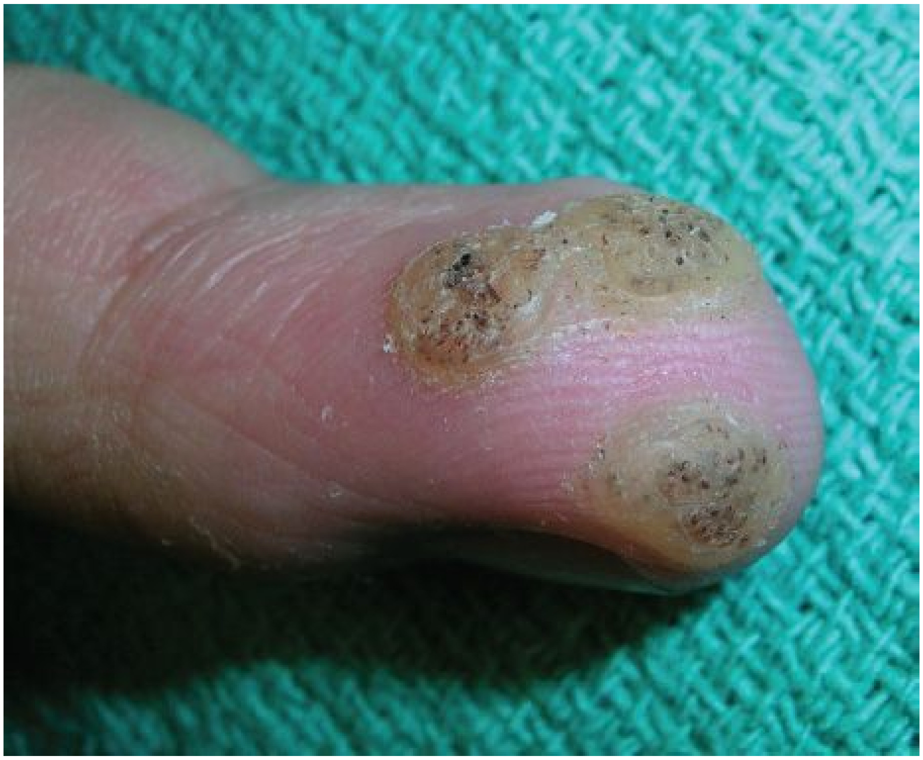

FIGURE 119-7 Close-up of plantar wart on a finger that also shows disruption of skin lines and black dots. (*Used with permission from Richard P. Usatine, MD*.)

- A thick, painful callus forms in response to the pressure that is induced as the size of the lesion increases. Even a minor wart can cause a lot of pain.
- A cluster of many warts that appear to fuse is referred to as a *mosaic wart* (**Figures 119-1** and **119-4**).

RISK FACTORS

- Young age.
- Decreased immunity.

DIAGNOSIS

CLINICAL FEATURES

Plantar warts present as thick, painful endophytic plaques located on the soles and/or palms. Warts have the following features:

- Begin as small shiny papules.
- Lack skin lines crossing their surface (**Figure 119-3**).
- Have a highly organized mosaic pattern on the surface when examined with a hand lens.
- Have a rough keratotic surface surrounded by a smooth collar of callused skin
- Painful when compressed laterally.
- May have centrally located black dots (thrombosed vessels) that may bleed with paring (**Figures 119-1** to **119-7**).

TYPICAL DISTRIBUTION

- They occur on the palms of the hands and soles of the feet. They are more commonly found on weight-bearing areas, such as under the metatarsal heads or on the heel.[5]

BIOPSY

- If the diagnosis is doubtful, a shave biopsy is indicated to confirm the diagnosis.[6]

DIFFERENTIAL DIAGNOSIS

- Corns and calluses are pressure-induced skin thickenings that occur on the feet and can be mistaken for plantar warts. Calluses are generally found on the sole and corns are usually found on the toes. Calluses and corns have skin lines crossing the surface, and are painless with lateral pressure.

- Black heel presents as a cluster of blue-black dots that result from ruptured capillaries. They appear on the plantar surface of the heel following the shearing trauma of sports that involve sudden stops or position changes. Examination reveals normal skin lines, and paring does not cause additional bleeding. The condition resolves spontaneously in a few weeks.
- Black warts are plantar warts undergoing spontaneous resolution, which may turn black and feel soft when pared with a blade.[7]
- Squamous cell carcinoma should be considered when lesions have irregular growth or pigmentation, ulceration, or resist therapy, particularly in immunosuppressed patients.
- Amelanotic melanoma, although extremely rare, can look similar to HPV lesions. Lesions that are treatment resistant or atypical, particularly on the palms or soles, should be monitored closely. A biopsy is required to establish the diagnosis (see Chapter 147, Melanoma).
- Palmoplantar keratoderma describes a rare heterogeneous group of disorders characterized by thickening of the palms and the soles that can also be an associated feature of different syndromes. They can be classified as having uniform involvement versus focal hyperkeratosis located mainly on pressure points and sites of recurrent friction (**Figure 119-8**). This latter type can be differentiated from plantar warts by the more diffuse locations on the palmoplantar surfaces, the mainly epidermal involvement, and biopsy, if necessary (**Figure 119-9**).

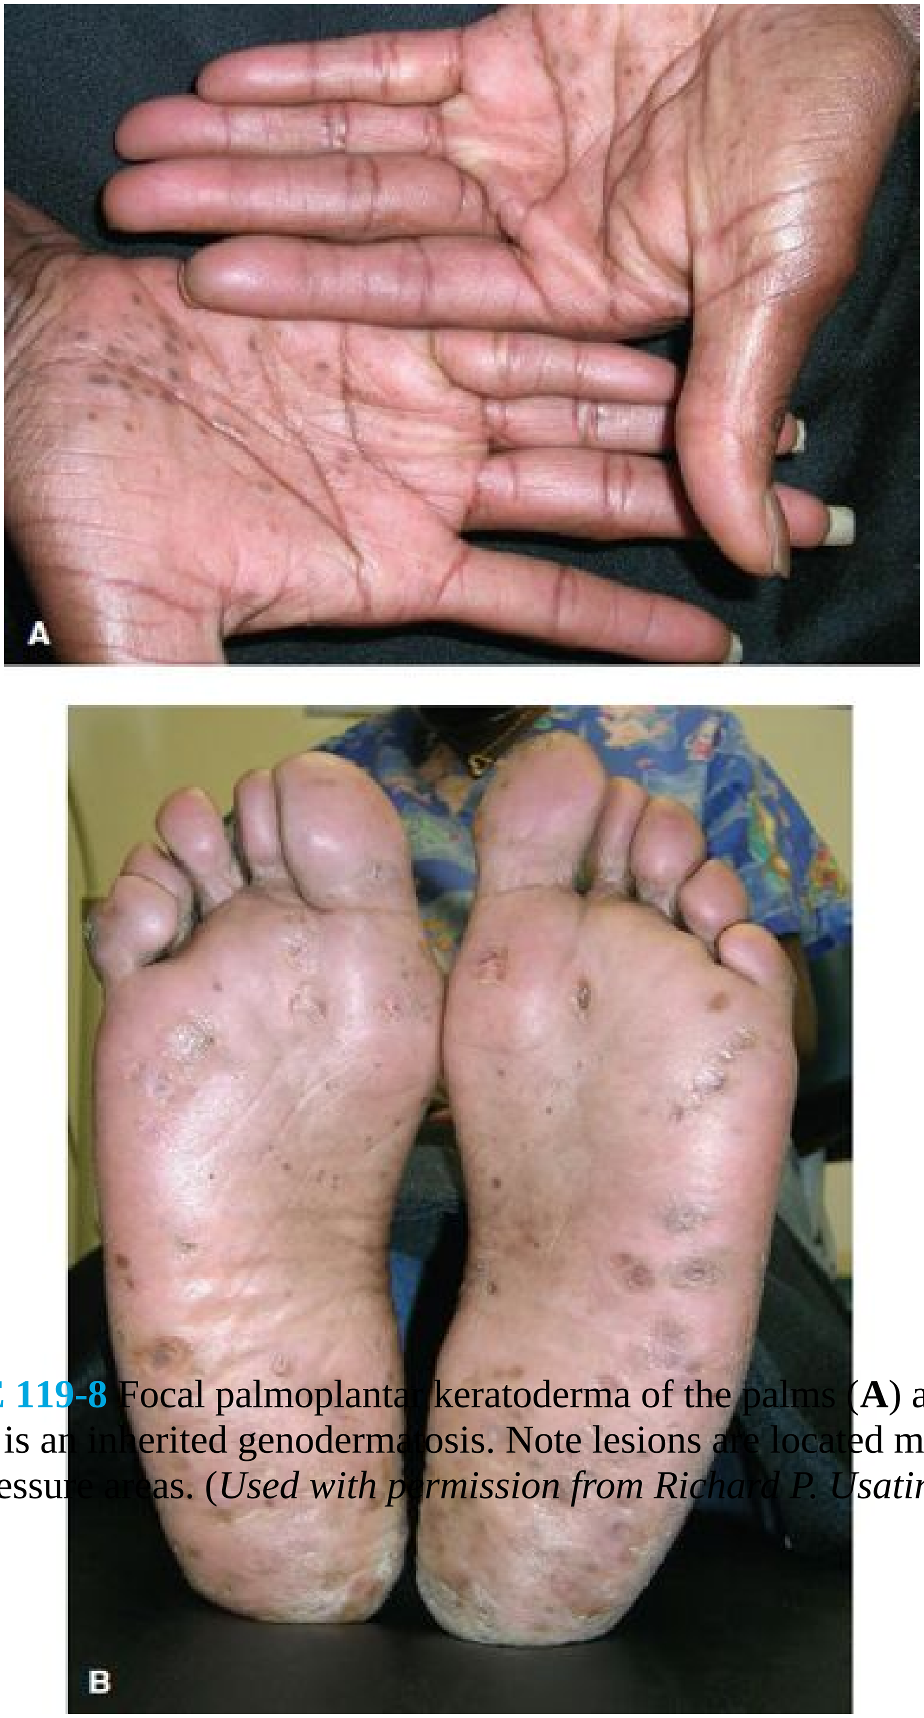

FIGURE 119-8 Focal palmoplantar keratoderma of the palms (**A**) and soles (**B**). This is an inherited genodermatosis. Note lesions are located mainly on higher pressure areas. (*Used with permission from Richard P. Usatine, MD.*)

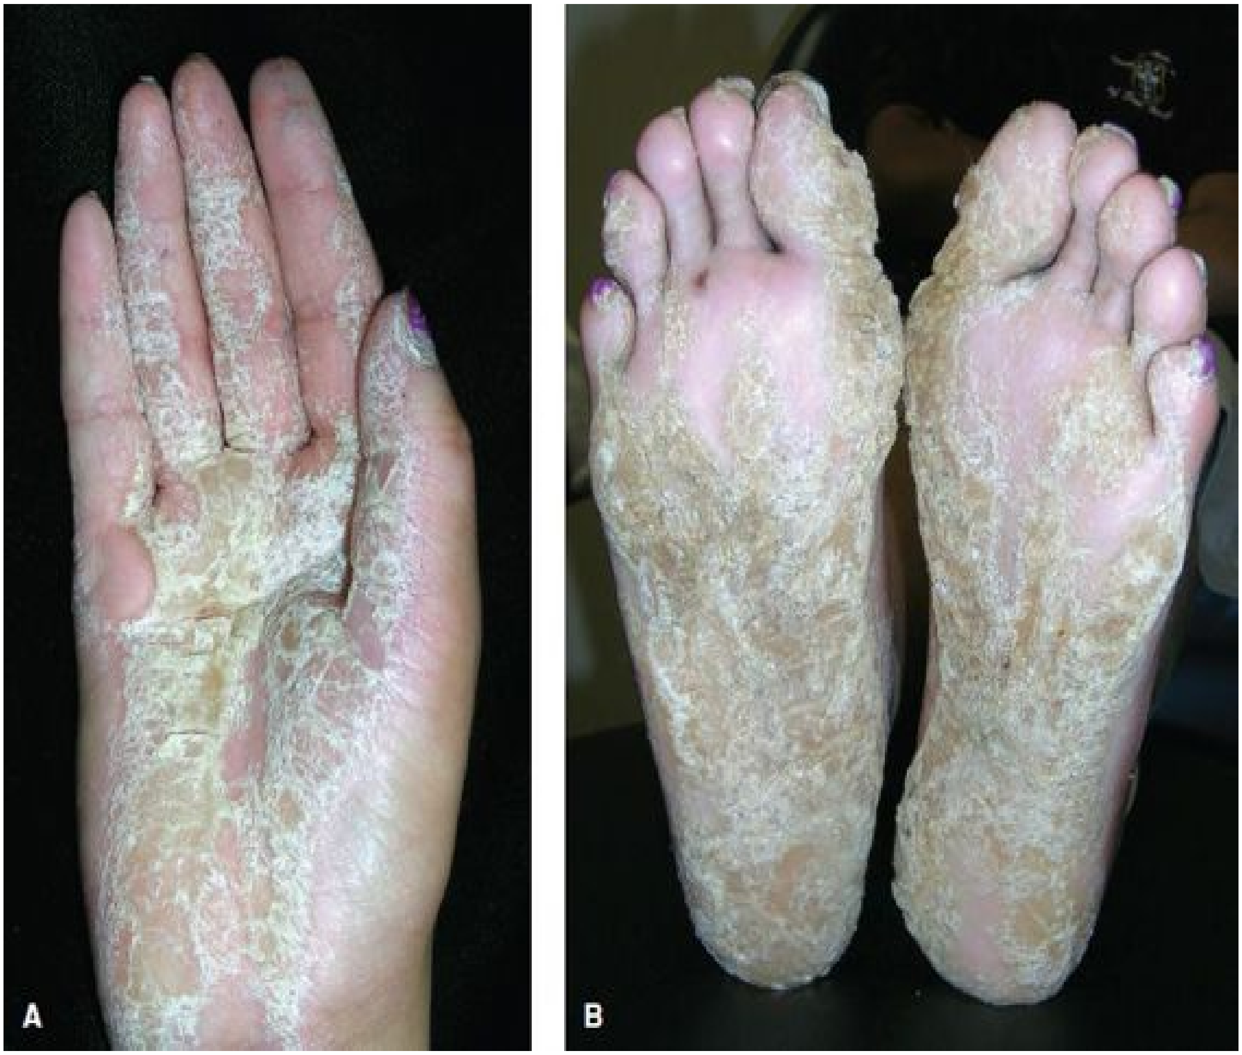

FIGURE 119-9 Diffuse palmoplantar keratoderma of the palms (**A**) and soles (**B**) in an 11-year-old girl. This is an inherited genodermatosis with severe functional consequences. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

NONPHARMACOLOGIC

- Painless plantar warts do not require therapy. Minimal discomfort can be relieved by periodically removing the hyperkeratosis with a blade or pumice stone.

- Painful warts should be treated using a technique that causes minimal scarring as scars on the soles of the feet are usually permanent and painful.
- Patients with diabetes must be treated with the utmost care to minimize complications.

MEDICATIONS

- Topical salicylic acid solutions are available in nonprescription form and provide conservative keratolytic therapy. These preparations are nonscarring, minimally painful, and relatively effective, but require persistent application of medication once each day for weeks to months. The wart is first pared with a blade, pumice stone, or emery board, and the area soaked in warm water. The solution is then applied, allowed to dry, reapplied, and occluded with adhesive tape.[8] White, pliable, keratin forms and should be pared away carefully until pink skin is exposed.[9] SOR B
- Seventeen to fifty percent salicylic acid solution and plasters are available in nonprescription and prescription forms. However, the 17 percent solutions are more prevalent and easier to find in nonprescription form. The treatment is similar to the previous process, except that with plasters the salicylic acid has been incorporated into a pad. They are particularly useful in treating mosaic warts covering a large area. Pain is quickly relieved in plantar warts, because a large amount of keratin is removed during the first few days of treatment.[9] SOR B A recent multicenter, open-label, randomized, controlled trial found that 50 percent salicylic acid and the cryotherapy were equally effective for clearance of plantar warts.[10] SOR A
- Acid chemotherapy with trichloroacetic acid (TCA) or bichloracetic acid (BCA) is commonly employed to treat plantar warts in the office. They are considered safe during pregnancy for external lesions. The excess keratin is first pared with a scalpel, then the entire lesion is coated with acid, and the acid is worked into the wart with a sharp toothpick. The process is repeated every 7 to 10 days. SOR C

- Cryotherapy with liquid nitrogen therapy is commonly used, but plantar warts are more resistant than other HPV lesions. The liquid nitrogen is applied to form a freeze ball that covers the lesion and 2 mm of surrounding normal tissue, usually 10 to 20 seconds per freeze. SOR Ⓒ There is no evidence that two freezing episodes are better than one, other than it allows for more freeze time in a way that is more acceptable to the patient. It is always better to underfreeze than to overfreeze in areas where scarring can produce permanent disability.
- Treatments for resistant lesions are often carried out in referral practices that have a high enough volume to use more expensive or specialized therapy. Cantharidin is an extract of the blister beetle that is applied to the wart after which blistering occurs. Intralesional immunotherapy with skin-test antigens (i.e., mumps, *Candida*, or *Trichophyton* antigens) may lead to the resolution both of the injected wart and other warts that were not injected. Contact immunotherapy using dinitrochlorobenzene, squaric acid dibutylester, and diphenylcyclopropenone may be applied to the skin to sensitize the patient and then to the lesion to induce an immune response. Intralesional bleomycin or laser therapy are also useful for recalcitrant warts. SOR Ⓒ

COMPLEMENTARY/ALTERNATIVE THERAPY

- Although many complementary and alternative therapies are promoted for wart therapy, there are no significant data supporting their use in the treatment of plantar warts.

PREVENTION

- Tools used for paring down warts, such as nail files and pumice stones, should not be used on normal skin or by other people.

PROGNOSIS

Most plantar warts will spontaneously disappear without treatment. Treatment often hastens resolution of lesions.

FOLLOW-UP

- Regular follow-up to assess treatment efficacy, adverse reactions, and patient tolerance are recommended to minimize treatment dropouts.

PATIENT EDUCATION

- Because spontaneous regression occurs, observation of painless lesions without treatment is preferable.
- Therapy often takes weeks to months, so patience and perseverance are essential for successful therapy.

SECTION 5 FUNGAL

120 FUNGAL OVERVIEW

Richard P. Usatine, MD

PATIENT STORY

An otherwise healthy 7-year-old boy is seen in a homeless shelter with a 2-month history of patchy hair loss (**Figure 120-1**). Various anti-dandruff shampoos had not helped. On physical exam, there are moderate areas of patchy alopecia with significant scaling of the scalp. Posterior cervical adenopathy could be seen and palpated on the left side. There was no fluorescence with a Wood's lamp indicating that this fungal infection was most likely *Trichophyton tonsurans*. The pediatrician easily identified this as tinea capitis but decided to confirm the diagnosis with a KOH preparation. Some of the scale was scraped from the scalp using two microscope slides (one to scrape and another to catch the scale). KOH was added and a coverslip placed. Branching hyphae were seen under the microscope. The child was treated with oral griseofulvin at 20 mg per kilogram per day. At the 4-week follow-up there was significant improvement, no reported side effects of the griseofulvin, and the treatment was continued for an additional 4 weeks.

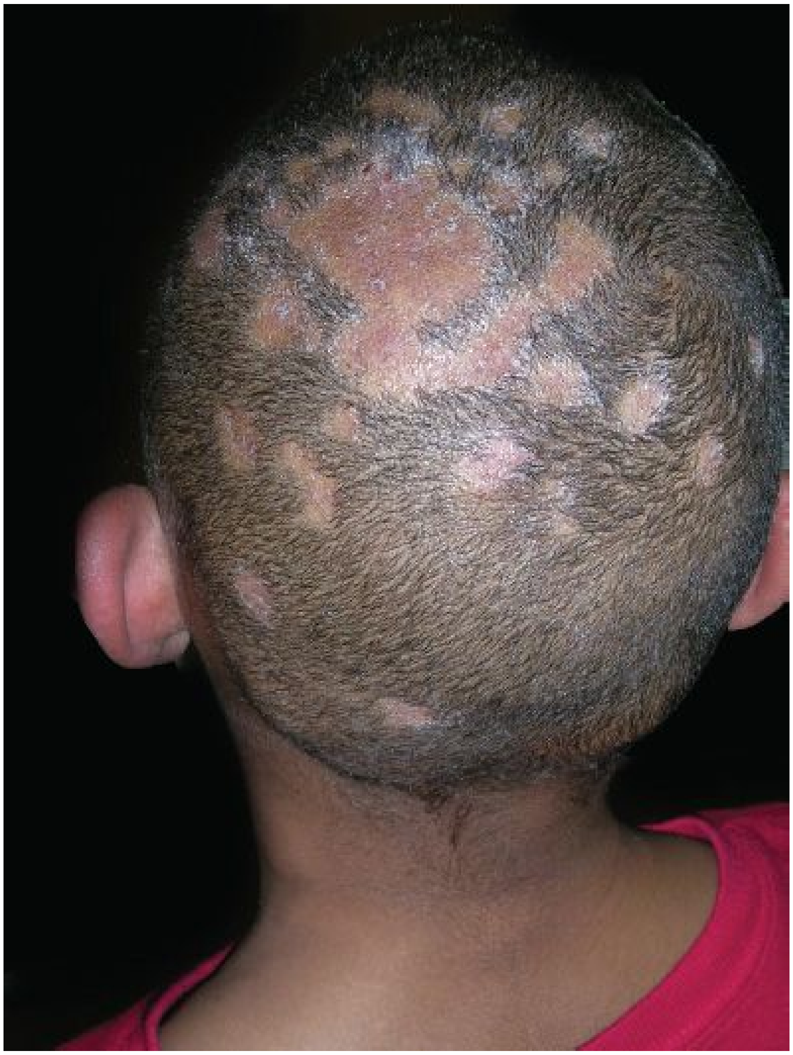

FIGURE 120-1 Tinea capitis in a young African American boy showing patchy alopecia and posterior cervical adenopathy. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Fungal infections of the skin and mucous membranes are ubiquitous and common. There are many types of fungus that grow on humans but they all share a predilection for warm and moist areas. Consequently, hot and humid climates promote fungal infections, but many areas of the skin can get warm and sweaty even in cold climates, such as the feet and groin.

SYNONYMS

Pityriasis versicolor equals tinea versicolor.

PATHOPHYSIOLOGY

Mucocutaneous fungal infections are caused by:

- Dermatophytes in three genera: *Microsporum*, *Epidermophyton*, and *Trichophyton*. There are approximately 40 species in the three genera and these fungi cause tinea pedis and manus, tinea capitis, tinea corporis, tinea cruris, tinea faciei, and onychomycosis (**Figures 120-1** to **120-6**).

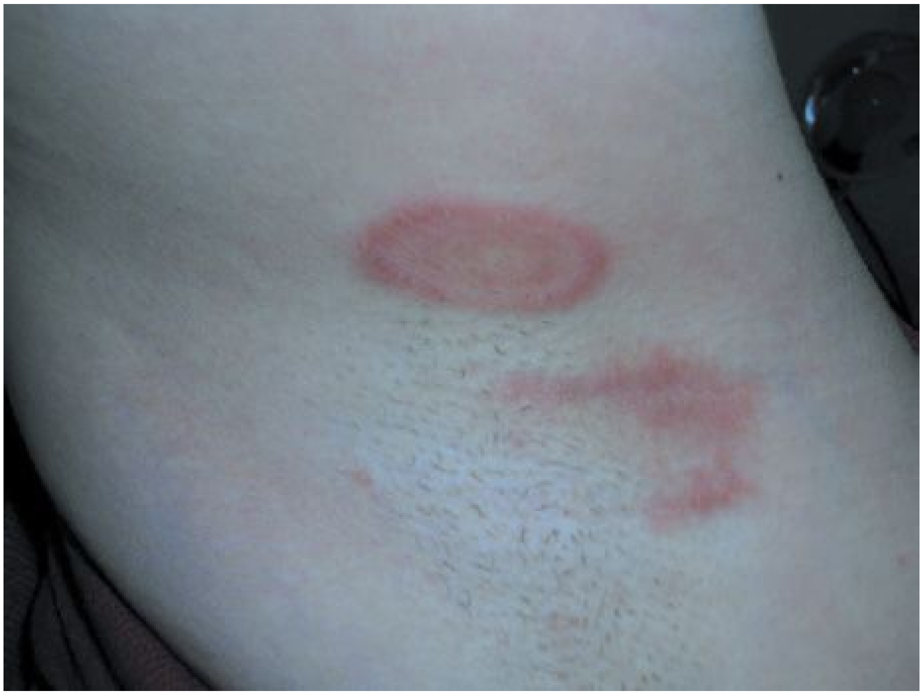

FIGURE 120-2 Annular pruritic lesion with concentric rings in the axilla of a young woman caused by tinea corporis. The concentric rings have a high specificity for tinea infections. (*Used with permission from Richard P. Usatine, MD.*)

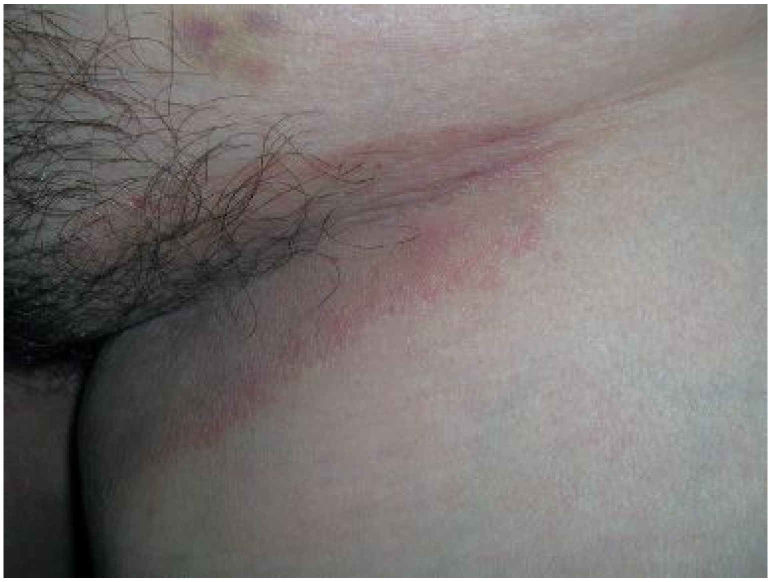

FIGURE 120-3 Tinea cruris with well-demarcated raised border and no central clearing. (*Used with permission from Richard P. Usatine, MD*.)

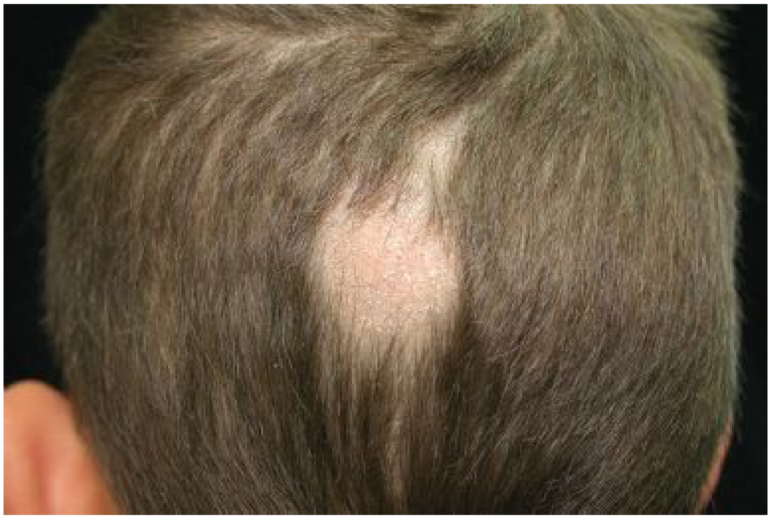

FIGURE 120-4 Tinea capitis in a 6-year-old boy with one major area of alopecia along with scale. (*Photo Credit: Dr. Patrick E. McCleskey, MD*.)

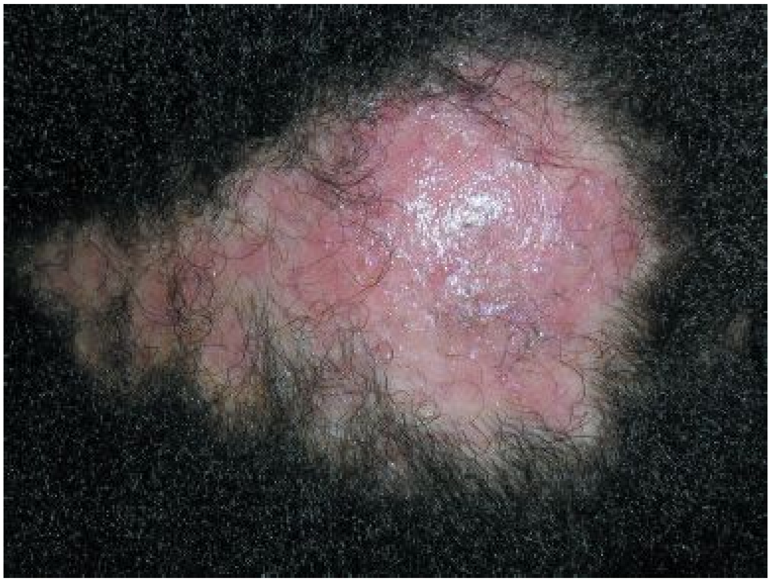

FIGURE 120-5 Tinea capitis in a 5-year-old black girl with hair loss and an inflammatory response. Her kerion is healing after initiating oral griseofulvin. (*Used with permission from Richard P. Usatine, MD*.)

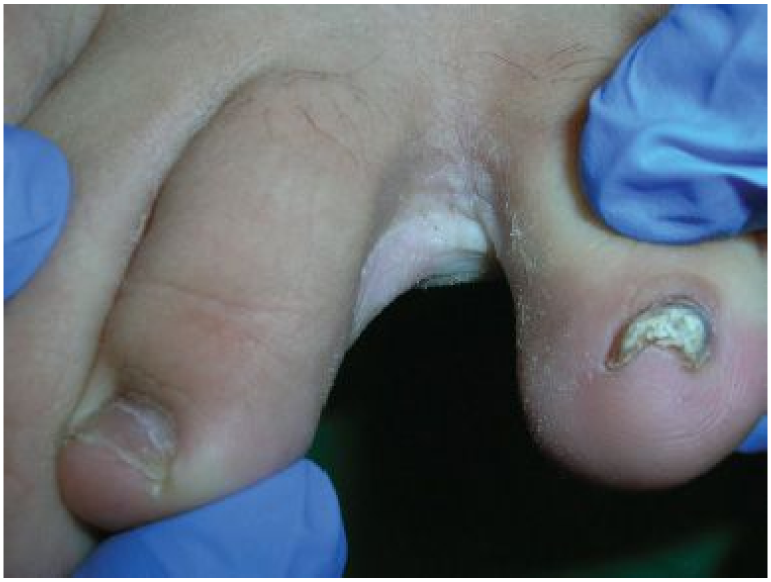

FIGURE 120-6 Tinea pedis with onychomycosis in a 14-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

- Yeasts in the genera of *Candida* and *Pityrosporum* (*Malassezia*)—There are also multiple types of species and the *Pityrosporum* that cause seborrhea and tinea versicolor (**Figures 120-7** and **120-8**). Although tinea versicolor has the name tinea in it, it is not a true dermatophyte and may be best called pityriasis versicolor.

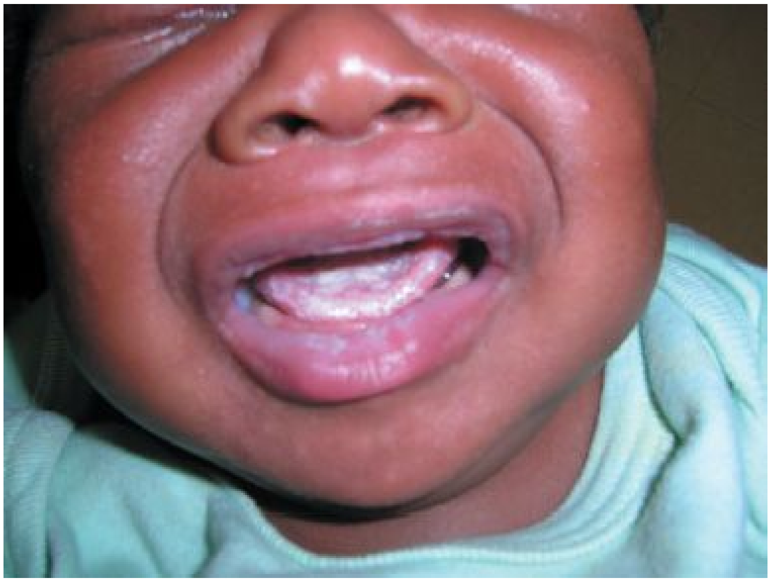

FIGURE 120-7 Thrush in the mouth of an infant caused by Candida. (*Used with permission from Richard P. Usatine, MD*.)

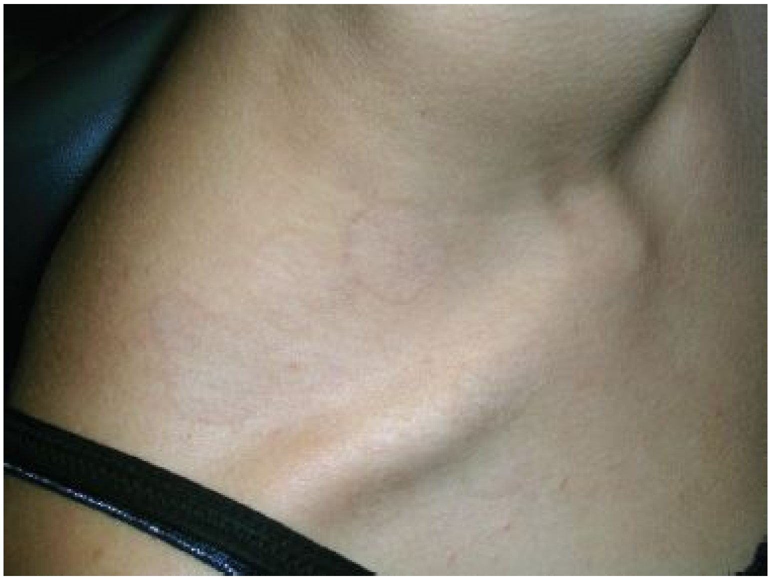

FIGURE 120-8 Tinea versicolor in a 13-year-old girl with an annular pattern on the shoulders. There is some central hypopigmentation and scale. The girl has seborrhea of the scalp also caused by Pityrosporum (Malassezia). The tinea versicolor was proven with a positive KOH. (*Used with permission from Richard P. Usatine, MD*.)

- There are a number of deep fungal skin infections that can occur in humans. They are all rare and will not be covered in this chapter which focuses on dermatophyte and yeast organisms. One deep fungal infection that is less rare is Sporotrichosis and can occur from minor trauma with a rosebush thorn (**Figure 120-9**).

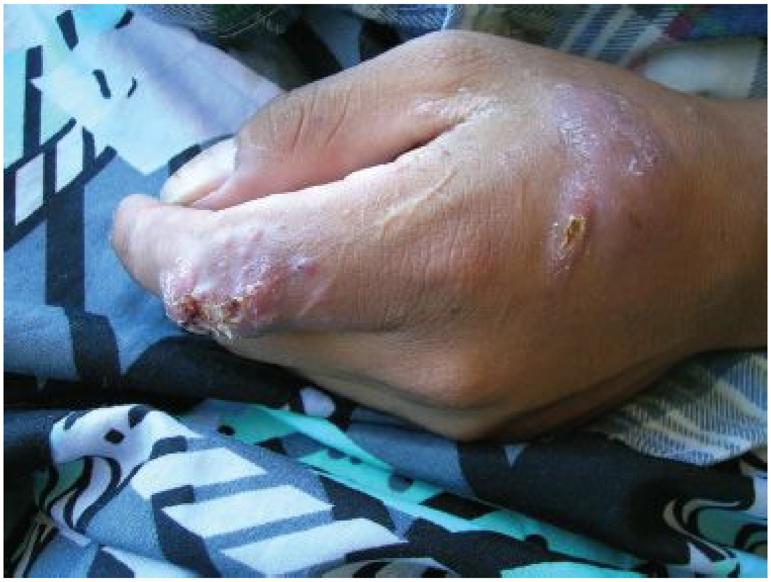

FIGURE 120-9 Sporotrichosis in a teenage boy. This deep fungal infection started with an inoculation to his index finger and spread up his arm. (*Used with permission from Richard P. Usatine, MD*.)

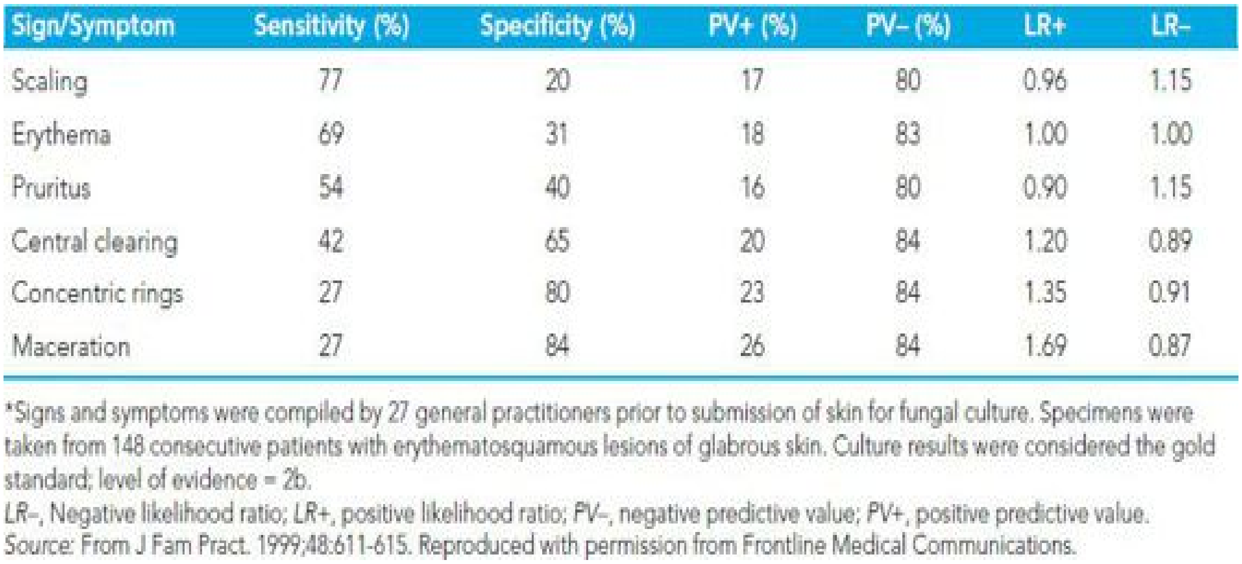
DIAGNOSIS

CLINICAL FEATURES

Clinical features of tinea infections include scaling, erythema, pruritus, central clearing, concentric rings, and maceration (**Table 120-1**). Changes in pigmentation are not uncommon in various types of tinea especially tinea versicolor.

TABLE 120-1 Diagnostic Value of Selected Signs and Symptoms in Tinea Infection*



Sign/Symptom	Sensitivity (%)	Specificity (%)	PV+ (%)	PV– (%)	LR+	LR–
Scaling	77	20	17	80	0.96	1.15
Erythema	69	31	18	83	1.00	1.00
Pruritus	54	40	16	80	0.90	1.15
Central clearing	42	65	20	84	1.20	0.89
Concentric rings	27	80	23	84	1.35	0.91
Maceration	27	84	26	84	1.69	0.87

*Signs and symptoms were compiled by 27 general practitioners prior to submission of skin for fungal culture. Specimens were taken from 148 consecutive patients with erythematosquamous lesions of glabrous skin. Culture results were considered the gold standard; level of evidence = 2b.

LR–, Negative likelihood ratio; *LR+*, positive likelihood ratio; *PV*–, negative predictive value; *PV+*, positive predictive value.

Source: From J Fam Pract. 1999;48:611-615. Reproduced with permission from Frontline Medical Communications.

- Note that tinea infections will not show central clearing in some cases, as in **Figure 120-3** in which tinea cruris has no central clearing. **Figure 120-11** shows tinea cruris with central clearing.

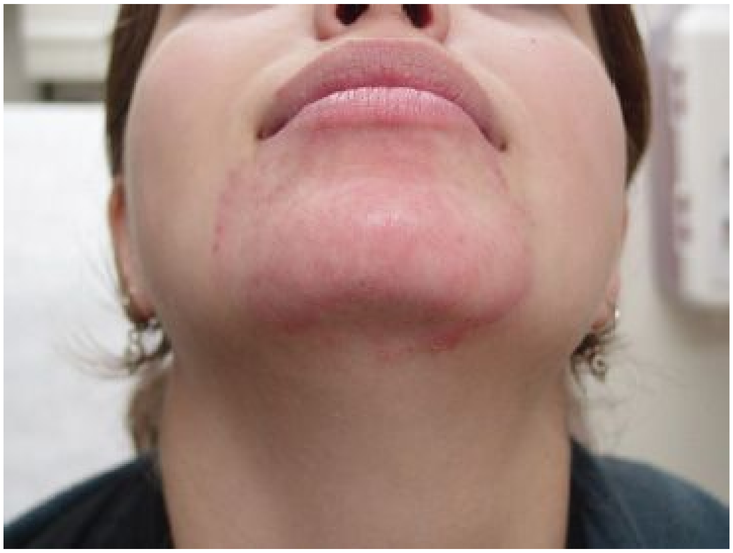


FIGURE 120-10 Tinea faciei on the face of a teenage female with typical scaling and a ring-like pattern (ringworm). Note the welldemarcated raised border and central clearing. (*Photo Credit: Dr. Patrick E. McCleskey, MD.*)

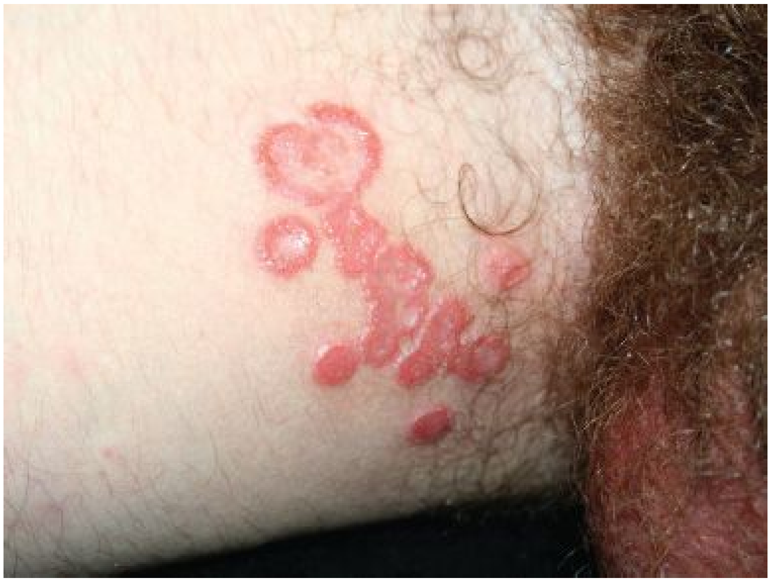

FIGURE 120-11 Inflammatory tinea cruris in a teenage boy on isotretinoin for his acne. The annular eruption is deep red. (*Photo Credit: Dr. Patrick E. McCleskey, MD*.)

- Hyperpigmentation secondary to the fungal infection is common in dark-skinned individuals, as seen in **Figure 120-12** on the flank of this young woman. Note the hyperpigmentation is seen in the tinea corporis.

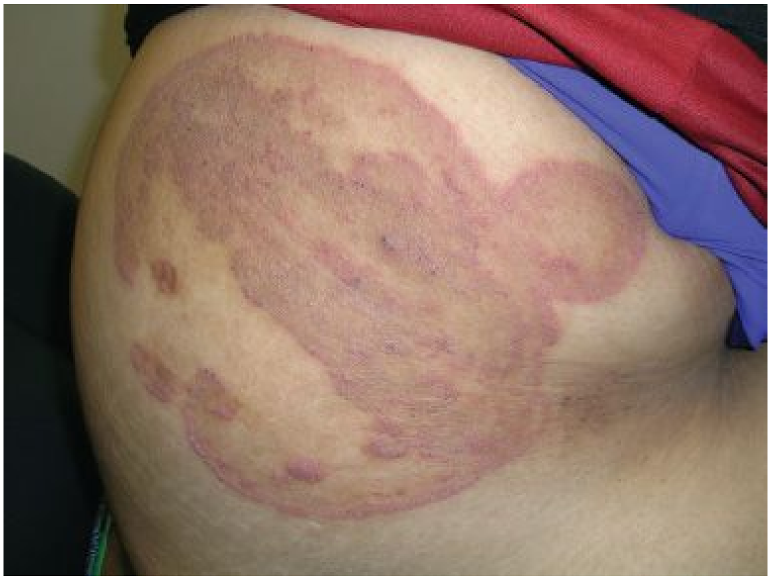

FIGURE 120-12 Tinea corporis on the right flank a young woman bending forward. Note the well-demarcated borders with multiple annular patterns

and some postinflammatory hyperpigmentation. (*Used with permission from Richard P. Usatine, MD.*)

- Hypopigmentation is frequently seen in tinea versicolor (**Figure 120-8**).

TYPICAL DISTRIBUTION

Literally found from head to toes:

- **Figure 120-5** shows tinea capitis in a 5-year-old black girl with hair loss and an inflammatory response. Her kerion is healing after initiating oral griseofulvin.
- **Figure 120-6** shows tinea pedis in a 14-year-old boy with onychomycosis.

LABORATORY STUDIES

Creating a KOH Prep:

- Scrape the leading edge of the lesion on to a slide using the side of another microscope slide or a #15 scalpel (**Figure 120-13**). For safety reasons with small moving children, it is best to use the 2 slide method and avoid the scalpel.

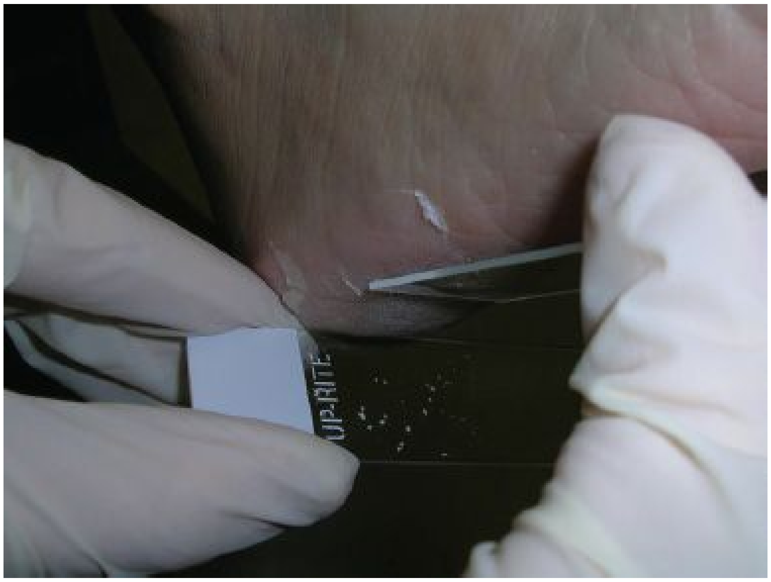

FIGURE 120-13 Making a KOH preparation by scraping in area of scale with two slides. This was a case of tinea pedis. (*Used with permission from Richard P. Usatine, MD.*)

- Use your coverslip to push the scale into the center of the slide.
- Add two drops of KOH (fungal stain with KOH is preferable) to the slide and place coverslip on top.
- Gently heat with flame from an alcohol lamp or lighter if the pieces of collected skin are large, the sample was from a nail, or if you are using plain KOH without dimethyl sulfoxide (DMSO). Avoid boiling.
- DMSO acts as a surfactant that helps to break up the cell membranes of the epithelial cells without heating. Fungal stains that come with KOH and a surfactant in the solution are very simple to use. These inexpensive stains come conveniently in small plastic squeeze bottles that have a shelf life of 1 to 3 years. Two useful stains that can that make it easier to identify fungus are chlorazol black and Swartz-Lamkins stains. Swartz-Lamkins stain has a longer shelf life.
- Examine with microscope starting with 10 power to look for the cells and hyphae and then switch to 40 power when ready to confirm the findings (**Figures 120-13** to **120-17**). The fungal stain helps the hyphae to stand out among the epithelial cells.

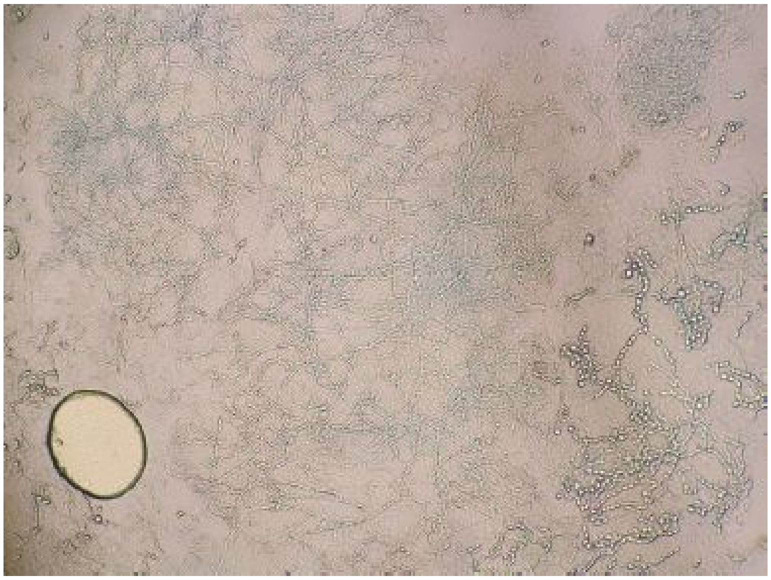

FIGURE 120-14 Trichophyton rubrum from tinea cruris visible among skin cells using light microscopy at 10 power and Swartz-Lamkins fungal stain. Start your search on 10 power and move to 40 power to confirm your findings. (*Used with permission from Richard P. Usatine, MD*.)

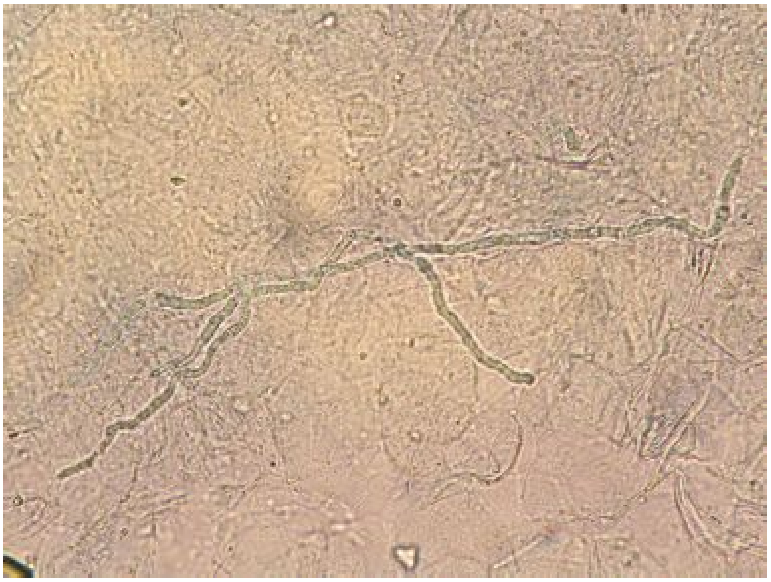

FIGURE 120-15 Trichophyton rubrum from tinea cruris using Swartz-Lamkins fungal stain at 40 power. Straight hyphae with visible septae. (*Used with permission from Richard P. Usatine, MD*.)

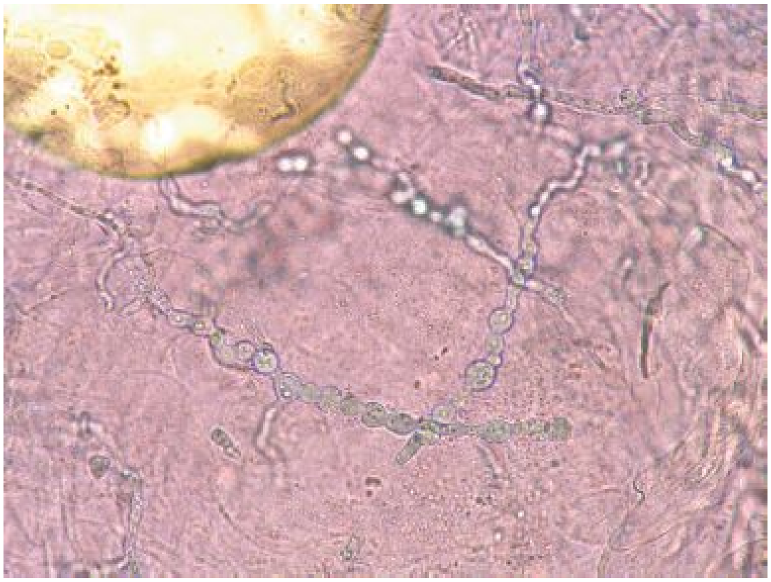

FIGURE 120-16 Arthroconidia visible from tinea cruris using Swartz-Lamkins fungal stain at 40 power. (*Used with permission from Richard P.*

Usatine, MD.)

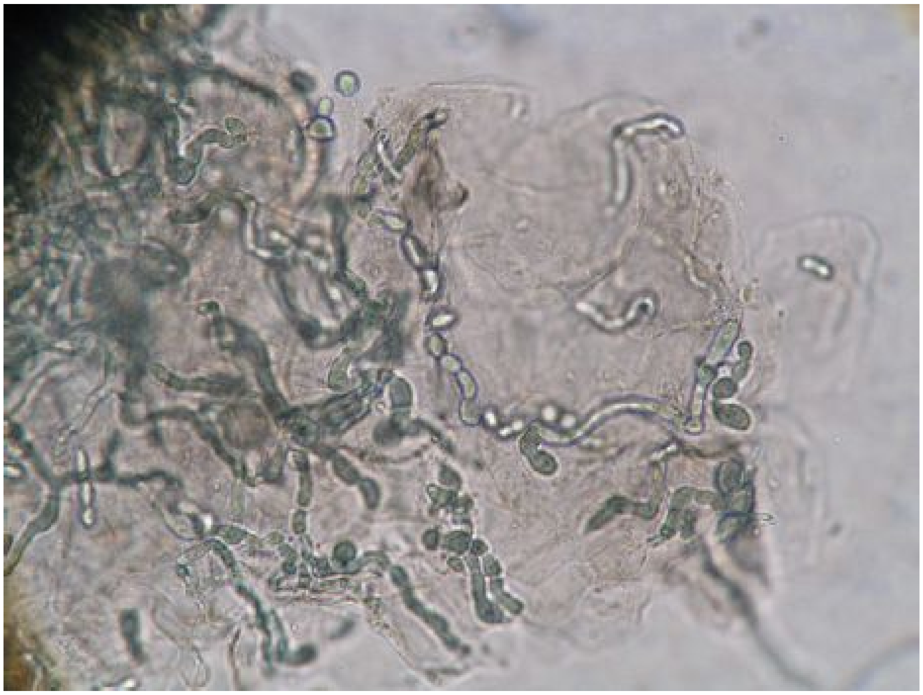

FIGURE 120-17 Trichophyton rubrum from tinea cruris using chlorazol black fungal stain at 40 power. (*Used with permission from Richard P. Usatine, MD.*)

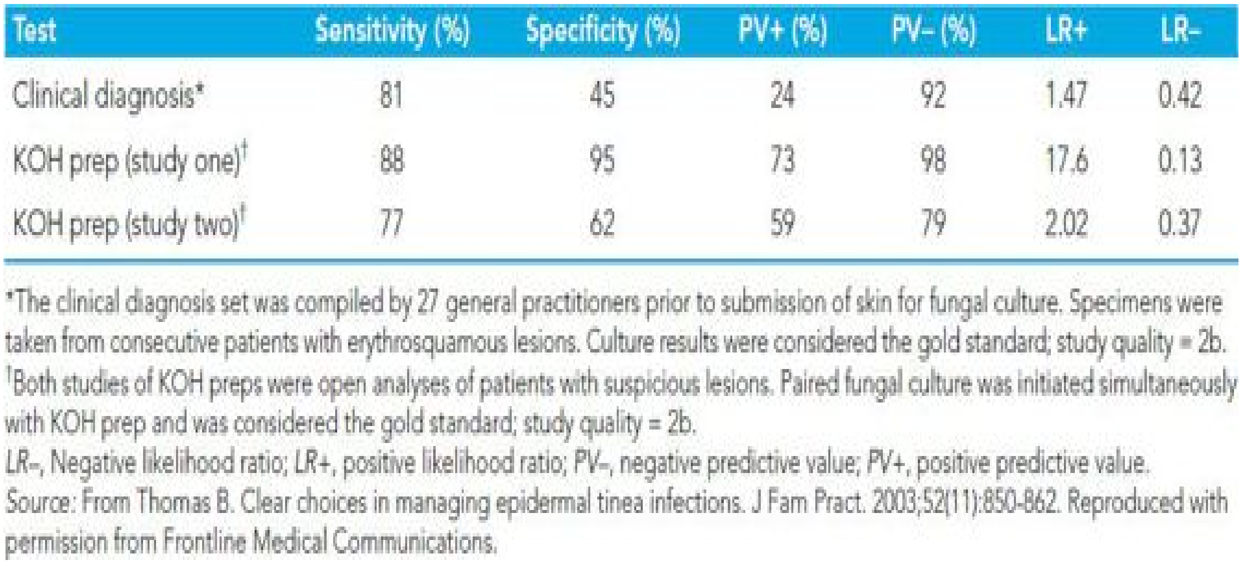
- It helps to start with 10 power to find the clumps of cells and look for groups of cells that appear to have fungal elements within them (**Figure 120-14**).
- Do not be fooled by cell borders that look linear and branching. True fungal morphology at 40 power should confirm the presence of real fungus and rule out artifact. The fungal stains bring out these characteristics including cell walls, nuclei, and Arthroconidia (**Figures 120-15** to **120-17**).
- KOH test characteristics[1] (without fungal stains)—Sensitivity 77 to 88 percent, specificity 62 to 95 percent (**Table 120-2**). The sensitivity and specificity should be higher with fungal stains and increased experience of the person performing the test.

TABLE 120-2 Diagnostic Value of Clinical Diagnosis and KOH Prep in Tinea Infection



Test	Sensitivity (%)	Specificity (%)	PV+ (%)	PV− (%)	LR+	LR−
Clinical diagnosis*	81	45	24	92	1.47	0.42
KOH prep (study one)†	88	95	73	98	17.6	0.13
KOH prep (study two)†	77	62	59	79	2.02	0.37

*The clinical diagnosis set was compiled by 27 general practitioners prior to submission of skin for fungal culture. Specimens were taken from consecutive patients with erythrosquamous lesions. Culture results were considered the gold standard; study quality = 2b.

†Both studies of KOH preps were open analyses of patients with suspicious lesions. Paired fungal culture was initiated simultaneously with KOH prep and was considered the gold standard; study quality = 2b.

LR−, Negative likelihood ratio; *LR*+, positive likelihood ratio; *PV*−, negative predictive value; *PV*+, positive predictive value.

Source: From Thomas B. Clear choices in managing epidermal tinea infections. J Fam Pract. 2003;52(11):850-862. Reproduced with permission from Frontline Medical Communications.

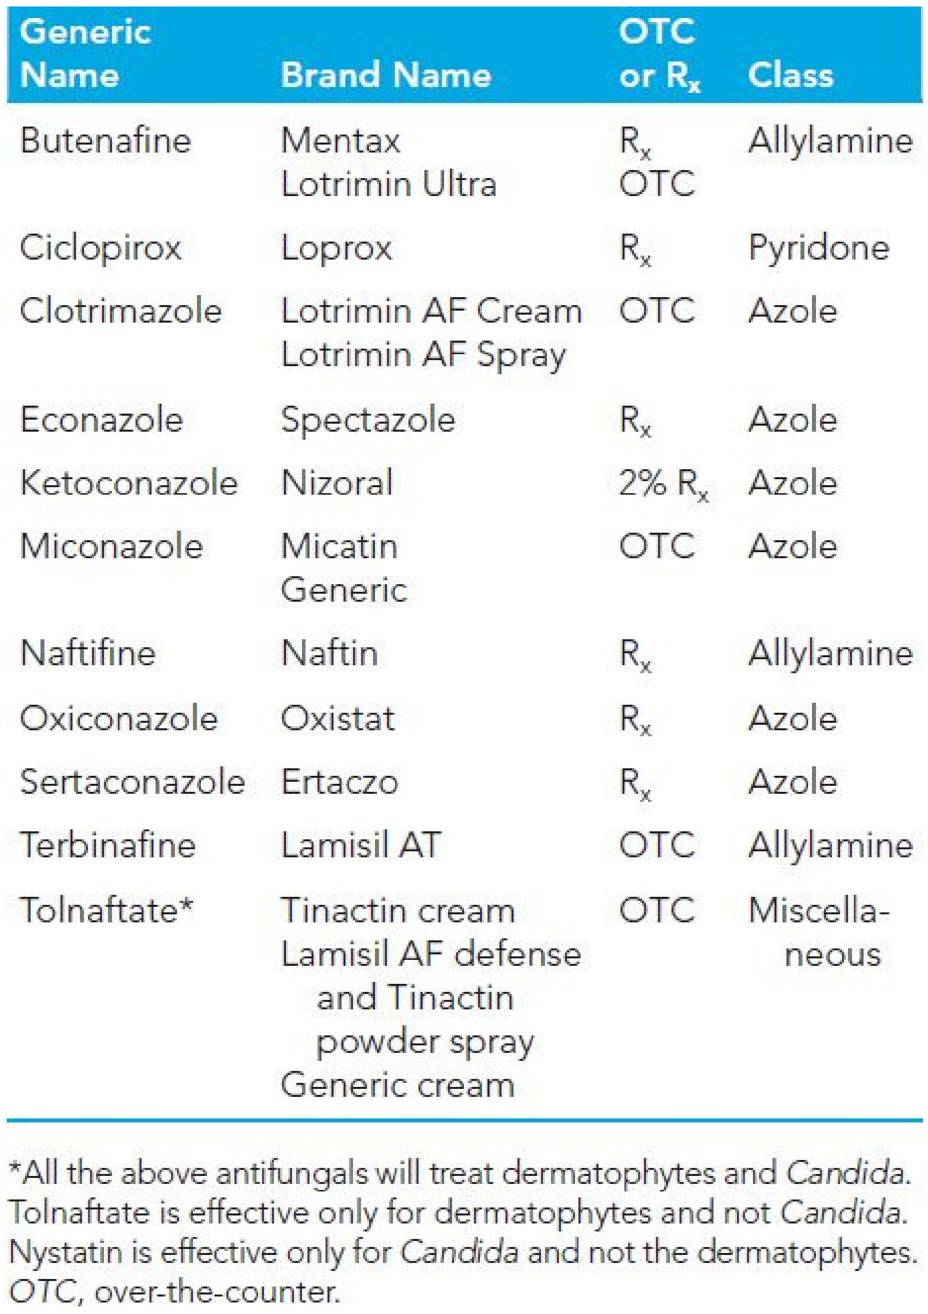
OTHER LABORATORY STUDIES

- Fungal culture—Send skin scrapings, hair, or nail clippings to the laboratory in a sterile container such as a urine cup. These will be plated out on fungal agar and the laboratory can report the species if positive.
- Biopsy specimens and nail clippings can be sent in formalin for periodic acid-Schiff (PAS) staining when KOH and fungal cultures seem to be falsely negative.
- UV light (Woods lamp), looking for fluorescence. The *Microsporum* species are most likely to fluoresce. However, the majority of tinea infections are caused by *Trichophyton* species that do not fluoresce.

MANAGEMENT

There is a wide variety of topical antifungal medications (**Table 120-3**). A Cochrane systematic review of 70 trials of topical antifungals for tinea pedis showed good evidence for efficacy compared to placebo[2] for:

TABLE 120-3 Topical Antifungal Preparations



Generic Name	Brand Name	OTC or R_x	Class
Butenafine	Mentax Lotrimin Ultra	R_x OTC	Allylamine
Ciclopirox	Loprox	R_x	Pyridone
Clotrimazole	Lotrimin AF Cream Lotrimin AF Spray	OTC	Azole
Econazole	Spectazole	R_x	Azole
Ketoconazole	Nizoral	2% R_x	Azole
Miconazole	Micatin Generic	OTC	Azole
Naftifine	Naftin	R_x	Allylamine
Oxiconazole	Oxistat	R_x	Azole
Sertaconazole	Ertaczo	R_x	Azole
Terbinafine	Lamisil AT	OTC	Allylamine
Tolnaftate*	Tinactin cream Lamisil AF defense and Tinactin powder spray Generic cream	OTC	Miscellaneous

*All the above antifungals will treat dermatophytes and *Candida*. Tolnaftate is effective only for dermatophytes and not *Candida*. Nystatin is effective only for *Candida* and not the dermatophytes. *OTC*, over-the-counter.

- Allylamines (naftifine, terbinafine, butenafine).
- Azoles (clotrimazole, miconazole, econazole).
- Allylamines cure slightly more infections than azoles but are more expensive.[2]
- No differences in efficacy found between individual topical allylamines or individual azoles.[2] SOR Ⓐ

Evidence for the management onychomycosis by topical treatments is sparse. There is some evidence that ciclopiroxolamine and butenafine are both effective, but they both need to be applied daily for at least 1 year.[3]

Oral antifungals are needed for all tinea capitis infections and for more severe infections of the rest of the body.[4] True dermatophyte infections that do not respond to topical antifungals may need an oral agent.

- A Cochrane systematic review of 12 trials of oral antifungals for tinea pedis showed oral terbinafine for 2 weeks cures 52 percent more patients than oral griseofulvin.[5] SOR Ⓐ
- Terbinafine is equal to itraconazole in patient outcomes.[5]
- No significant differences in comparisons between a number of other oral agents.[5]

Oral antifungals used for fungal infections of the skin, nails, or mucous membranes:

- Itraconazole (Sporanox).
- Fluconazole (Diflucan).
- Griseofulvin.
- Ketoconazole (Nizoral).
- Terbinafine (Lamisil).

One metaanalysis suggests that terbinafine is more efficacious than griseofulvin in treating tinea capitis caused by *Trichophyton* species, whereas griseofulvin is more efficacious than terbinafine in treating tinea capitis caused by *Microsporum* species.[6] SOR Ⓐ

Details of treatments for multiple types of fungal skin infections are supplied in Chapter 121–126.

121 CANDIDIASIS

Richard P. Usatine, MD

PATIENT STORY

A 2-month-old infant is being seen for a diaper rash and the pediatrician notes that the tongue and mouth are covered in white (**Figure 121-1**). A diagnosis of thrush and Candida diaper dermatitis is made. The child is treated with oral nystatin for the mouth and topical clotrimazole for the diaper dermatitis.

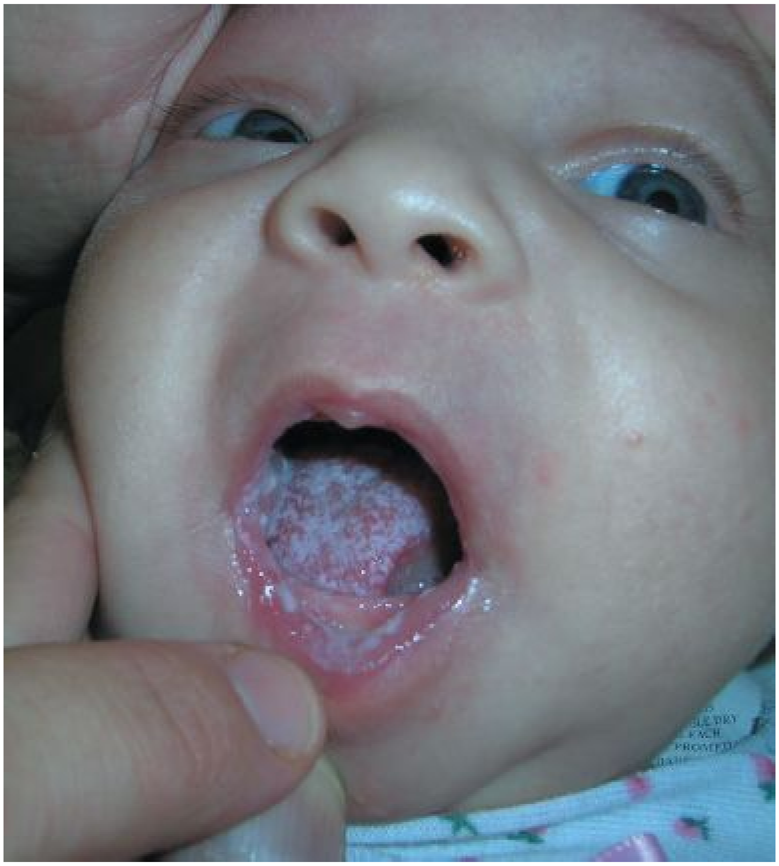

FIGURE 121-1 Thrush in an otherwise healthy infant. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Cutaneous and mucosal *Candida* infections are seen commonly in infants with thrush and diaper rash (**Figure 121-2**). Also children and teens with obesity, diabetes, and/or immunodeficiency are at higher risk of developing Candida infections.

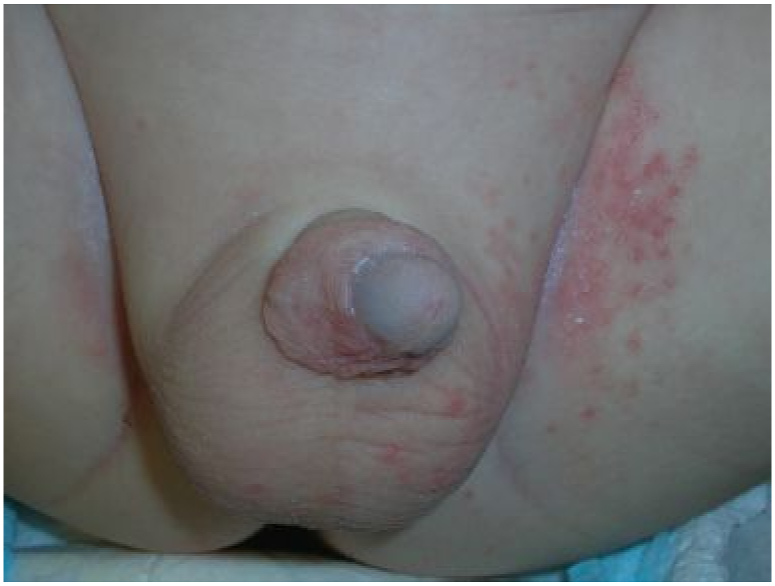

FIGURE 121-2 *Candida* diaper dermatitis in an otherwise healthy infant. Note the satellite lesions and the pink color. (*Used with permission from Richard P. Usatine, MD*.)

SYNONYMS

Thrush.

EPIDEMIOLOGY

- *Candida* superinfected diaper dermatitis is highly prevalent in healthy infants (**Figures 121-2** and **121-3**).

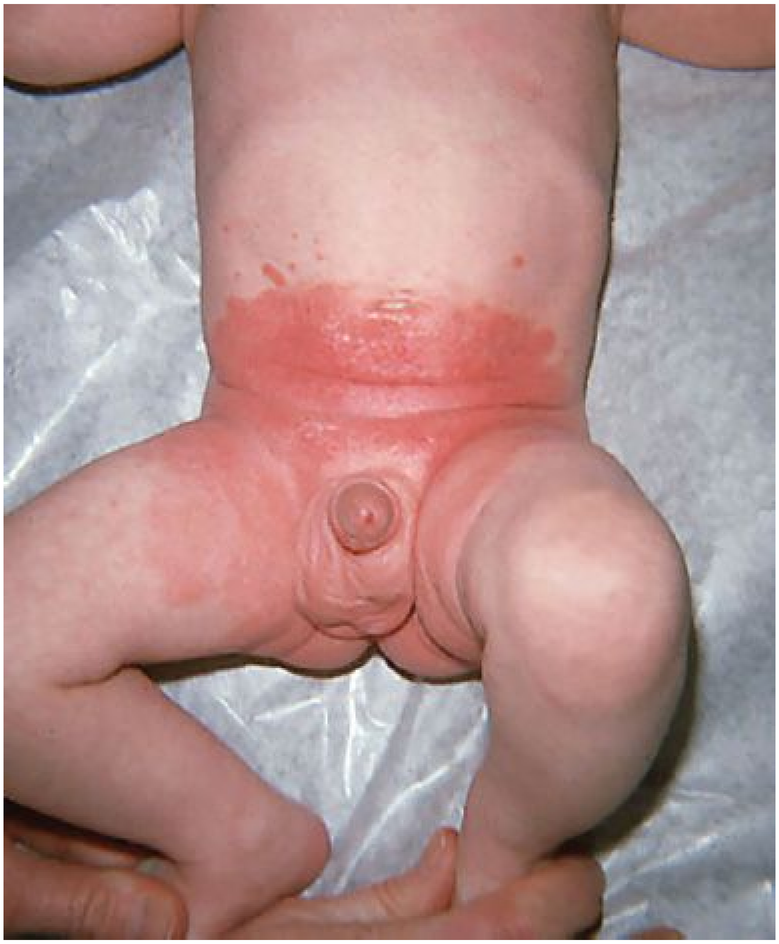

FIGURE 121-3 *Candida* diaper dermatitis after a course of antibiotics for otitis media. Note how the dermatitis has spread up the abdomen but follows the diaper distribution. There are visible satellite lesions. (*Used with permission from the Cleveland Clinic Children's Hospital Photo Files*.)

- *Candida* thrush is not uncommon in healthy infants (**Figure 121-1**).
- Candidemia is a major source of morbidity and mortality in neonatal intensive care units (NICU).[1] This chapter focuses on cutaneous Candida infections only.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cutaneous infections caused by *Candida* species are primarily *Candida albicans*.
- *C. parapsilosis and C. albicans* infections are the most frequent causes of candidemia in the NICU.[1]
- *C. albicans* has the ability to exist in both hyphal and yeast forms (termed *dimorphism*). If pinched cells do not separate, a chain of cells is produced and is termed *pseudohyphae*.[2]

RISK FACTORS

Infancy, prematurity, hospitalization, being in the NICU, obesity, diabetes, immunodeficiency, HIV, use of oral antibiotics, and use of inhaled or systemic steroids.

DIAGNOSIS

CLINICAL FEATURES

- Ask about recent antibiotic or steroid use in the history.
- Typical distribution—Diaper area (**Figure 121-3**), glans penis, vulva, inframammary (**Figure 121-4**), under abdominal pannus, between fingers, in the creases of the neck, and in the corners of mouth in angular cheilitis.

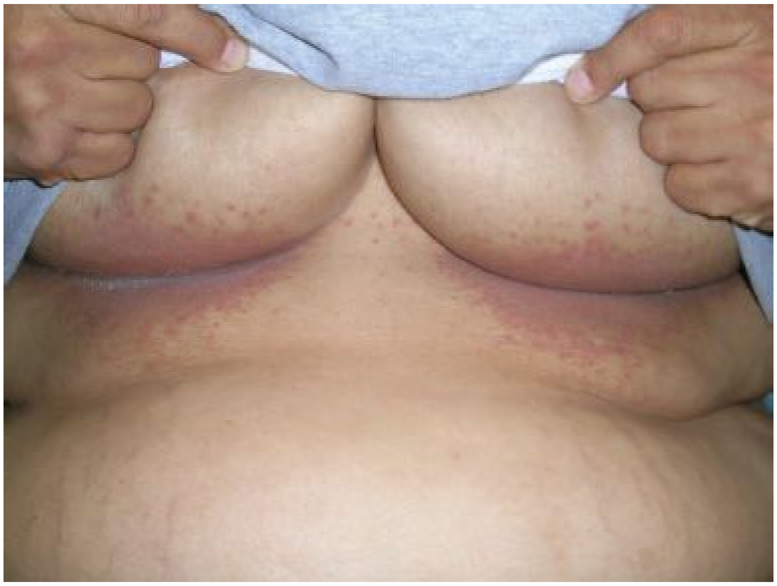

FIGURE 121-4 *Candida* under the breasts of an obese young woman. The border is not well-demarcated and there are satellite lesions. (*Used with permission from Richard P. Usatine, MD.*)

- Morphology on the skin—Macules, patches, plaques that are pink to bright red with small peripheral satellite lesions (**Figure 121-3**).
- Physical exam—Thrush appears as a white coating (velvety or cottage cheese like) on the oral mucosa including the tongue, palate, and buccal mucosa (**Figure 121-1**). Thrush will not be as easy to remove from the buccal mucosa and tongue as breast milk or formula. A gauze-covered finger can be used to test this out. If the white coating does come off and there is red friable tissue below, it is most likely thrush.

▶Teens

Candida balanitis is more common in uncircumcised males than in those that have been circumcised (**Figure 121-5**). It presents with penile pruritus and a white discharge under the foreskin.

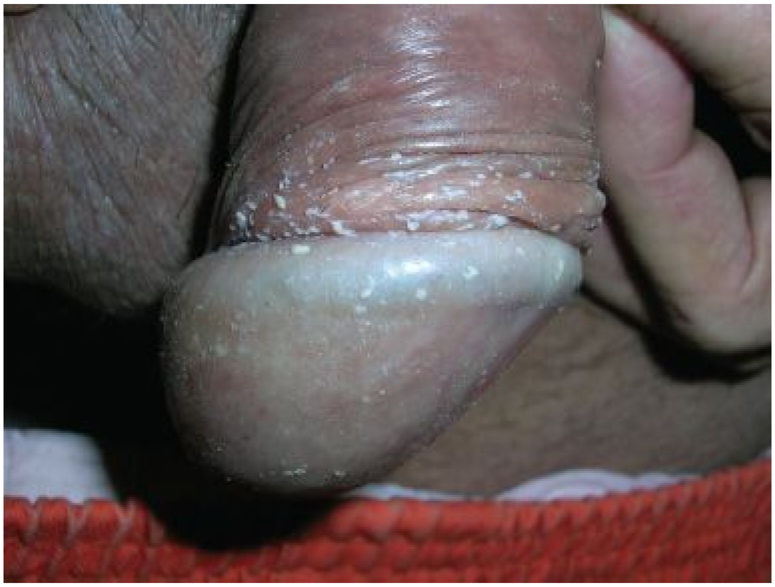

FIGURE 121-5 Candida balanitis in an uncircumcised young man. (*Used with permission from Richard P. Usatine, MD.*)

Candida vaginitis presents with pruritus and a white discharge (**Figure 121-6**). Trichomonas can also present in the same manner so a wet mount is needed to determine the correct diagnosis.

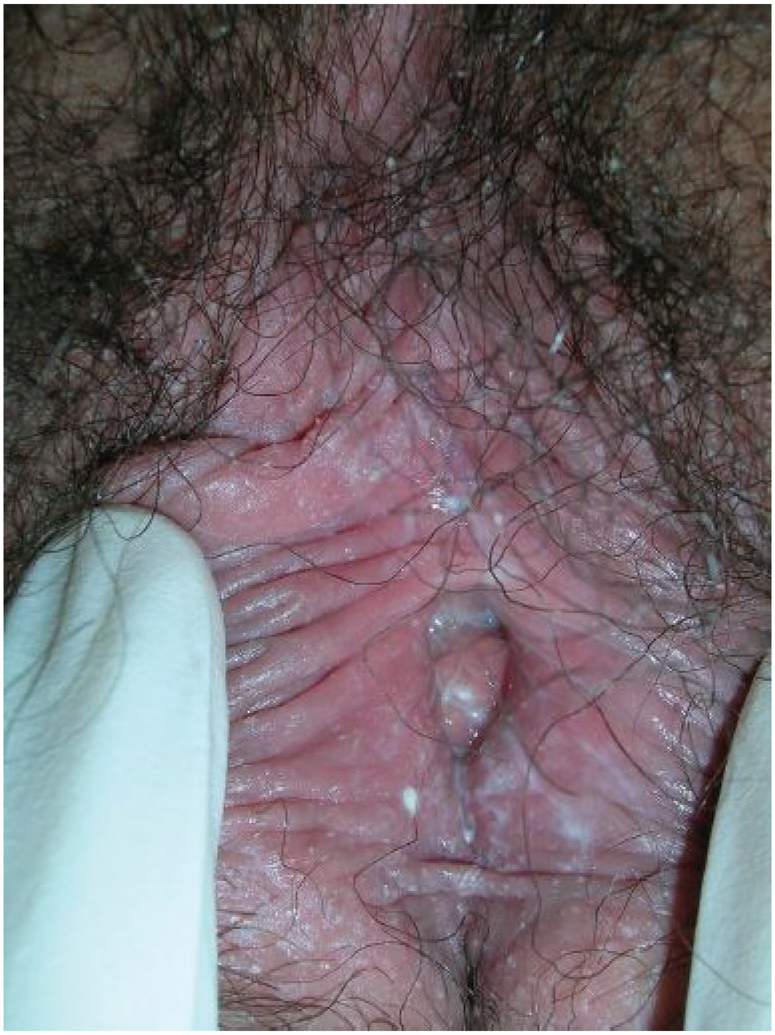

FIGURE 121-6 Candida vulvovaginitis in a young woman. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY STUDIES

Scrape involved area and add to a slide with KOH (DMSO optional). *C. albicans* exist in both hyphal and yeast forms (dimorphism). Look for pseudohyphae and/or budding yeast (**Figure 121-7**).

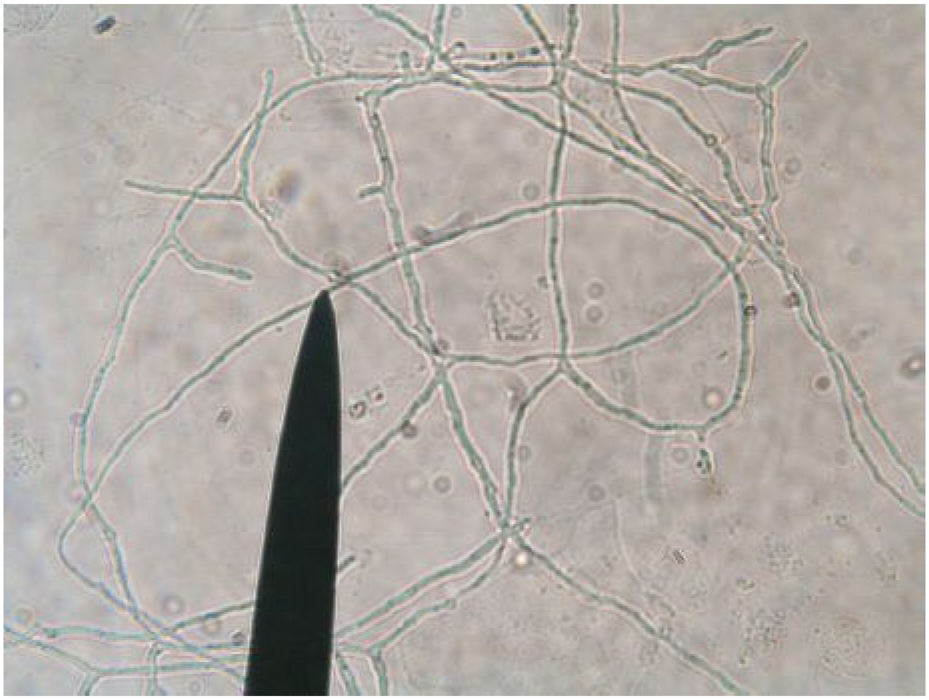

FIGURE 121-7 The branching pseudohyphae and budding yeast of Candida under high power. (*Used with permission from Richard P. Usatine, MD.*)

DIFFERENTIAL DIAGNOSIS

- Intertrigo is a nonspecific inflammatory condition of the skin folds. It is induced or aggravated by heat, moisture, maceration, and friction. The condition frequently is worsened by infection with *Candida* or dermatophytes (**Figures 121-4**).
- Tinea corporis or cruris—Can be distinguished from *Candida* when you see an annular pattern or concentric circles in the tinea. Typically there is no scrotal involvement in tinea cruris. *Candida* intertrigo may have scrotal involvement (see Chapters 123, Tinea Corporis and 124, Tinea Cruris).
- Erythrasma—Occurs in the inguinal area and axillae. It may be pink or brown and glows a coral red with UV light (see Chapter 102, Erythrasma).

- Seborrhea—Inflammation related to overgrowth of *Pityrosporum*, a yeast-like organism (see Chapter 135, Seborrheic Dermatitis).
- For a full discussion of the differential diagnosis of diaper dermatitis, see Chapter 95, Diaper Rash and Perianal Dermatitis.

MANAGEMENT

PRIMARY CANDIDAL SKIN INFECTIONS

- Topical azoles, including clotrimazole, miconazole, and nystatin (polyenes), are effective.[4] SOR Ⓑ
- Keeping the infected area of the skin dry is important.[3] SOR Ⓒ
- For more details of the topical antifungals, see **Table 120-3** in Chapter 120, Fungal Overview.
- In one study, miconazole ointment was well tolerated and significantly more effective than the zinc oxide/petrolatum vehicle control for treatment of diaper dermatitis complicated by candidiasis.[4]
- Do not use tolnaftate, which is active against dermatophytes but not *Candida*.
- If recurrent or recalcitrant, consider oral fluconazole.

OROPHARYNGEAL CANDIDIASIS

- Treat initial episodes with oral nystatin suspension.[3] SOR Ⓑ
- Oral fluconazole is as effective as—and, in some studies, superior to—topical therapy.[3] SOR Ⓐ
- Itraconazole solution is as effective as fluconazole.[3] SOR Ⓐ

- Ketoconazole and itraconazole capsules are less effective than fluconazole, because of variable absorption.[3] SOR Ⓐ
- HIV/AIDS patients with oral candidiasis may be treated with clotrimazole troches (when old enough to use these safely) or oral fluconazole.[3] SOR Ⓐ

CHRONIC MUCOCUTANEOUS CANDIDIASIS

- Chronic mucocutaneous candidiasis (**Figure 121-8**) is a spectrum of disorders in which the patients have persistent and/or recurrent candidiasis of the skin, nails and mucous membranes. The patient's T-cells fail to produce cytokines that are essential for expression of cell-mediated immunity to Candida.[5]

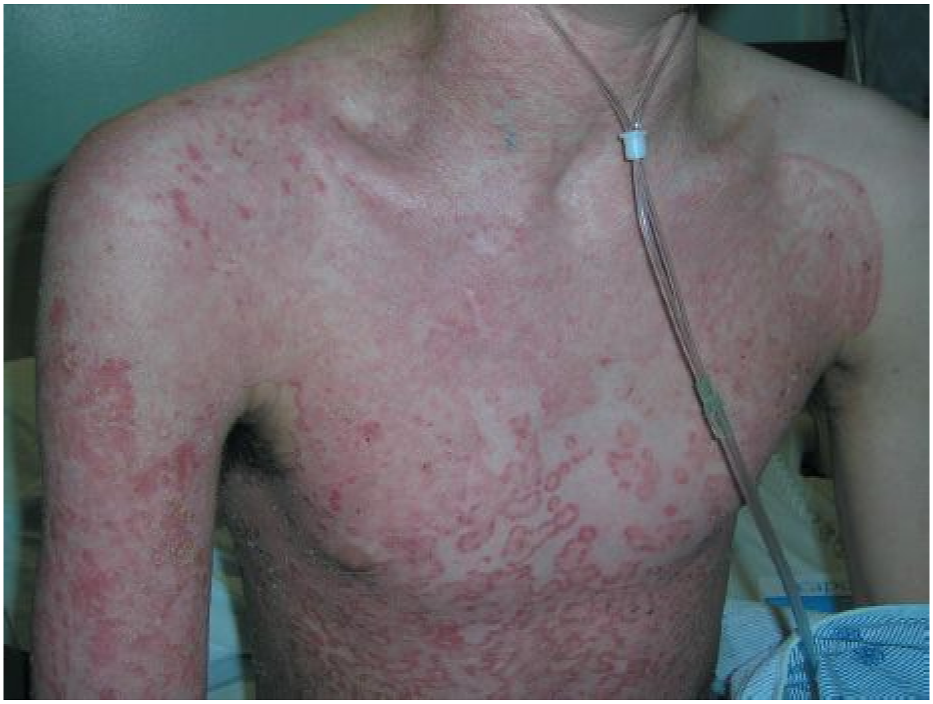

FIGURE 121-8 Chronic mucocutaneous candidiasis. This young man has had persistent candidiasis of his skin, nails and mucous membranes since childhood due to a failure of his T-cell immunity. (*Used with permission from Richard P. Usatine, MD.*)

- Chronic mucocutaneous candidiasis requires a long-term approach that is analogous to that used in patients with AIDS.[3]
- Systemic therapy is needed, and azole antifungal agents (ketoconazole, fluconazole, and itraconazole) have been used successfully.[3]
- Treatments that restore cellular immunity have produced long term remissions.[5]

PROGNOSIS

Prognosis is based upon the type of Candida infection and the immune status of the host. Healthy infants with thrush and/or Candida diaper dermatitis have an excellent prognosis for full recovery.

PATIENT EDUCATION

For skin infections, keep the infected area clean and dry. For thrush in a baby, treat sources of infection such as the mother’s breasts and bottle nipples. If the baby is bottle fed, boil the nipples between uses.

122 TINEA CAPITIS

Richard P. Usatine, MD
Congjun Yao, MD

PATIENT STORY

An 11-year-old boy has a history of 2 months of progressive patchy hair loss (**Figure 122-1**). He has some itching of the scalp but his mother is worried about his hair loss. Physical examination reveals alopecia with scaling of the scalp and broken hairs looking like black dots in the areas of hair loss. A KOH preparation is created by scraping an area of alopecia onto a slide. A few loose hairs are added to the slide before the KOH and cover slip are placed. Fungal elements are seen under the microscope. After 6 weeks of griseofulvin, the tinea capitis is fully resolved.

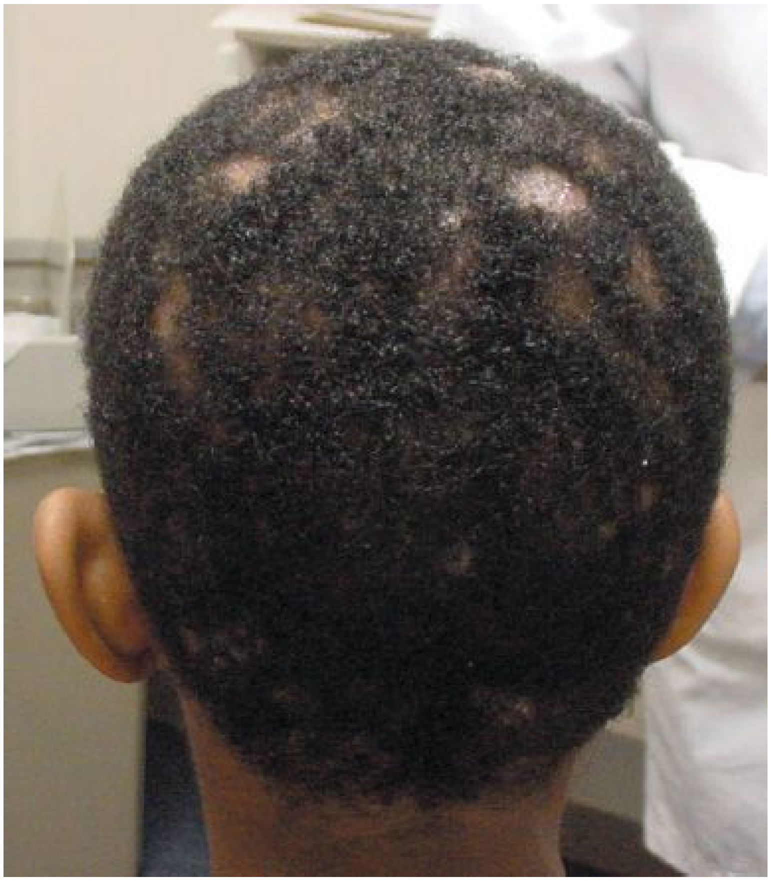

FIGURE 122-1 Tinea capitis in a young black boy. The most likely organism is *Trichophyton tonsurans*. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Tinea capitis is a fungal infection involving the scalp and hair. It is the most common type of dermatophytoses in children younger than 10 years of age. Common signs include hair loss, scaling, erythema, and impetigo-like plaques.

SYNONYMS

Ringworm of the scalp.

EPIDEMIOLOGY

- Tinea capitis is more common in young, black boys as it has a preference for the follicles of short curly hairs.
- Tinea capitis is the most common type of dermatophytoses in children younger than 10 years (**Figures 122-1** to **122-5**). It rarely occurs after puberty or in adults.[1] The infection has a worldwide distribution.

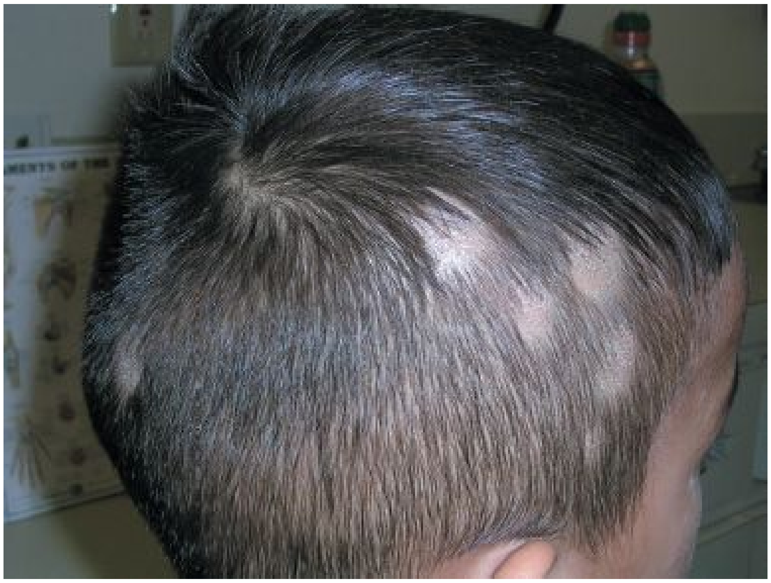

FIGURE 122-2 Tinea capitis with patchy hair loss and scaling of the scalp in a young boy. (*Used with permission from Richard P. Usatine, MD.*)

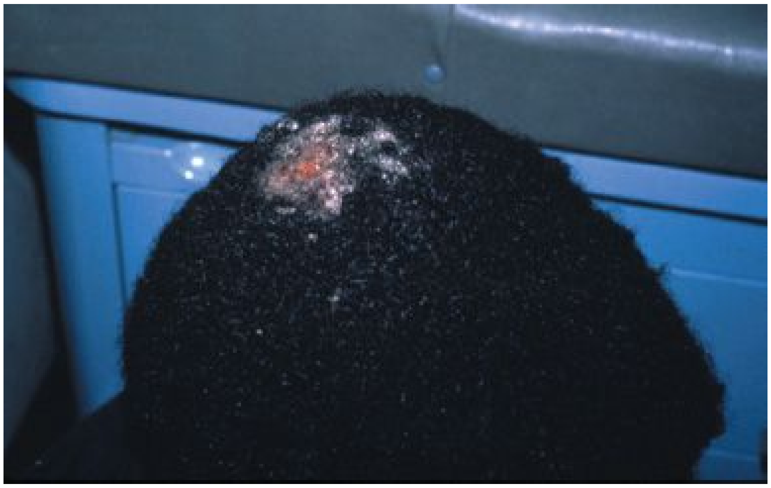

FIGURE 122-3 A kerion resulting from inflammation of the tinea capitis on this young boy. The kerion looks superinfected but it is nothing more than an exuberant inflammatory response to the dermatophyte. (*Used with permission from Richard P. Usatine, MD*.)

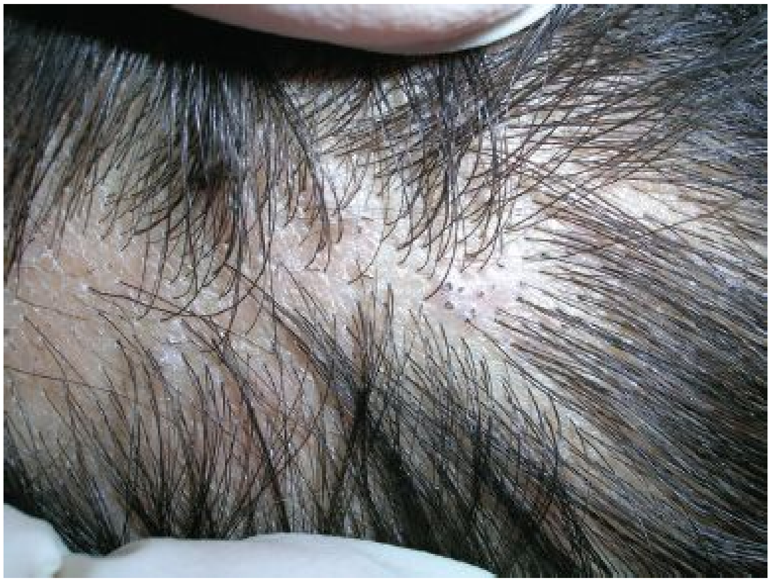

FIGURE 122-4 Close-up of black dot alopecia in a 7-year-old girl showing the black dots where infected hairs have broken off. (*Used with permission from Richard P. Usatine, MD*.)

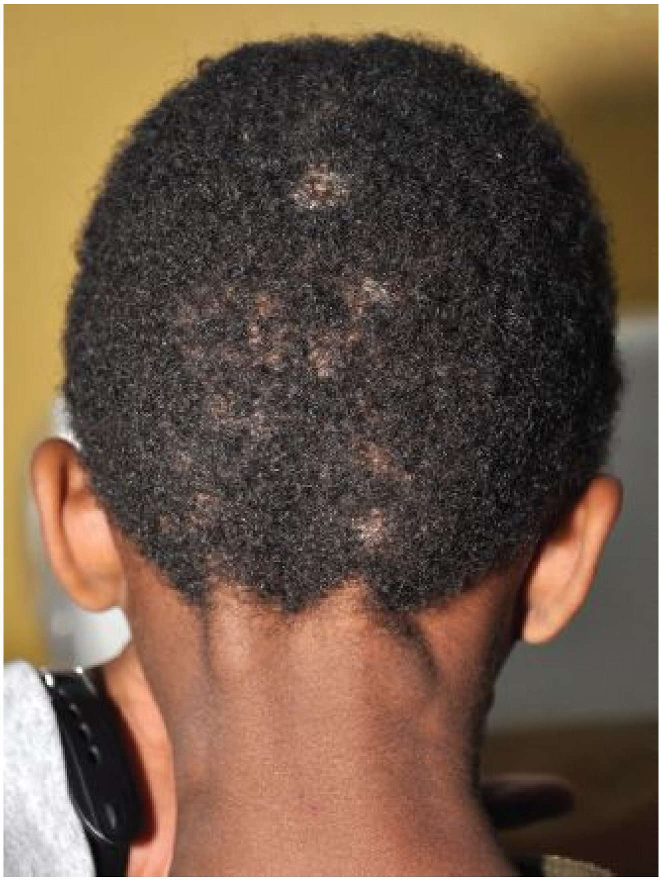

FIGURE 122-5 Lymphadenopathy visible in the neck of this young boy with tinea capitis. The fungal infection shows more scaling and crusting than actual hair loss. The lymphadenopathy is a reaction to the tinea and not a bacterial superinfection. (*Used with permission from Richard P. Usatine, MD*.)

- Combs, brushes, couches, and sheets may harbor the live dermatophyte for a long period of time.
- Spread from person to person with direct contact or through fomites.
- Occasionally spread from cats and dogs to humans.

ETIOLOGY AND PATHOPHYSIOLOGY

- Tinea capitis is a superficial fungal infection affecting hair shafts and follicles on the scalp but could involve the eyebrows and eyelashes.
- Caused by *Trichophyton* and *Microsporum* dermatophytes. The most common organism in the US is *Trichophyton tonsurans*, which is associated with black dot alopecia. *Microsporum canis* is less common now than decades ago. *M. canis* is still highly prevalent in developing countries. The natural reservoir of *M. canis* is dogs and cats.

RISK FACTORS

- Lack of access to clean water and soap.
- Poverty and living in rural areas.
- African descent as the dermatophytes grow well in the follicles of short curly hairs.
- Crowded living arrangements in which infected individuals spread the tinea to others.
- Sharing combs, brushes, and hair ornaments.

DIAGNOSIS

- The clinical appearance is often adequate to make the diagnosis.
- Confirm the diagnosis by scraping the scaling areas on the scalp and placing a few loose hairs on a microscope slide with KOH. (DMSO and a fungal stain will help.) Look for hyphae and spores (**Figure 122-6**). Look for endoectothrix invasion of the hair shaft with fungus.

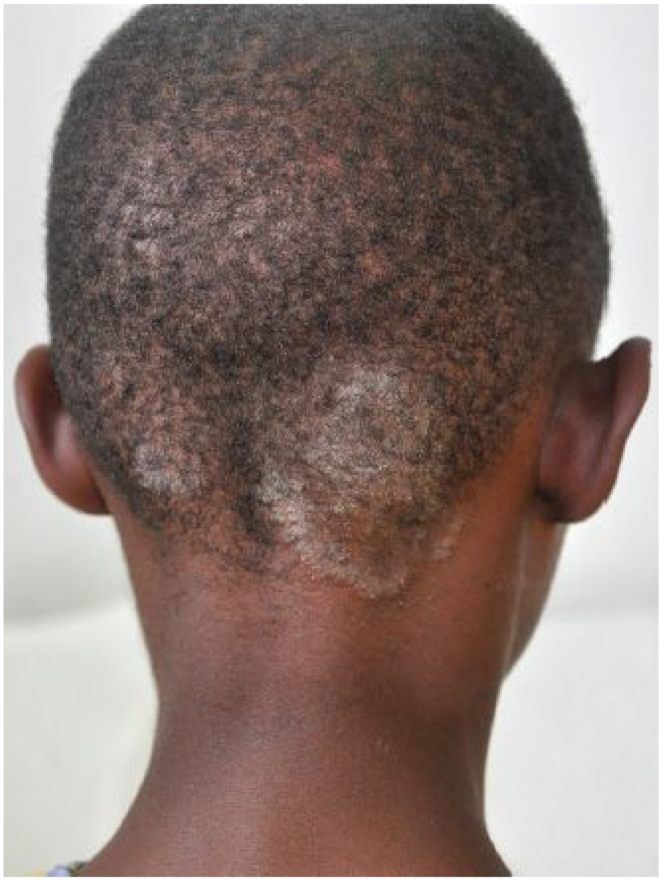

FIGURE 122-6 Tinea capitis with an annular configuration. (*Used with permission from Richard P. Usatine, MD.*)

CLINICAL FEATURES

- Alopecia and scaling of the scalp (**Figures 122-1** and **122-2**).
- A kerion occurs when there is an inflammatory response to the tinea. The scalp gets red, swollen, and boggy. There may be serosanguineous discharge and some crusting as this dries (**Figure 122-3**).
- There may be broken hairs that look like black dots in the areas of hair loss (**Figure 122-4**).
- Cervical lymphadenopathy is common from the tinea capitis (**Figure 122-5**).
- Tinea capitis can even be annular and have the rings of ringworm (**Figure 122-6**).

TYPICAL DISTRIBUTION

By definition it occurs on the head, but usually is found on the scalp. Rarely involves the eyebrows and eyelashes.

LABORATORY STUDIES

Whenever possible it is very important to confirm or dispel ones' clinical suspicion with mycologic evidence before starting weeks of oral antifungal medicines.

- KOH preparation—Scrape the scale and infected hairs using a #15 blade. Then use KOH or a fungal stain to dissolve the keratin. Use the microscope to look for septate, branching hyphae under 10 and 40 power (**Figure 122-7**). The hyphae of *Microsporum* may also be found on the exterior of the hair (exothrix) while the hyphae of *Trichophyton* is found in the interior of the hair (endothrix) (**Figure 122-8**).

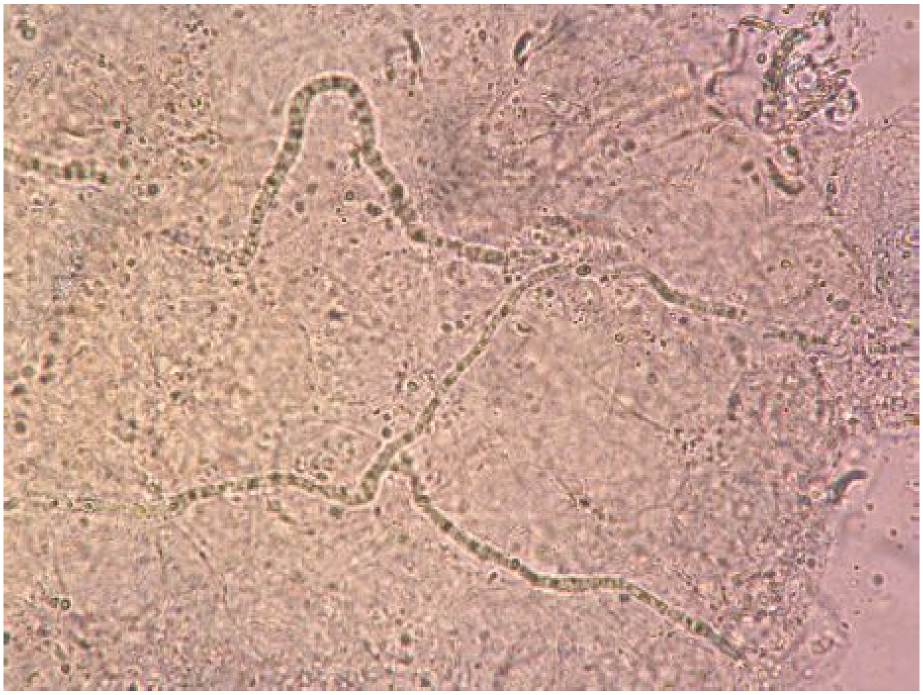

FIGURE 122-7 *Trichophyton tonsurans* from tinea capitis visible among skin cells at 40 power after adding Swartz-Lamkins fungal stain. (*Used with permission from Richard P. Usatine, MD*.)

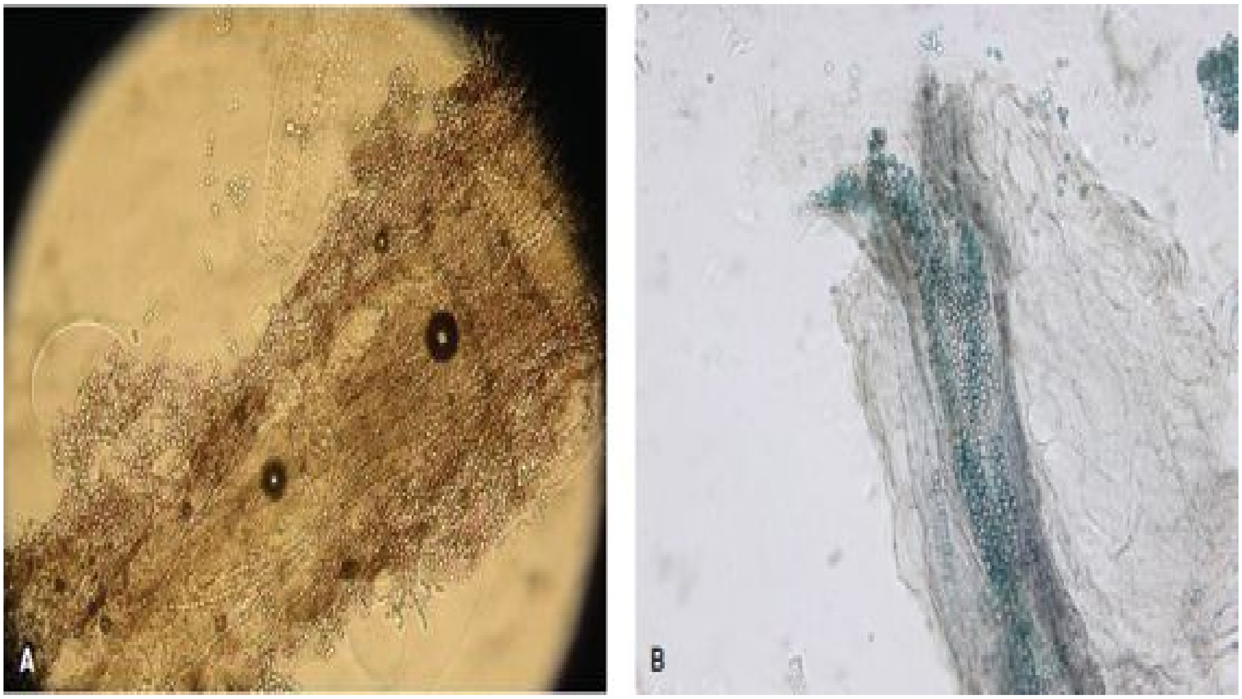

FIGURE 122-8 **A.** *M. canis* showing hyphae on the exterior of the hair (exothrix) at 40 power explaining why this type of tinea fluoresces. (*Used with permission from Eric Kraus, MD*.) **B.** *T. tonsurans* showing hyphae in the interior of the hair (endothrix) at 40 power after adding Swartz-Lamkins fungal stain. This type of tinea capitis does not fluoresce because the fungus is inside the hair. (*Photo Credit: Dr. Patrick E. McCleskey, MD*.)

- If the diagnosis is uncertain, send a few loose hairs and a scraping of the scalp scale for a fungal culture.
- You may look at the scalp with a UV light (Woods lamp), looking for fluorescence, but the yield is low. Only the *Microsporum* species will fluoresce (**Figure 122-9**) and this organism is the involved dermatophyte less than 30 percent of the time.

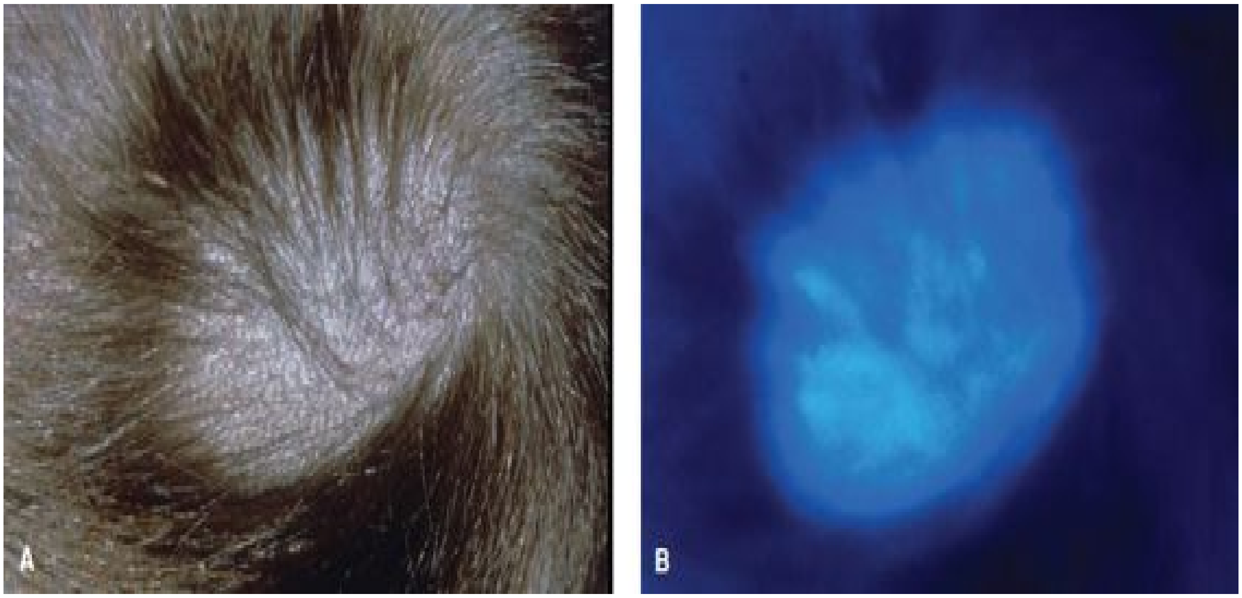

FIGURE 122-9 **A.** Tinea capitis in a young boy. **B.** Fluorescence with an ultraviolet light indicating that this is a *Microsporum* species causing the tinea capitis. (*Used with permission from Jeff Meffert, MD*.)

DIFFERENTIAL DIAGNOSIS

- Alopecia areata—Produces areas of hair loss with no scaling, inflammation, or scarring in the underlying scalp. It is an autoimmune process in which the immune system attacks the person's own hair follicles (see Chapter 158, Alopecia Areata).
- Seborrhea of the scalp (dandruff)—is caused by the *Pityrosporum* yeast, resulting in scaling and inflammation but rarely causing hair loss. The scalp involvement tends to be more widespread than patchy and localized as seen in tinea capitis (see Chapter 135, Seborrheic Dermatitis).
- Scalp psoriasis—Rarely causes alopecia. There are mild cases with slight, fine scaling on the scalp, or severe cases with silvery, thick, crusted plaques covering the majority of the scalp. Often psoriatic plaques are seen elsewhere on the body and nail changes are visible.
- Trichotillomania—Self-inflicted alopecia caused when the patient pulls and twists her/his own hair (see Chapter 159, Traction Alopecia and a

Trichotillomania).

- Traction alopecia—Alopecia that occurs when the patient or parent pulls the hair to style it into braids or ponytails. There should be no scaling of the scalp (unless there is coexisting seborrhea) and the pattern of hair loss should match the hairstyle (**Figure 122-10**) (see Chapter 159, Traction Alopecia and Trichotillomania).

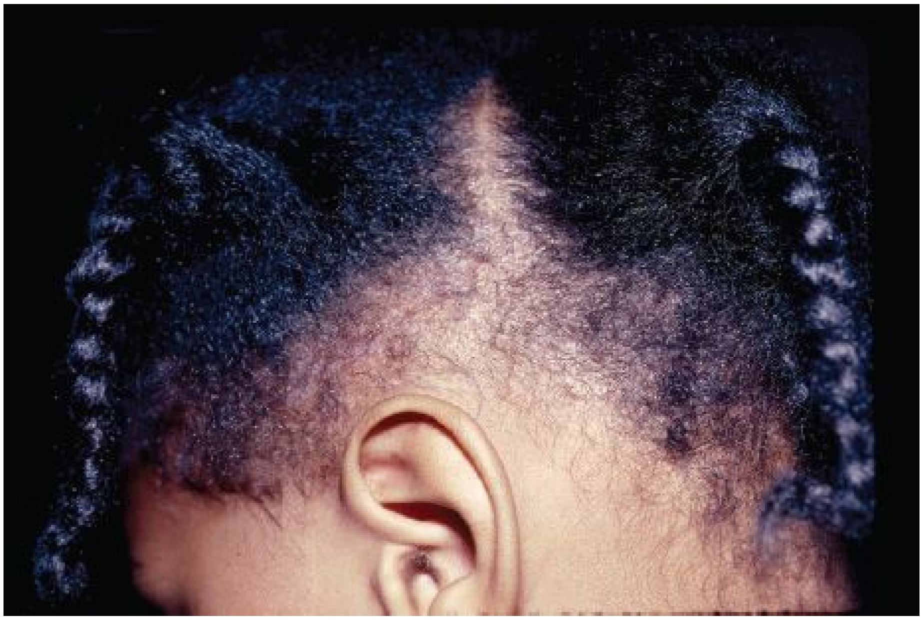

FIGURE 122-10 Traction alopecia that is related to the tight braids that put pressure on the hair follicle. The slight scaling was caused by seborrhea but tinea capitis must be in the differential diagnosis. (*Used with permission from Richard P. Usatine, MD*.)

MANAGEMENT

- Topical antifungal therapy is not adequate and oral treatment is needed.
- Griseofulvin remains the treatment of choice for tinea capitis even if it requires a somewhat longer course than the newer antifungal agents.[2–5] SOR Ⓑ
- Griseofulvin is available in a liquid form for children and often covered by insurance. Prescribe a 6- to 8-week course or longer (12-week course) of

griseofulvin for tinea capitis. SOR Ⓒ

- Griseofulvin is available in many forms, including liquid (125 mg microsize/5 cc) for children. Taking the drug with fatty food increases absorption and aids bioavailability. The dose for microsize griseofulvin is 20 mg/kg per day and ultramicrosize griseofulvin tablets is 5 to 15 mg/kg per day. Ultramicrosize preparations are stronger per mg than the microsize, but do not come in liquid form. The tablets are less expensive than the liquids and can be used for children that can swallow a pill. The standard course should be 6 to 12 weeks for tinea capitis to deal with increasing resistance patterns.
- Expert opinion in a recent article suggests that griseofulvin microsize should be given at at a dose of 20 to 25 mg/kg per day for 2 to 3 months along with adjunctive shampooing with 2.5 percent selenium sulfide.[6] SOR Ⓒ
- A 2- to 4-week course of terbinafine, fluconazole, and itraconazole are at least as effective as a 6- to 8-week course of griseofulvin for the treatment of *Trichophyton* infections of the scalp.
- A number of RCTs of oral terbinafine (doses ranging from 3 to 8 mg/kg/day and durations of treatment from 2 to 4 weeks) have shown faster and higher cure rates when compared to griseofulvin for treatment of inner city tinea capitis caused by *Trichophyton tonsurans*.[6–10] SOR Ⓐ
- Griseofulvin is likely to be superior to terbinafine for the rare cases caused by *Microsporum* species and inflammatory Trichophyton species.[10,11]
- Terbinafine is effective and offers a shorter course of therapy than griseofulvin. It is not available in liquid form. Recommended dosage for 10- to 20-kg children is 62.5 mg/day; for 20- to 40-kg children, 125 mg daily; and for children who weigh more than 40 kg, 250 mg daily. Treatment duration for *Trichophyton* is 2 to 4 weeks; it is 8 to 12 weeks for *Microsporum* infection.
- Fluconazole is available in liquid form and appears to be effective and safe to treat cutaneous fungal infections. Recommended dosage is 5 to 6 mg/kg per day. Treatment duration for *Trichophyton* is 3 to 6 weeks; 8 to 12 weeks for *Microsporum* infection.

- Itraconazole is also available in liquid form. The recommended dose is 3 mg/kg per day for liquid form. For capsules: 5 mg/kg per day. Treatment duration is 2 to 6 weeks.
- None of these agents require laboratory monitoring at the recommended lengths of treatment for tinea capitis.[1]
- A kerion may resolve with oral antifungal treatment alone. If it is severe and painful, consider a short pulse of oral steroids to speed up resolution (**Figure 122-11**). SOR C

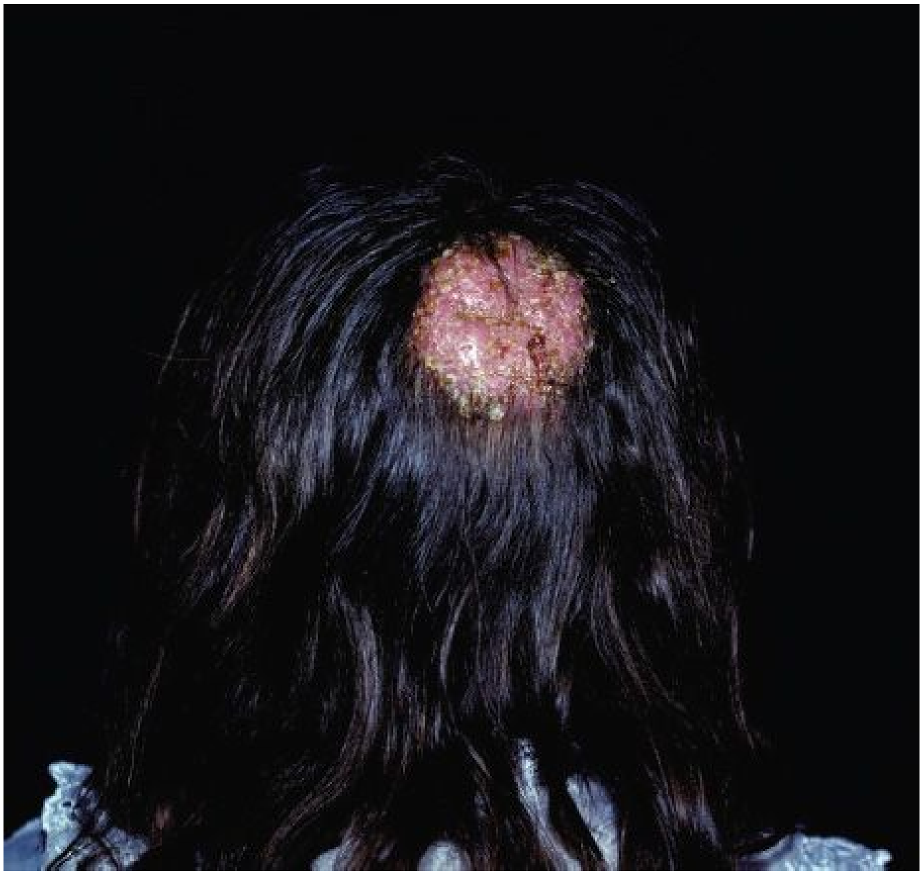

FIGURE 122-11 A kerion in a 5-year-old girl infected with Trichophyton rubrum. (*Used with permission from Eric Kraus, MD.*)

- Although oral therapy is still the recommended treatment for tinea capitis, topical treatment can be used as adjuvant therapy: 1 to 2.5 percent selenium sulfide, 1 percent ciclopirox, or 2 percent ketoconazole shampoo should be applied to the scalp and hair for 5 minutes 2 or 3 times a week for 8 weeks.[12-13] SOR B Shampoos with selenium sulfide or ciclopirox have been shown to be of equal efficacy.[13] SOR B

- Another use for antifungal shampoo is empirical treatment while waiting for a culture to come back in an equivocal case. Topical antifungal shampoo may decrease the spread of the tinea in crowded living environments while waiting for the oral therapy to work (**Figure 122-12**). SOR C

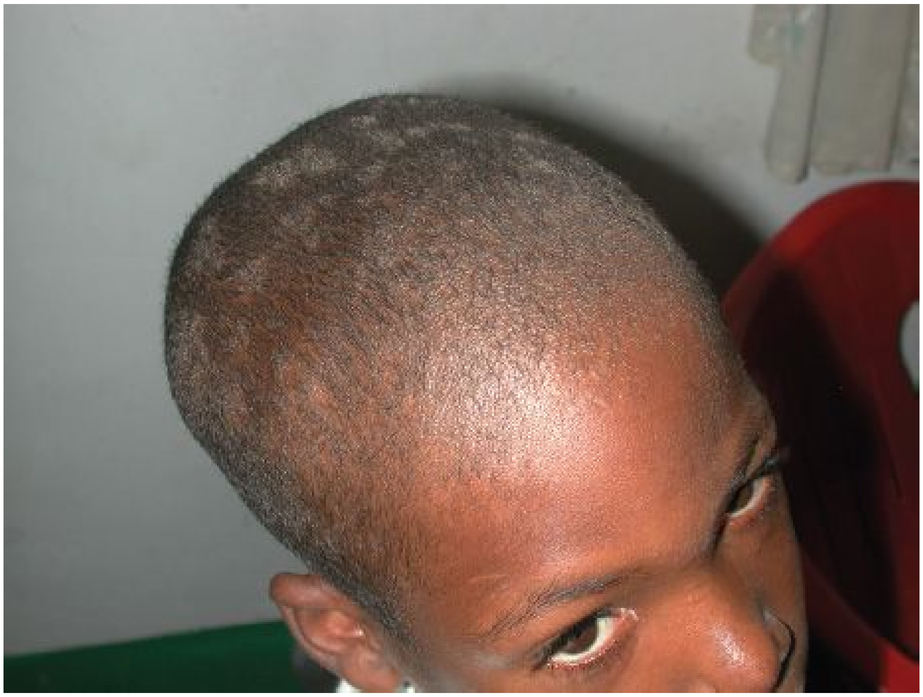

FIGURE 122-12 Tinea capitis in a schoolboy in Panama. Many of his classmates also had tinea capitis. An antifungal shampoo was prescribed for the children while waiting to obtain the needed systemic antifungal agent. (*Used with permission from Richard P. Usatine, MD.*)

PREVENTION

Family members or playmates should be screened and asymptomatic carriers should be treated. Close physical contact and sharing of toys or combs/hairbrushes should be avoided.[14] SOR B

PROGNOSIS

Severe hair loss and scarring alopecia can occur if tinea capitis is left untreated.

PATIENT EDUCATION

Patients and parents need to exercise care to avoid spreading the infection to others. Explain the importance of not sharing combs, brushes, and towels.

FOLLOW-UP

Follow-up may be scheduled to check for full resolution of the infection by negative culture or hair regrowth.

123 TINEA CORPORIS

Richard P. Usatine, MD
Adeliza Jimenez, MD

PATIENT STORY

A 6-year-old girl is brought to the office for a round, itchy rash on her body (**Figure 123-1**). It was first noted 2 weeks ago. The family cat does have some patches of hair loss. Note the concentric rings with scaling, erythema, and central sparing. UV light showed green fluorescence (*Microsporum* species) and the KOH is positive for branching and septate hyphae. The child was treated with a topical antifungal cream bid and the tinea resolved in 3 to 4 weeks. The family cat was also taken to the veterinarian for treatment.

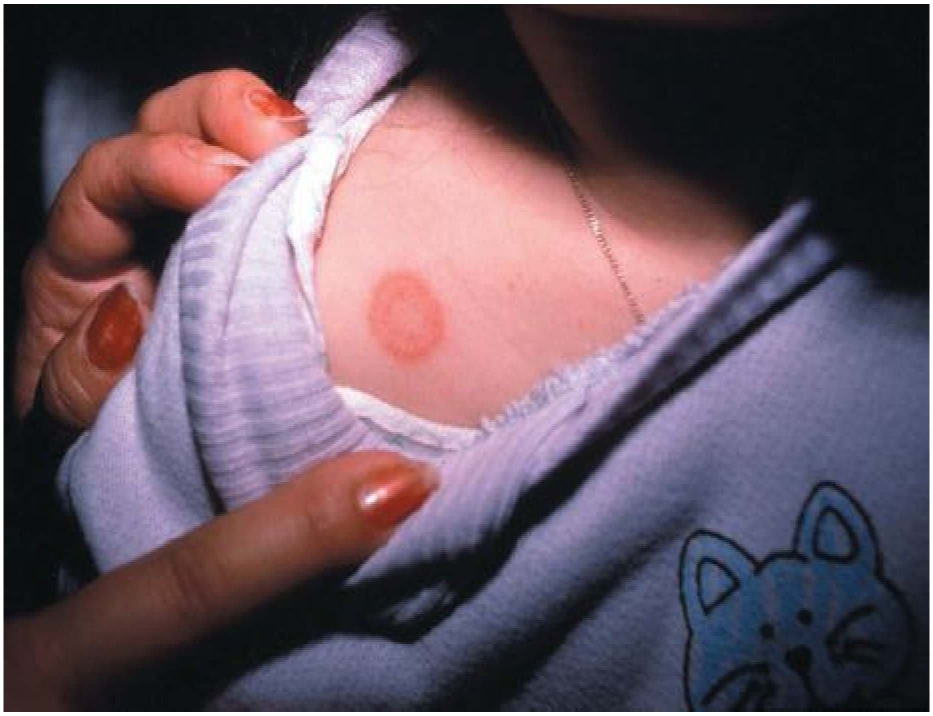

FIGURE 123-1 Tinea corporis on the shoulder of this young girl. This is a very typical annular pattern and the cat on a sweatshirt might be a clue to an infected pet at home spreading a *Microsporum* dermatophyte to the young girl. Note the concentric rings with scaling, erythema, and central sparing. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Tinea corporis is a common superficial fungal infection of the body, characterized by well-demarcated, annular lesions with central clearing, erythema, and scaling of the periphery.

EPIDEMIOLOGY

Dermatophytes are the most prevalent agents causing fungal infections in the US, with *Trichophyton rubrum* causing the majority of cases of tinea corporis, tinea cruris, tinea manuum, and tinea pedis.

- Excessive heat and humidity make a good environment for fungal growth.
- Dermatophytes are spread by exposure to infected animals or persons and contact with contaminated items.

ETIOLOGY AND PATHOPHYSIOLOGY

Tinea corporis is caused by fungal species from any one of the following three dermatophyte genus': *Trichophyton*, *Microsporum*, and *Epidermophyton*. *T. rubrum* is the most common causative agent of tinea corporis.

- Dermatophytes produce enzymes such as keratinase that penetrate keratinized tissue. Their hyphae invade the stratum corneum and keratin and spread centrifugally outward.

RISK FACTORS

- Participation in daycare centers.
- Poor personal hygiene.
- Living conditions with poor sanitation.
- Warm, humid environments.
- Conditions that cause weakening of the immune system (e.g., AIDS, cancer, organ transplantation, diabetes).

DIAGNOSIS

The diagnosis can be made from history, clinical presentation, culture, and direct microscopic observation of hyphae in infected tissue and hairs after KOH preparation.

CLINICAL FEATURES

- Pruritus of affected area.
- Well-demarcated, annular lesions with central clearing, erythema, and scaling of the periphery. Concentric rings are highly specific (80%) for tinea infections (**Figure 123-1**).
- Central clearing is not always present (**Figure 123-2**).

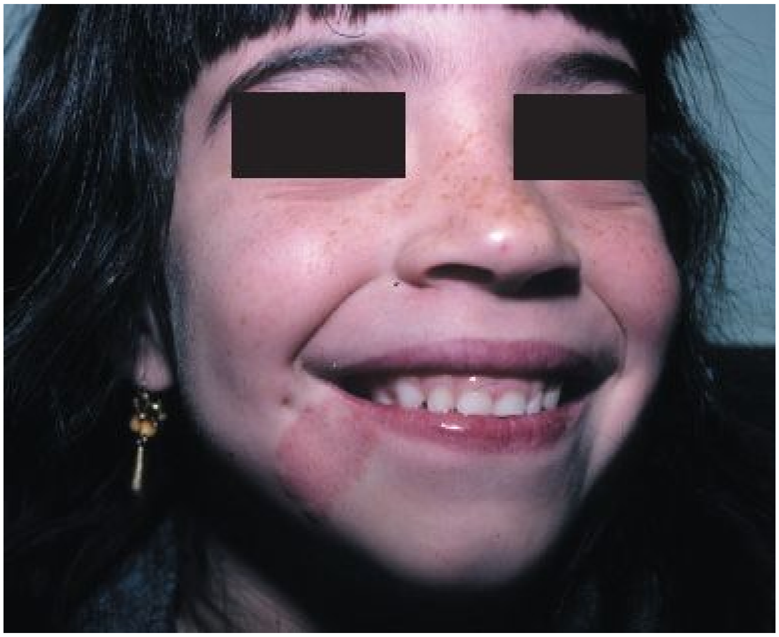

FIGURE 123-2 Tinea faciei in a young girl. There is no central clearing or annular pattern here but the KOH preparation was positive for branching hyphae. It resolved with a topical antifungal medicine. (*Used with permission from Richard P. Usatine, MD.*)

- Although scale is the most prominent morphologic characteristic, some tinea infections will actually cause pustules from the inflammatory response (**Figure 123-3**).

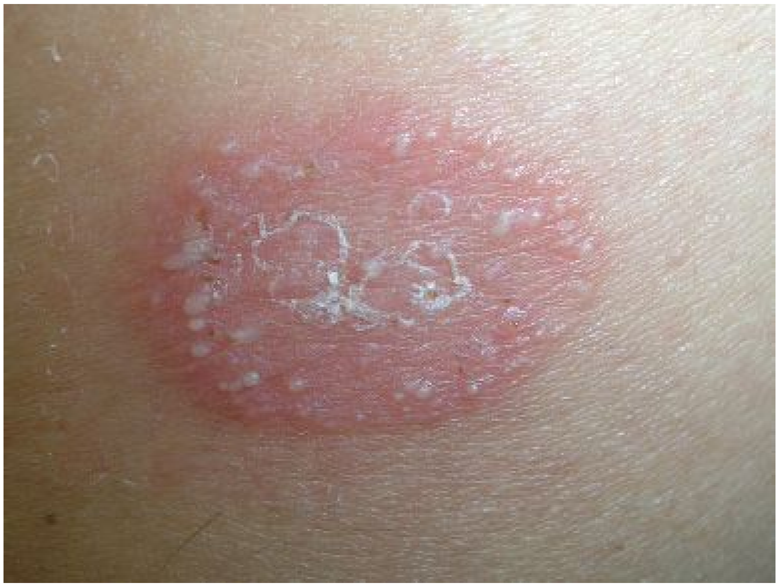

FIGURE 123-3 Tinea corporis with pustules and scale. KOH preparation was positive for branching hyphae. The pustules are a manifestation of an inflammatory response to the dermatophyte infection. (*Used with permission from Richard P. Usatine, MD*.)

TYPICAL DISTRIBUTION

- Any part of the body can be involved including the face and extremities (**Figures 123-4**).

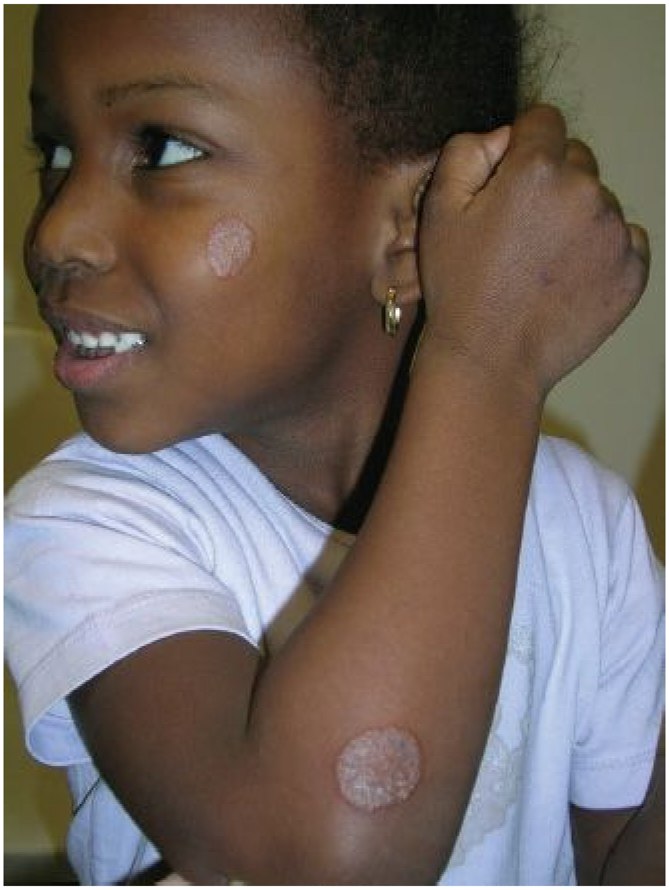

FIGURE 123-4 Tinea corporis with classic scaling rings on the arm and face of this young girl. (*Used with permission from Richard P. Usatine, MD*.)

- Tinea incognito is a type of tinea infection that was previously not recognized by the physician or patient and topical steroids were used on the site. While applying the steroid, the dermatophyte continues to grow and form concentric rings (**Figures 123-5** and **123-6**).

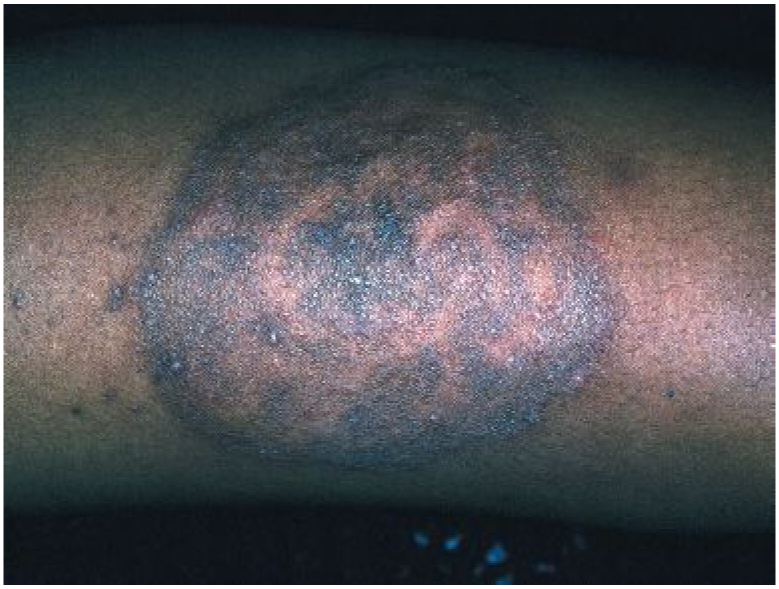

FIGURE 123-5 Tinea incognito on the arm with concentric rings as this dermatophyte infection continued to grow under the influence of the topical steroids mistakenly given to her by her physician. There is an extensive amount of postinflammatory hyperpigmentation. (*Used with permission from Richard P. Usatine, MD*.)

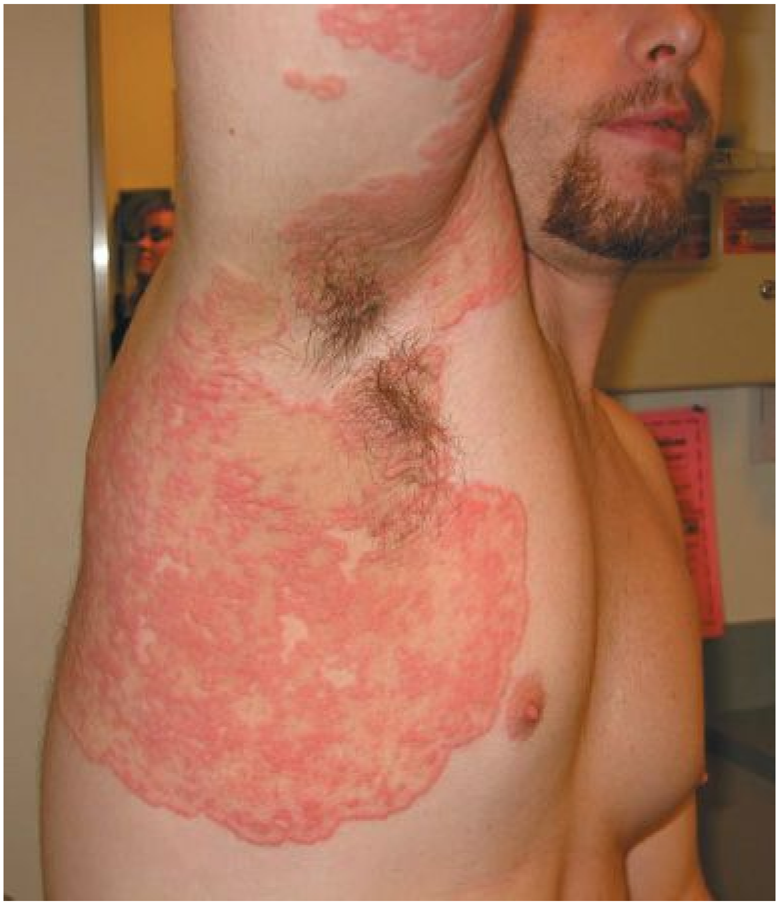

FIGURE 123-6 Tinea incognito in the axillary region of a young man who was prescribed topical steroids. Although there is some hyperpigmentation, erythema is most prominent. (*Used with permission from Chris Wenner, MD*.)

- Tinea corporis can cover large parts of the body as in **Figure 123-7**.

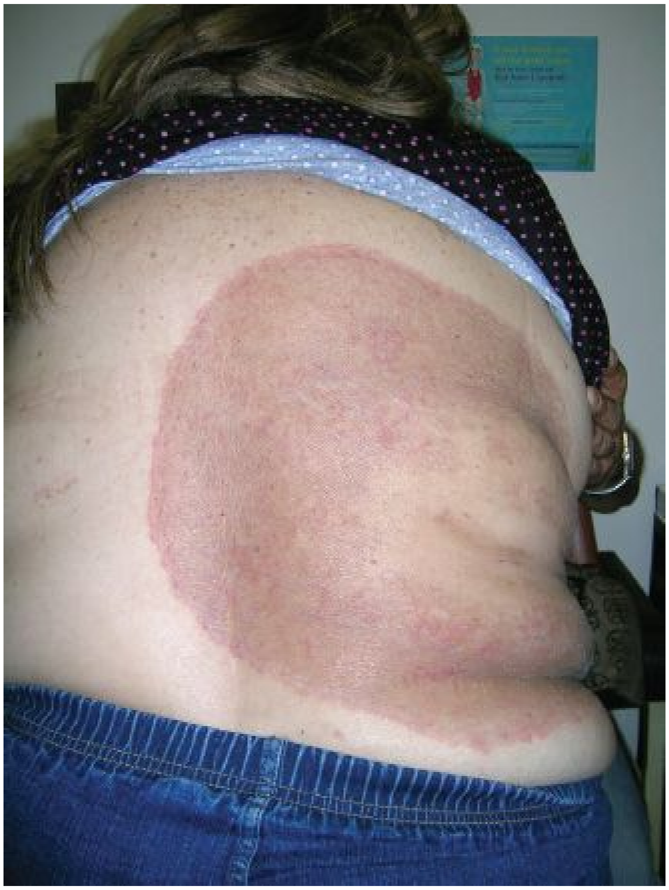

FIGURE 123-7 Tinea corporis covering the back and showing welldemarcated borders. (*Used with permission from Richard P. Usatine, MD*.)

- In some cases, the infection may cause hyperpigmentation (**Figures 123-5** to **123-7**).

LABORATORY STUDIES

- KOH preparation of skin scraping can be very useful to confirm a clinical impression or when the diagnosis is not certain. Scrape the skin with the side of a slide or scalpel, making sure to scrape the periphery and the erythematous part. Scrape hard enough to get some stratum corneum without causing significant bleeding. False negatives can occur secondary to inadequate scraping, patient using topical antifungals, or an inexperienced microscopist.

- Use KOH (plain, with dimethyl sulfoxide [DMSO], or in a fungal stain) to break up the epithelial cells more rapidly without heating (**Figure 123-8**). It is easy to purchase a small bottle of Swartz-Lamkins fungal stain that includes KOH, a surfactant, and blue ink. The blue ink allows the hyphae to stand out, thereby saving time and decreasing the chance of a false-negative result (**Figure 123-9**). If the epithelial cells are not breaking up sufficiently, use a flame under the slide for approximately 5 seconds to speed up the process.

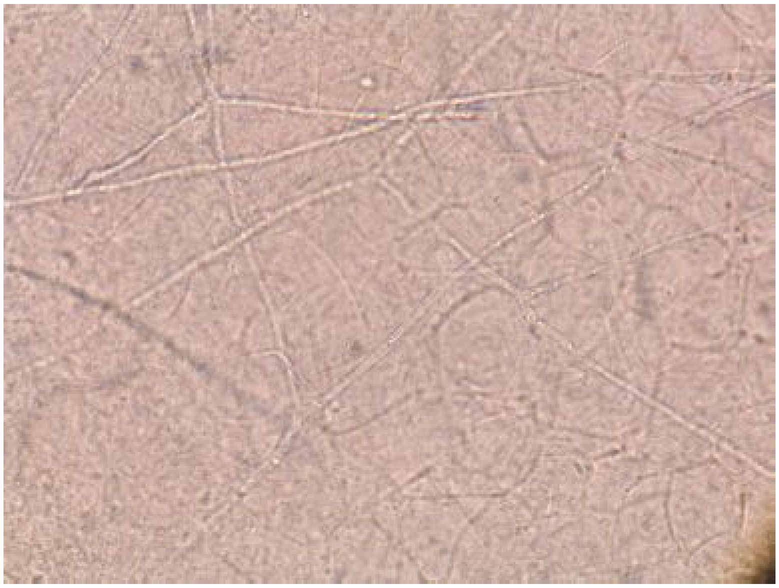

FIGURE 123-8 Branching hyphae at 40× high power from KOH preparation of tinea corporis. (*Used with permission from Richard P. Usatine, MD.*)

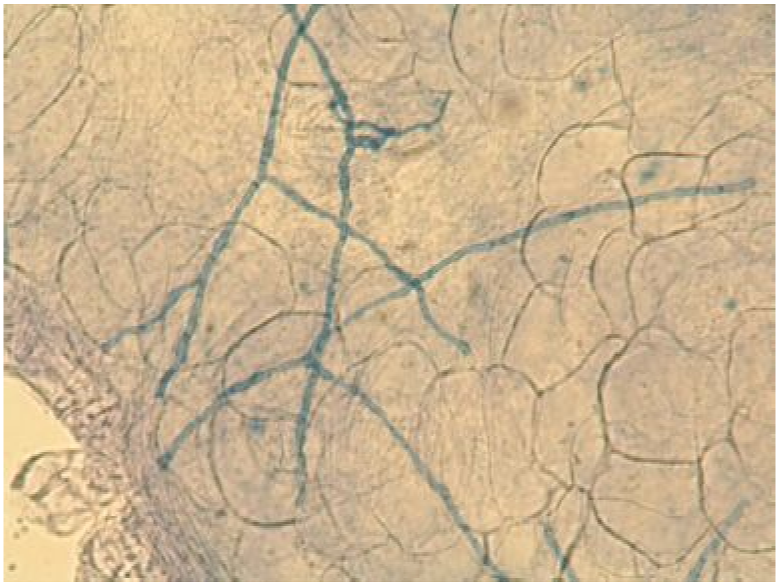

FIGURE 123-9 Branching hyphae easily seen at 40× high power using fungal stain (Swartz-Lamkins) from a scraping of tinea corporis. Note how the hyphae stand out with the blue ink color. (*Used with permission from Richard P. Usatine, MD.*)

- Skin scraping and culture—Gold standard, but more costly and may take up to 2 weeks for the culture to grow. Consider culture if the KOH is negative but tinea is still suspected, or when a microscope is not available.
- Skin biopsy sent in formalin for periodic acid-Schiff (PAS) staining when the KOH and culture remain negative but the clinical picture is consistent with a fungal infection.

DIFFERENTIAL DIAGNOSIS

- Granuloma annulare—Inflammatory, benign dermatosis of unknown cause, characterized by both dermal and annular papules (**Figure 123-10**) (see Chapter 148, Granuloma Annulare).

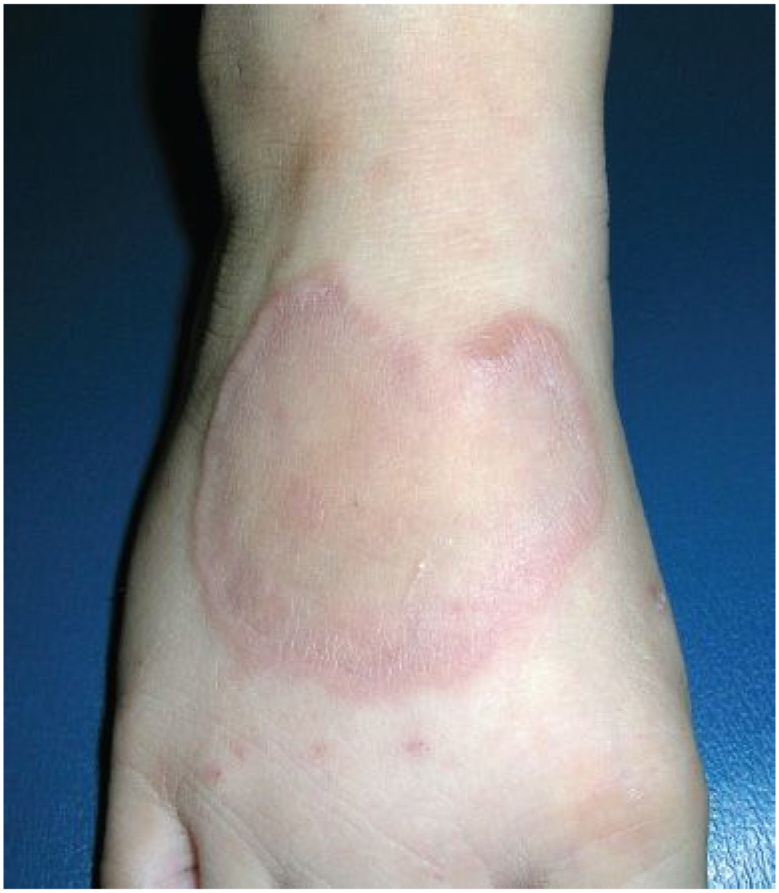

FIGURE 123-10 Granuloma annulare producing an annular lesion on the dorsum of the foot of this 3-year-old boy. No scale is visible. (*Used with permission from Richard P. Usatine, MD*.)

- Psoriasis—Plaque with scale on extensor surfaces and trunk. Occasionally, the plaques can have an annular appearance (**Figure 123-11**). Inverse psoriasis in intertriginous areas can also mimic tinea corporis (see Chapter 136, Psoriasis).

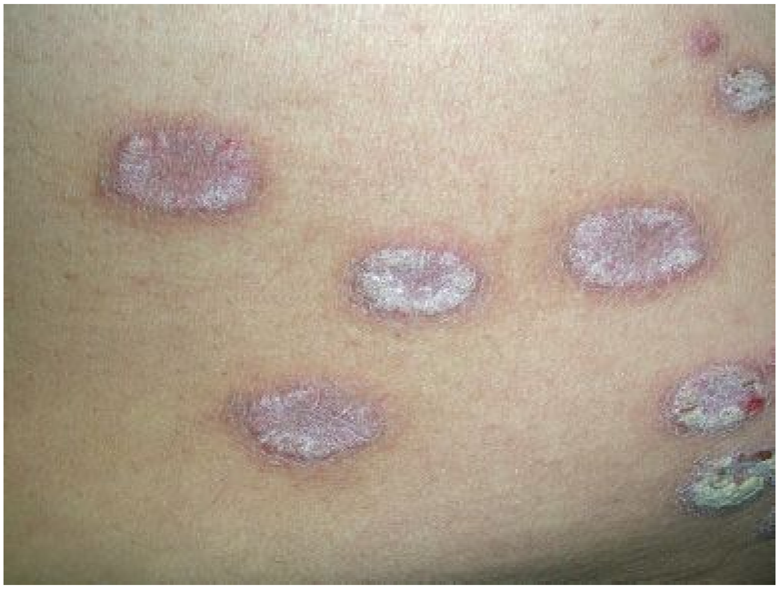

FIGURE 123-11 Annular lesions caused by psoriasis. Not all lesions that are annular with scale are tinea corporis. (*Used with permission from Richard P. Usatine, MD.*)

- Cutaneous larva migrans has serpiginous burrows made by the hookworm larvae, and these burrows can look annular and be confused with tinea corporis (see Chapter 129, Cutaneous Larva Migrans).
- Nummular eczema—Round coin-like red scaly plaques without central clearing (see Chapter 133, Nummular Eczema).

MANAGEMENT

- Use topical antifungal medications for tinea corporis that involves small areas of the body as seen in **Figures 123-12** and **123-13**.

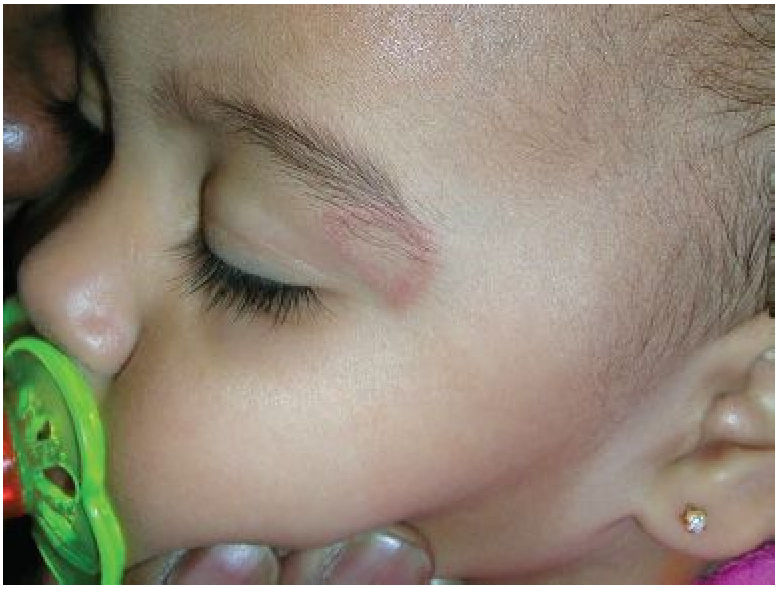

FIGURE 123-12 Tinea faciei near the eyebrow of this infant. (*Used with permission from Richard P. Usatine, MD*.)

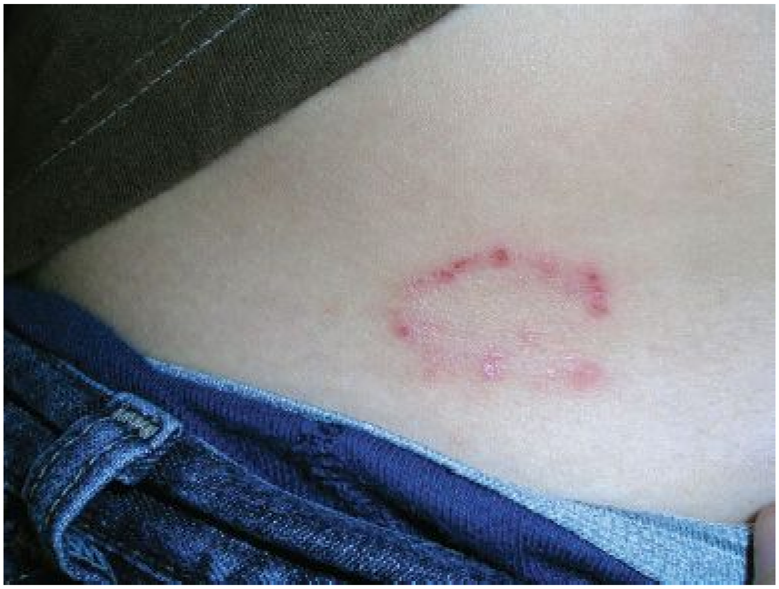

FIGURE 123-13 Tinea corporis producing an open ring near the waist of this 10-year-old boy. Note the erythema and scale along with central clearing. (*Used with permission from Richard P. Usatine, MD*.)

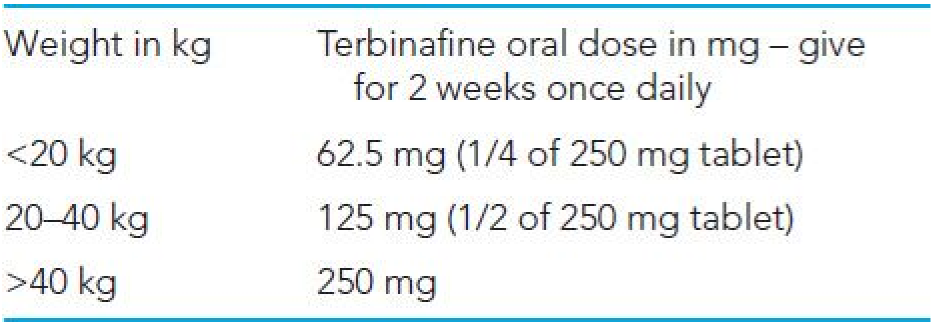
- Although all the topical antifungal agents may be effective, the evidence supports the greater effectiveness of the allylamines (terbinafine) over the less-expensive azoles for tinea pedis and corporis. Allylamines cure slightly more infections than azoles and are now available over the counter.[1,2] SOR Ⓐ

- Studies show that terbinafine 1 percent cream or solution applied once daily for 7 days is highly effective for tinea corporis/cruris.[3,4] The 1 percent cream (which is available over the counter as Lamisil AF) produced a mycologic cure of 84.2 percent versus 23.3 percent with placebo. Number needed to treat (NNT) = 1.6.[3] SOR Ⓐ
- Oral antifungal agents should be considered for first-line therapy for tinea corporis covering large areas of the body, as seen in **Figures 123-6** and **123-7**. However, it is not wrong to attempt topical treatment if the size of the area infected is on the borderline. The patient with tinea incognito in **Figure 123-5** did need oral therapy to resolve her infection. Unfortunately, the postinflammatory hyperpigmentation did not resolve well.
- One randomized controlled trial (RCT) showed that oral itraconazole 200 mg daily for 1 week is similarly effective, equally well tolerated, and at least as safe as itraconazole 100 mg for 2 weeks in the treatment of tinea corporis or cruris.[5] SOR Ⓑ
- In one study, patients with mycologically diagnosed tinea corporis and tinea cruris were randomly allocated to receive either 250 mg of oral terbinafine once daily or 500 mg of griseofulvin once daily for 2 weeks. The cure rates were higher for terbinafine at 6 weeks.[6] SOR Ⓑ
- In summary, if an oral agent is needed, the evidence is greatest for the use of:
  - Terbinafine orally daily for 2 weeks.[6] SOR Ⓑ (Terbinafine is available as an inexpensive generic prescription on the $4 and $5 plans in the US. It also has less drug interactions than itraconazole. For these reasons it is usually the preferred treatment when an oral agent is needed.) See **Table 123-1** for dosing.

TABLE 123-1 Dosing of Terbinafine By Weight for Tinea Corporis (for Children > 2 Years of Age)



Weight in kg	Terbinafine oral dose in mg – give for 2 weeks once daily
<20 kg	62.5 mg (1/4 of 250 mg tablet)
20–40 kg	125 mg (1/2 of 250 mg tablet)
>40 kg	250 mg

- Itraconazole (10 mg/kg/day) for 1 week or Itraconazole (5 mg/kg/day) daily for 2 weeks.[5] SOR Ⓑ (More expensive with more drug interactions than terbinafine.)

PREVENTION

Tinea corporis and cruris are dermatophyte infections that are particularly common in areas of excessive heat and moisture. A dry, cool environment may play a role in reducing infection. In addition, avoiding contact with farm animals and other individuals infected with tinea corporis and cruris may help in preventing infection. Preventative measures for tinea infections include practicing good personal hygiene; keeping the skin dry and cool at all times; and avoiding sharing towels, clothing, or hair accessories with infected individuals.[7]

In individuals involved in contact sports such as wrestling, a comprehensive skin disease prevention protocol includes some combination of the following: washing of wrestling mats before and after each practice and competition; showers before and after each practice; use of clean clothing before each practice; and exclusion of infected athletes.[8]

FOLLOW-UP

Consider follow-up appointments in 4 to 6 weeks for difficult and more widespread cases. If there are concerns about bacterial superinfection, follow-up should be sooner.

PATIENT EDUCATION

Keep the skin clean and dry. Infected pets should be treated.

124 TINEA CRURIS

Richard P. Usatine, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 17-year-old girl presents with a rash and itching in the groin (**Figure 124-1**). On examination, she was found to have an expanding scaly erythematous well-demarcated ring in the inguinal area. A skin scraping was treated with Swartz-Lamkins stain and the dermatophyte was highly visible under the microscope (**Figure 124-2**). The clinician diagnosed tinea cruris. She was offered a choice between an oral or topical antifungal medicine and she preferred to have the systemic treatment. She was given 2 weeks of oral terbinafine 250 mg daily and her tinea cruris resolved.

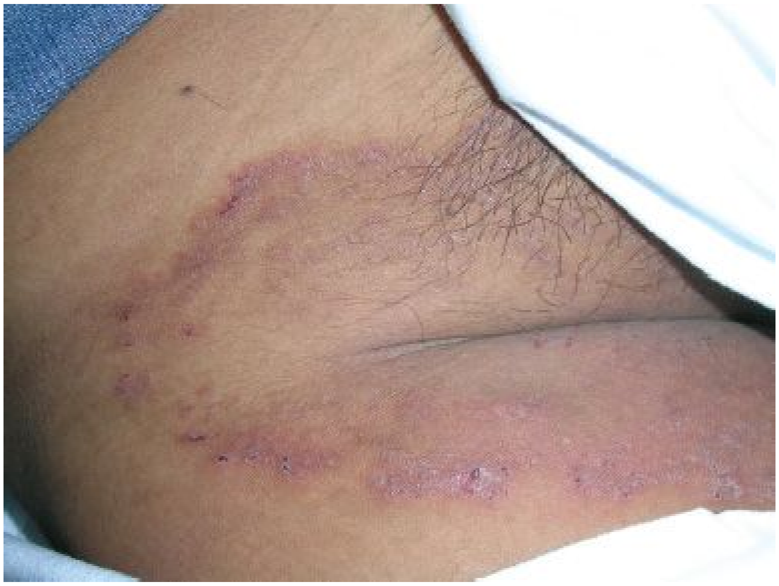

FIGURE 124-1 A 17-year-old woman with tinea cruris showing erythema and scale in an annular pattern. Central clearing is less common in tinea

cruris than tinea corporis but can occur. (*Used with permission from Richard P. Usatine, MD.*)

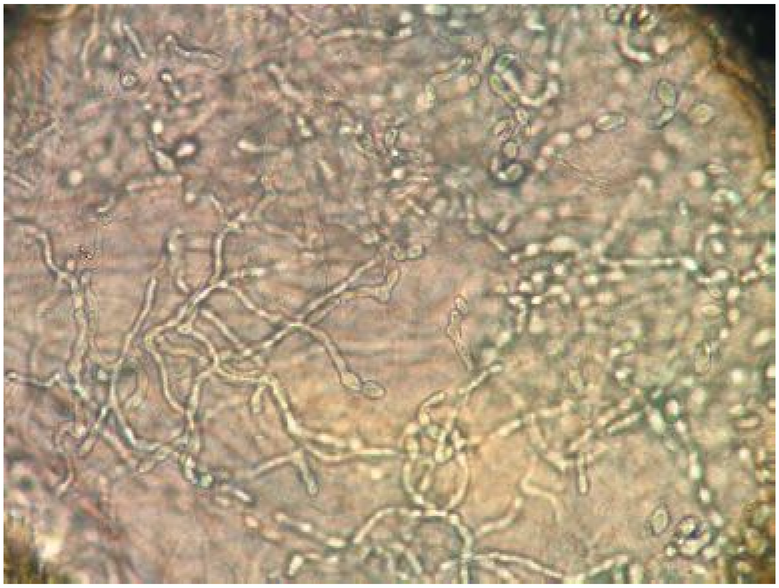

FIGURE 124-2 Microscopic view of the scraping of the groin in a patient with tinea cruris. The hyphae are easy to see under 40-power with Swartz-Lamkins stain. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Tinea cruris is an intensely pruritic superficial fungal infection of the groin and adjacent skin.

SYNONYMS

Crotch rot and jock itch.

EPIDEMIOLOGY

- Using data from the National Ambulatory Medical Care Survey and the National Hospital Ambulatory Medical Care Survey (NHAMCS) (1995–2004), there were more than 4 million annual visits for dermatophytoses and 8.4 percent were for tinea cruris.[1]
- Tinea cruris is more common in men than women (three-fold) and rare in children. However, it may be seen in teens after puberty.

ETIOLOGY AND PATHOPHYSIOLOGY

- Most commonly caused by the dermatophytes: *Trichophyton rubrum, Epidermophyton floccosum, Trichophyton mentagrophytes*, and *Trichophyton verrucosum. T. rubrum* is the most common organism.[2]
- Can be spread by fomites, such as contaminated towels.
- The fungal agents cause keratinases, which allow invasion of the cornified cell layer of the epidermis.[2]
- Autoinoculation can occur from fungus on the feet or hands.

RISK FACTORS

- Wearing tight-fitting or wet clothing or underwear has traditionally been suggested; however, in a study of Italian soldiers, none of the risk factors analyzed (e.g., hyperhidrosis, swimming pool attendance) were significantly associated with any fungal infection.[3]
- Obesity and diabetes mellitus may be risk factors.[4]

DIAGNOSIS

CLINICAL FEATURES

The cardinal features are scale and signs of inflammation. In light-skinned persons, inflammation often appears pink or red and in dark-skinned persons, the inflammation often leads to hyperpigmentation (see **Figure 124-4**). Occasionally, tinea cruris may show central sparing with an annular pattern as in **Figure 124-1**, but most often is homogeneously distributed as in **Figures 124-3** and **124-4**. If the tinea cruris was missed and the patient was given topical steroids to treat the itching, the tinea cruris can become tinea incognito and the eruption can expand down the thighs (**Figure 124-5**). Tinea incognito often shows concentric rings within the scaling plaques.

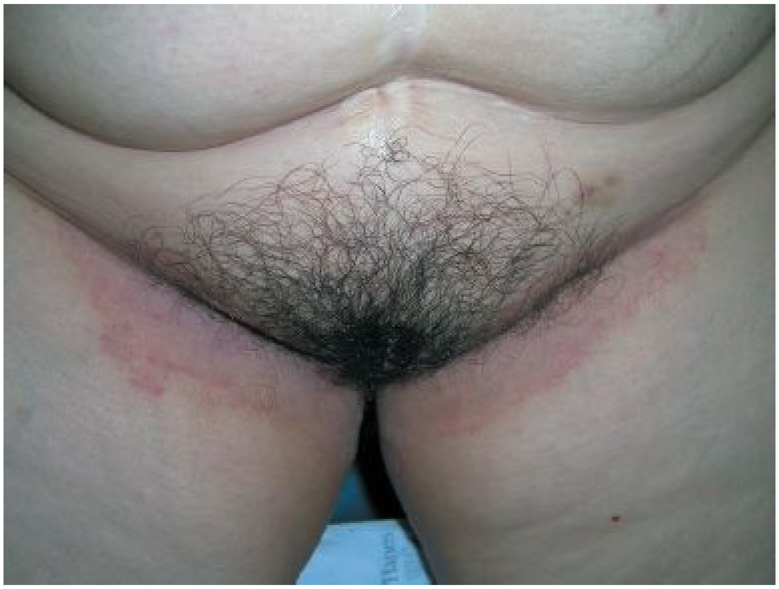

FIGURE 124-3 A woman with tinea cruris showing erythema and scale. This patient had tinea on her feet, face, and under her breasts. (*Used with permission from Richard P. Usatine, MD*.)

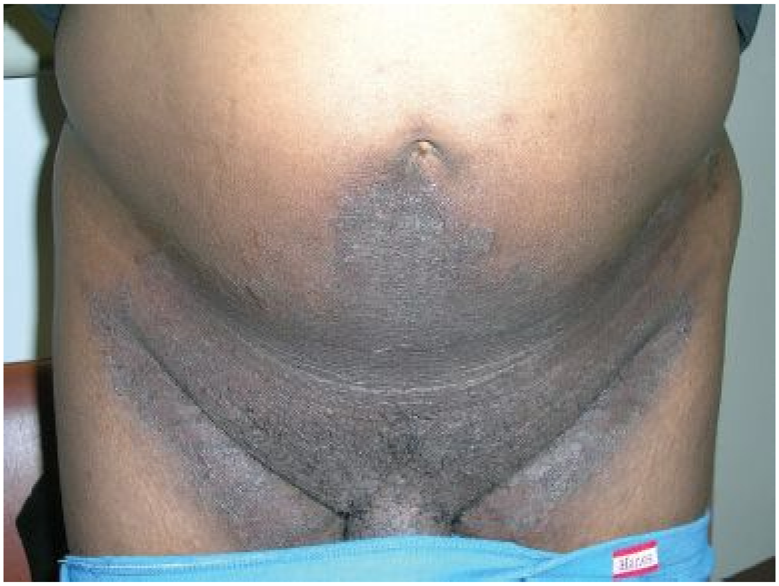

FIGURE 124-4 Tinea cruris that has expanded beyond the inguinal area in this young black man. Postinflammatory hyperpigmentation is visible throughout the infected area. (*Used with permission from Richard P. Usatine, MD.*)

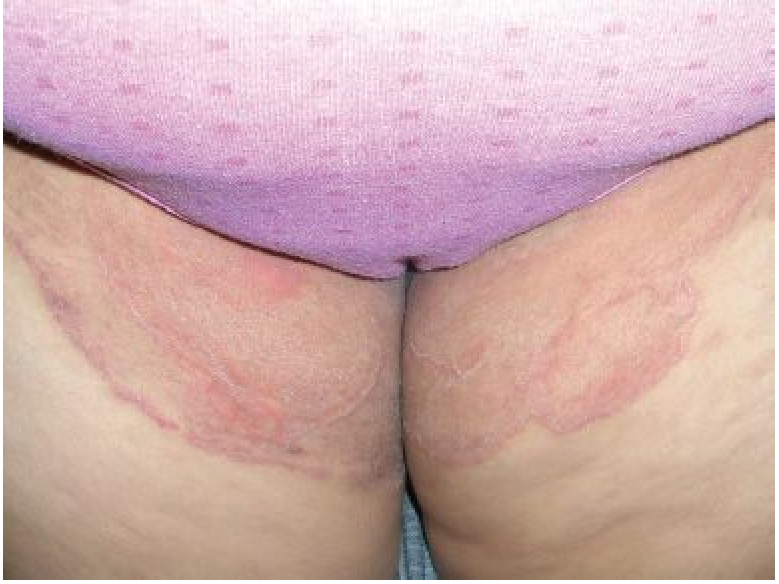

FIGURE 124-5 Tinea incognito with concentric rings within the scaling plaques. The original tinea cruris was misdiagnosed and the patient was given topical steroids for the itching. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

By definition tinea cruris is in the inguinal area. However, the fungus can grow outside of this area to involve the abdomen and thighs (**Figures 124-4** and **124-5**). Tinea may be present in multiple locations simultaneously including the feet.

LABORATORY STUDIES

Diagnosis is often made based on clinical presentation, but a skin scraping treated with KOH and a fungal stain analyzed under the microscope can be helpful (**Figure 124-2**). False negatives may occur if scraping is inadequate, patient is using topical antifungals, or the viewer is inexperienced. See Chapter 120, Fungal Overview, for more information on doing a good KOH preparation.

Skin scraping and culture is definitive but expensive, and may take up to 2 weeks for the culture to grow.

UV lamp can be used to look for the coral red fluorescence of erythrasma (see Chapter 102, Erythrasma). Most tinea cruris is caused by *T. rubrum* so will not fluoresce.

DIFFERENTIAL DIAGNOSIS

- Cutaneous *Candida* in the groin can become red and have scaling that extends to the thigh and scrotum. Tinea cruris does not often involve the scrotum. *Candida* often has satellite lesions. However, tinea cruris can also have a few satellite lesions (see Chapter 120, Candidiasis).
- Erythrasma in the groin appears similar to tinea cruris. It is less common than tinea cruris and may show coral red fluorescence with a UV light (**Figure 124-6**) (see Chapter 102, Erythrasma).

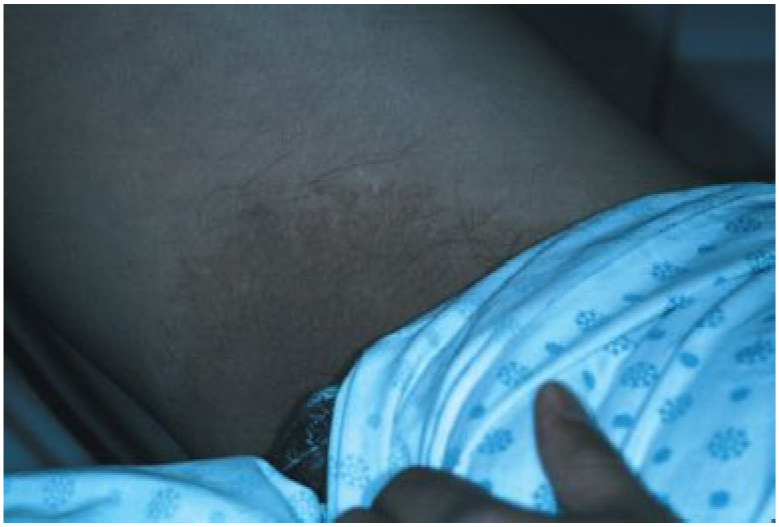

FIGURE 124-6 Erythrasma in the groin can be mistaken for tinea cruris. This erythrasma fluoresced coral red with an ultraviolet light. (*Used with permission from Richard P. Usatine, MD*.)

- Contact dermatitis can occur anywhere on the body. If the contact is near the groin this can be mistaken for tinea cruris (see Chapter 131, Contact Dermatitis).
- Inverse psoriasis causes inflammation in the intertriginous areas of the body. It does not have the thick plaques of plaque psoriasis. Inverse psoriasis may be misdiagnosed as a fungal infection until an astute clinician recognizes the pattern or does a biopsy (**Figure 124-7**; see Chapter 136, Psoriasis).

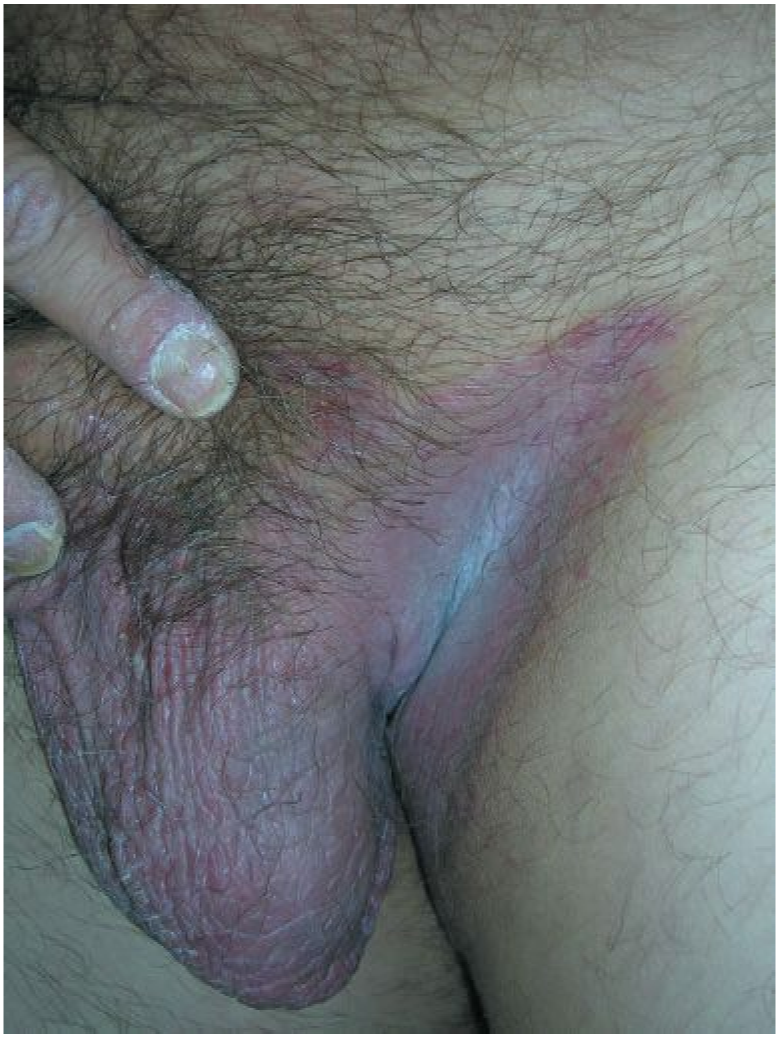

FIGURE 124-7 Inverse psoriasis in a man who also has the nail changes of psoriasis. (*Used with permission from Richard P. Usatine, MD*.)

- Intertrigo is an inflammatory condition of the skin folds. It induced or aggravated by heat, moisture, maceration, and friction.[5] The condition frequently is worsened by infection with *Candida* or dermatophytes so there is some overlap with tinea cruris.

MANAGEMENT

- Tinea cruris (**Figure 124-8**) is best treated with a topical allylamine or an azole antifungal (SOR A, based on multiple randomized controlled trials [RCTs]).[6] Differences in current comparison data are insufficient to stratify the two groups of topical antifungals.[7] In one RCT, cure rates were higher at 1 week with butenafine (once daily for 2 weeks) versus clotrimazole (twice daily for 4 weeks) (26.5% vs. 2.9%, respectively), but were not significantly different at 4 or 8 weeks.[8]

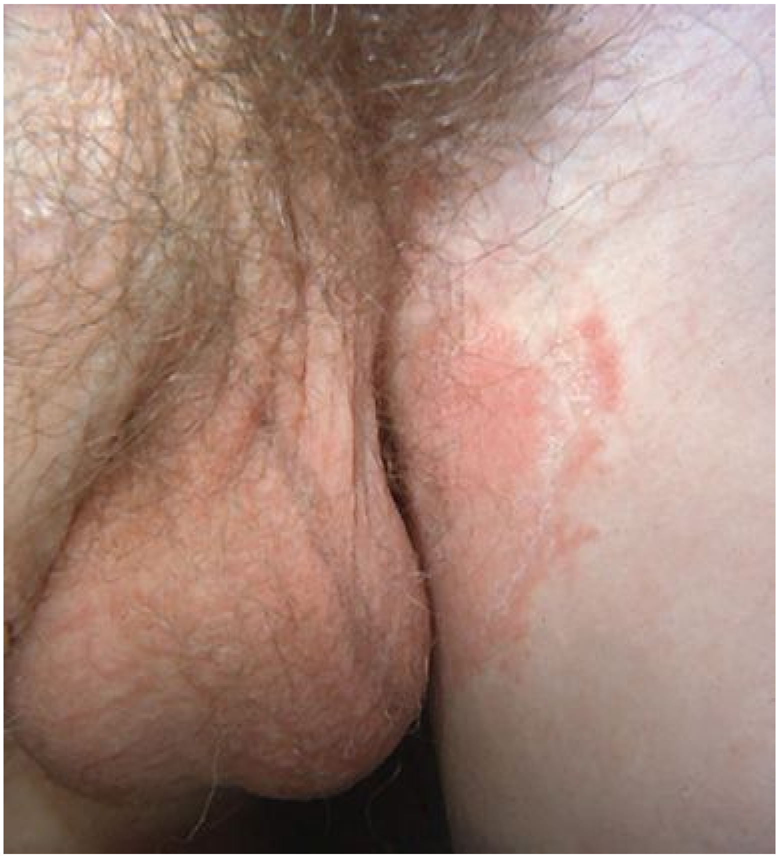

FIGURE 124-8 Tinea cruris in this teenage boy. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- The fungicidal allylamines (naftifine and terbinafine) and butenafine (allylamine derivative) are a more costly group of topical tinea treatments, yet they are more convenient as they allow for a shorter duration of treatment compared with fungistatic azoles (clotrimazole, econazole, ketoconazole, oxiconazole, miconazole, and sulconazole).[7]

- Topical azoles should be continued for 4 weeks and topical allylamines for 2 weeks or until clinical cure.[6–8] SOR Ⓐ
- Fluconazole 150 mg once weekly for 2 to 4 weeks appears to be effective in the treatment of tinea cruris in adults.[9] SOR Ⓑ This could be applied to teens as well.
- One RCT showed that itraconazole 200 mg daily for 1 week is similarly effective, equally well tolerated, and at least as safe as itraconazole 100 mg daily for 2 weeks in the treatment of tinea corporis or cruris (clinical response: 73% and 80% at the end of follow-up, respectively).[10] SOR Ⓑ While the study was performed in adults this could be applied to teens.
- Adult patients with mycologically diagnosed tinea corporis and tinea cruris were randomly allocated to receive either 250 mg of oral terbinafine once daily or 500 mg of griseofulvin once daily for 2 weeks. The cure rates were higher for terbinafine at 6 weeks.[11] SOR Ⓑ Oral terbinafine is a good and affordable choice for teenagers if topical treatment fails. SOR Ⓒ
- If there are multiple sites infected with fungus, treat all active areas of infection simultaneously to prevent reinfection of the groin from other body sites. If the tinea is widespread as in the patient in **Figure 124-3**, an oral agent is warranted.

FOLLOW-UP

As needed.

PATIENT EDUCATION

- Advise patients with tinea pedis to put on their socks before their undershorts to reduce the possibility of direct contamination. SOR Ⓒ

- Dry the groin completely after bathing. SOR Ⓒ

125 TINEA PEDIS

Richard P. Usatine, MD
Katie Reppa, MD

PATIENT STORY

An 8-year-old boy presents with itching between his toes for 1 month (**Figure 125-1**). The pediatrician looks between his toes and sees maceration with white material. The patient was diagnosed with tinea pedis and treated successfully with a topical nonprescription antifungal medication.

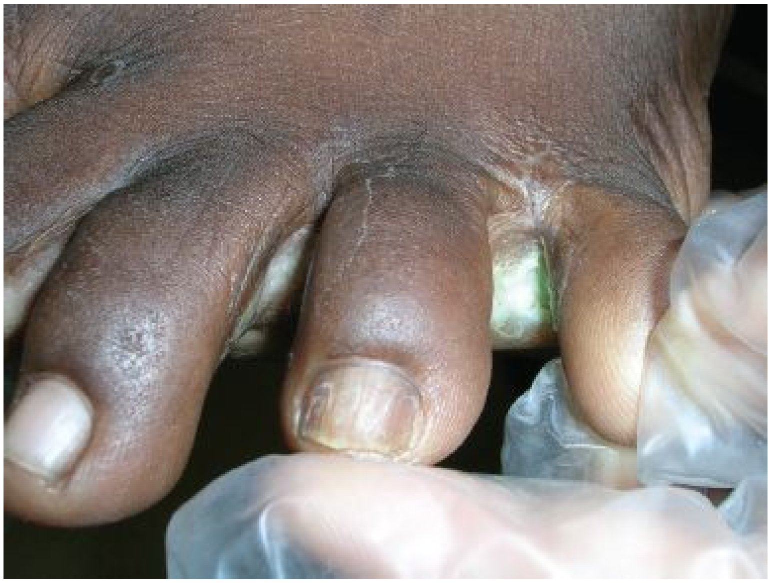

FIGURE 125-1 Tinea pedis seen in the interdigital spaces of an 8-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Tinea pedis is a common cutaneous infection of the feet caused by dermatophyte fungus. The clinical manifestation presents in 1 of 3 major patterns: interdigital, moccasin, and inflammatory. Concurrent fungal infection of the nails (onychomycosis) occurs frequently.

SYNONYMS

Athlete’s foot.

EPIDEMIOLOGY

- Tinea pedis is thought to be the world’s most common dermatophytosis.[1]
- 70 percent of the population will be infected with tinea pedis at some time.[1]
- More commonly affects males than females.[1]
- Prevalence increases with age and it is rare before adolescence.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- A cutaneous fungal infection most commonly caused by *Trichophyton rubrum*.[1]
- *Trichophyton mentagrophytes* and *Epidermophyton floccosum* follow in that order.
- *T. rubrum* causes most tinea pedis and onychomycosis.

RISK FACTORS

- Male gender.
- Use of public showers, baths, or pools.[2]
- Household member with tinea pedis infection.[2]
- Certain occupations (miners, farmers, soldiers, meat factory workers, or marathon runners).[2]
- Use of immunosuppressive drugs.

DIAGNOSIS

TYPICAL DISTRIBUTION AND MORPHOLOGY

Three types of tinea pedis:

- Interdigital type—Most common (**Figure 125-2**).

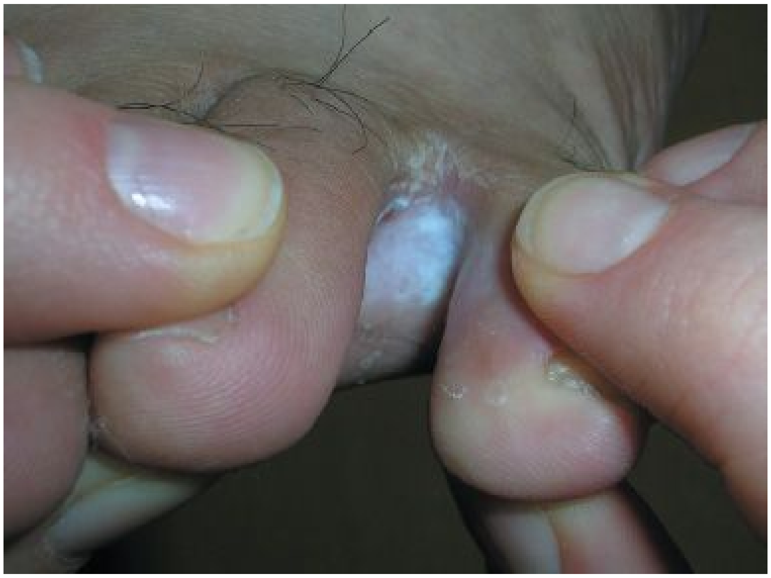

FIGURE 125-2 Tinea pedis seen in the interdigital space between the fourth and fifth digits. This is the most common area to see tinea pedis. (*Used with*

permission from Richard P. Usatine, MD.)

- Moccasin type (**Figure 125-3**).

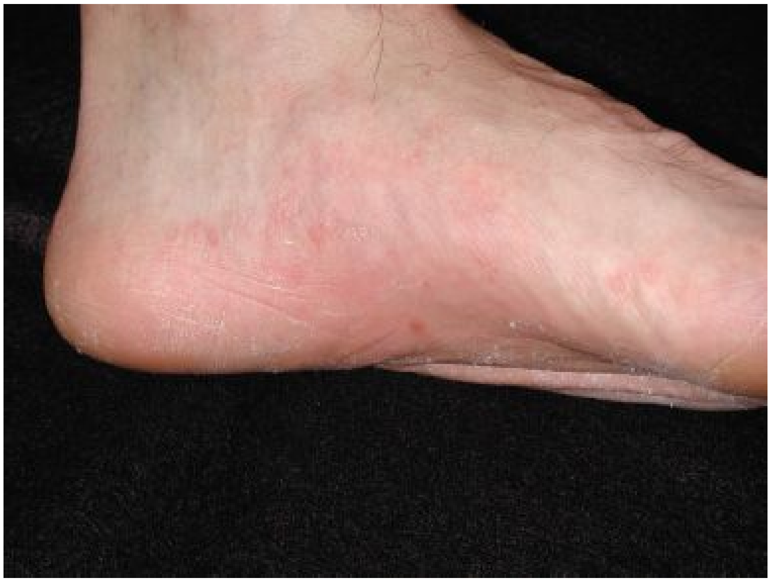

FIGURE 125-3 Tinea pedis in the moccasin distribution. (*Used with permission from Richard P. Usatine, MD.*)

- Inflammatory/vesicular type—Least common (**Figure 125-4**).

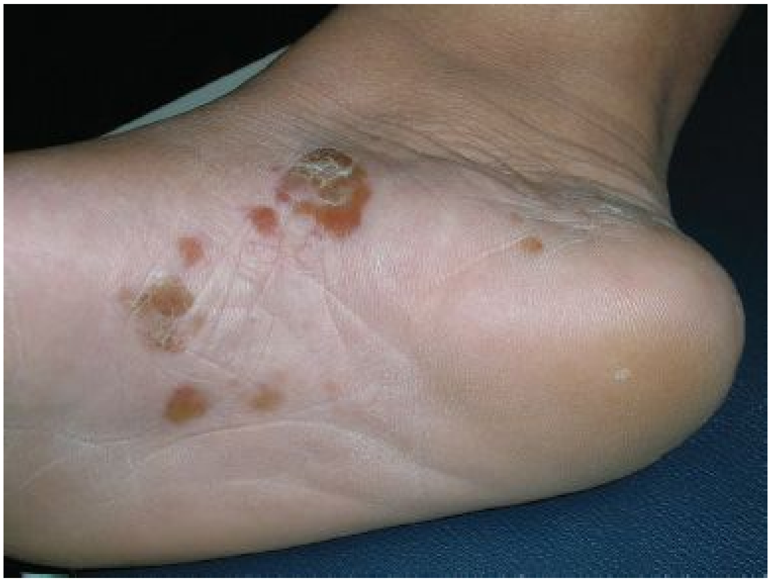

FIGURE 125-4 Vesicular tinea pedis with vesicles and bullae over the arch region of the foot. The arch is a typical location for vesiculobullous tinea

pedis. (*Used with permission from Richard P. Usatine, MD.*)

Some authors describe an ulcerative type (**Figure 125-5**).

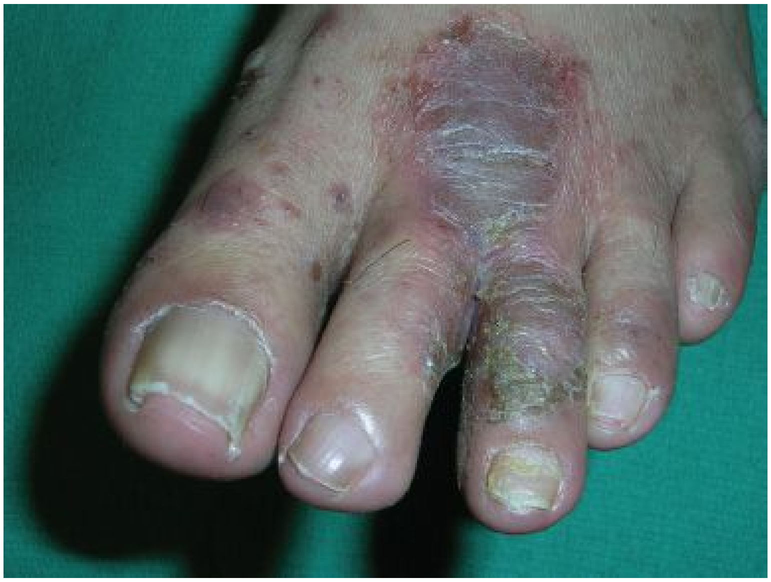

FIGURE 125-5 Ulcerative tinea pedis with spreading vesicles related to a bacterial superinfection. The patient was treated with antifungals and antibiotics. (*Used with permission from Richard P. Usatine, MD.*)

CLINICAL FEATURES

- Interdigital—White or green fungal growth between toes with erythema, maceration, cracks, and fissures—especially between fourth and fifth digits (**Figures 125-1** and **125-2**). The dry type has more scale and the moist type becomes macerated.
- Moccasin—Scale on sides and soles of feet (**Figure 125-3**).
- Vesicular—Vesicles and bullae on feet especially around the arch (**Figure 125-4**).
- Ulcerative tinea pedis is characterized by rapidly spreading vesiculopustular lesions, ulcers, and erosions, typically in the web spaces (**Figure 125-5**). It is accompanied by a secondary bacterial infection. This can lead to cellulitis or lymphangitis.

- Examine nails for evidence of onychomycosis—Fungal infections of nails may include subungual keratosis, yellow or white discolorations, dysmorphic nails (Chapter 163, Onychomycosis).
- Examine to exclude cellulitis that may show erythema, swelling, tenderness with red streaks tracking up the foot and lower leg (Chapter 103, Cellulitis).

TYPICAL DISTRIBUTION

Between the toes, on the soles, and lateral aspects of the feet.

LABORATORY STUDIES

Diagnosis is often made based on clinical presentation but a skin scraping treated with KOH and a fungal stain analyzed under the microscope can be helpful (**Figure 125-6**). The child with the itching foot in **Figure 125-7** could have tinea pedis, dyshidrotic eczema, juvenile plantar dermatosis, or a contact allergy. The positive KOH made the diagnosis easy.

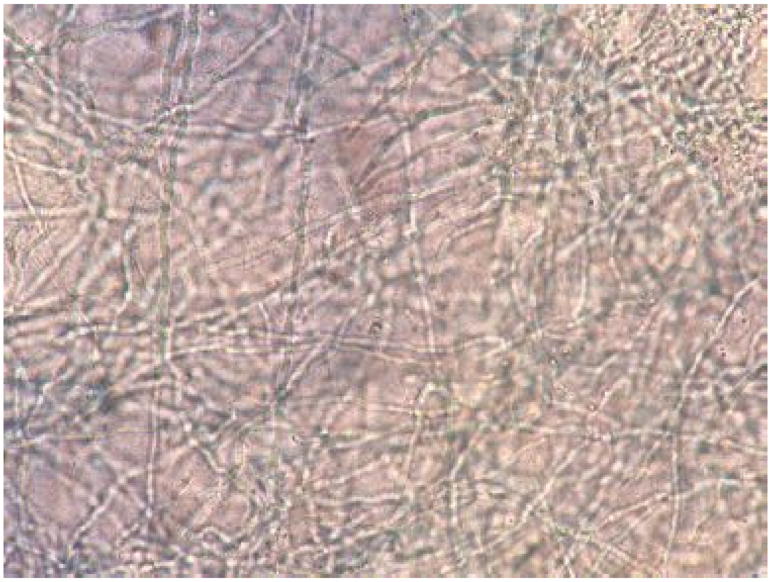

FIGURE 125-6 Microscopic view of the scraping of tinea pedis. The hyphae are easy to see under 40-power with Swartz-Lamkins stain. (*Used with permission from Richard P. Usatine, MD.*)

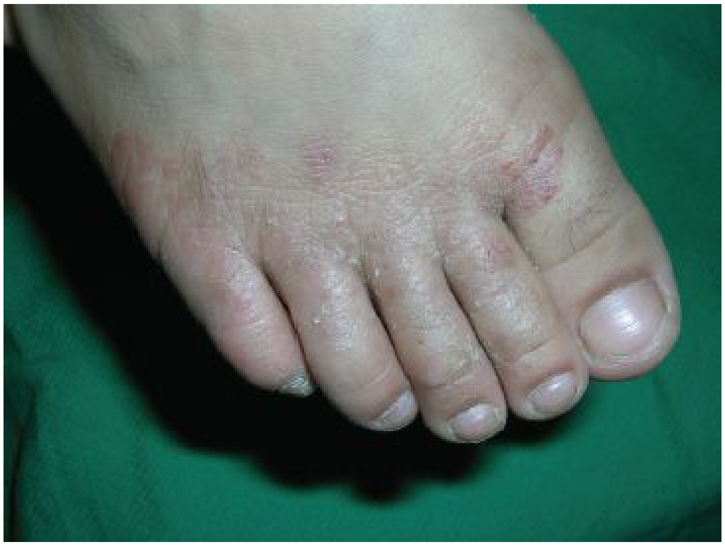

FIGURE 125-7 Tinea pedis around the toes and the forefoot of this child. A KOH preparation was made to confirm the suspicion of tinea pedis as this presentation could be caused by other etiologies. (*Used with permission from Richard P. Usatine, MD.*)

A culture of a skin scraping is helpful if the KOH is negative and there is a fear that it is a false negative. Unfortunately it may take up to 2 weeks for the culture to grow and the cost is higher than a simple KOH.

DIFFERENTIAL DIAGNOSIS

- Juvenile plantar dermatosis causes erythema, scale, cracking and fissures on the weight-bearing surface of the foot in children (**Figure 125-8**). It is also called “sweaty sock syndrome” as these children often have hyperhidrosis and sweaty socks. Another name is “wet-dry foot syndrome” as it is caused by excessive sweating of the feet in occlusive footwear and rapid drying in a low-humidity environment. It tends to be worse in the winter and more common in children with atopic dermatitis. The use of emollient ointments is helpful. A KOH preparation will be negative.

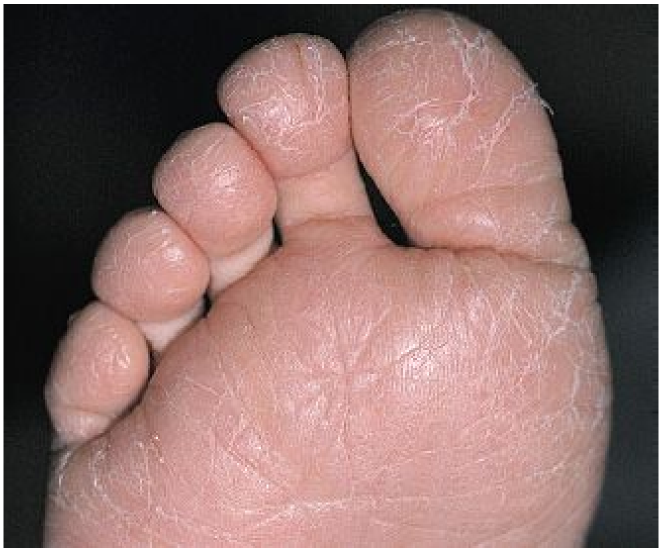

FIGURE 125-8 Juvenile plantar dermatitis causes erythema, scale, cracking and fissures on the weight-bearing surface of the foot. It is also called “sweaty sock syndrome” as these children often have hyperhidrosis and sweaty socks. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th ed. Figure 6-13, New York, NY: McGraw-Hill, 2008*.)

- Pitted keratolysis: well-demarcated pits or erosions in the sole of the foot caused by bacteria (**Figure 125-9**; Chapter 101, Pitted Keratolysis).

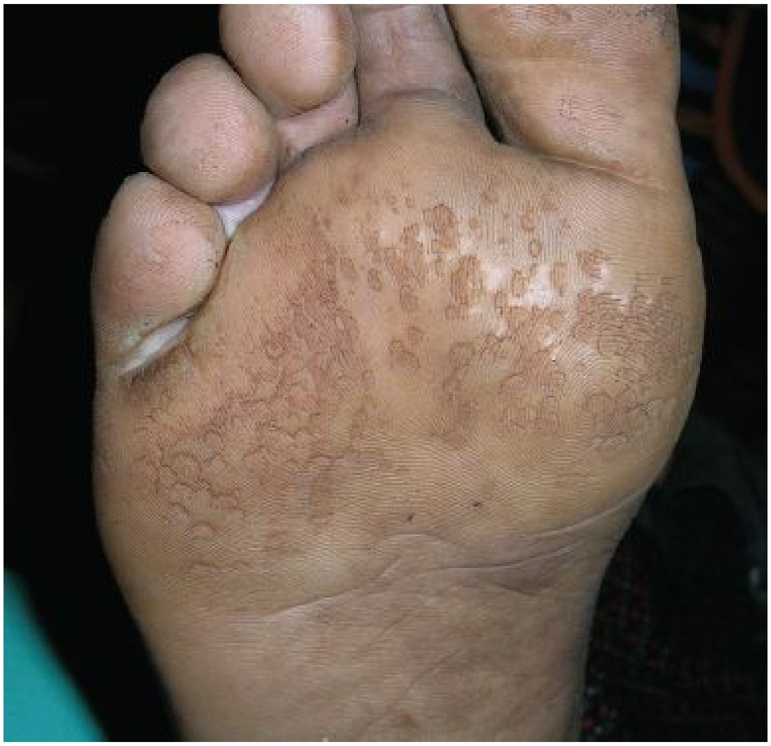

FIGURE 125-9 Pitted keratolysis on the sole of the foot with some interdigital tinea pedis. The pits are caused by bacteria and treatment involves an antibiotic. (*Used with permission from Richard P. Usatine, MD.*)

- Contact dermatitis: tends to be seen on the dorsum and sides of the foot (**Figure 125-10**) often related to allergens in rubber or leather. It is more common in children with atopic dermatitis (Chapter 131, Contact Dermatitis).

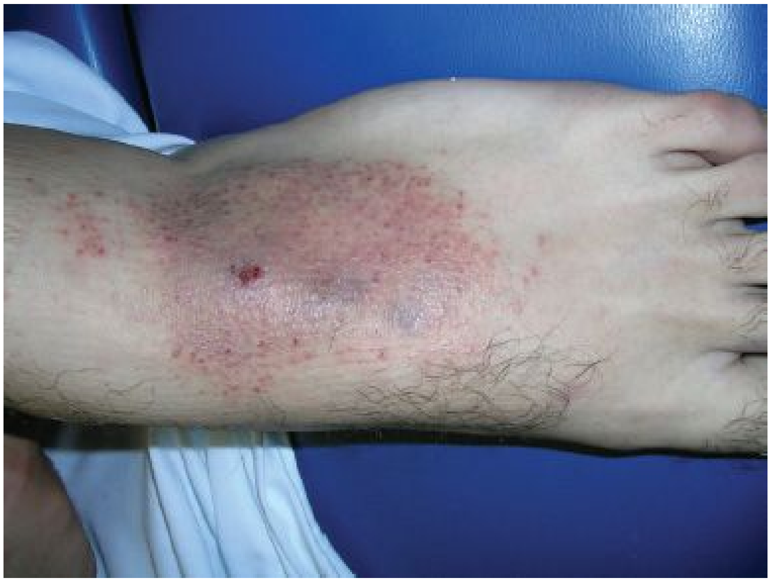

FIGURE 125-10 Contact dermatitis to a chemical in the rubber of the shoes with typical distribution that crosses the dorsum of the foot. (*Used with permission from Richard P. Usatine, MD.*)

- Dyshidrotic eczema is characterized by scale and tapioca-like vesicles on the hands and feet (**Figure 125-11**). It is also more common in children with atopic dermatitis.

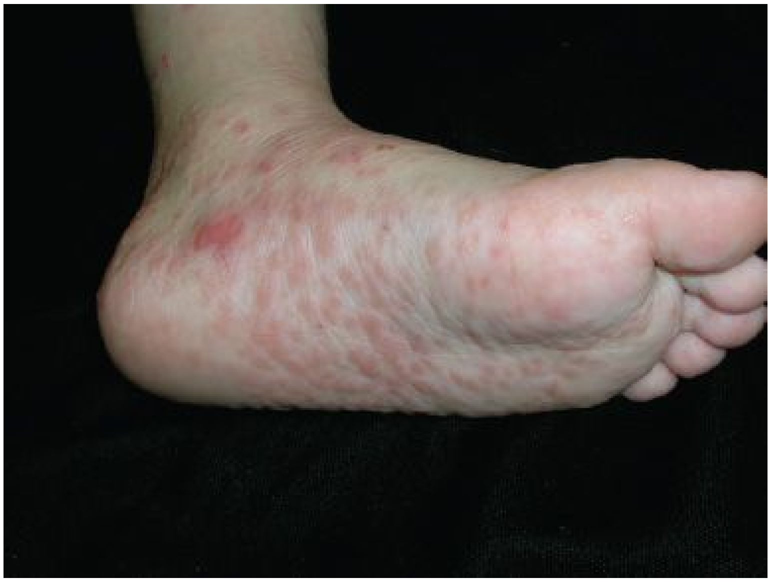

FIGURE 125-11 Dyshidrotic eczema on the foot of a 4-year-old boy showing tapioca vesicles and scaling on the sides and bottom of the foot.

This boy also has severe atopic dermatitis. (*Used with permission from Richard P. Usatine, MD.*)

- Friction blisters—Blisters on the feet of persons leading an active athletic lifestyle.
- Psoriasis—Can mimic tinea pedis but will usually be present in other areas as well (**Figure 125-12**; Chapter 152, Psoriasis).

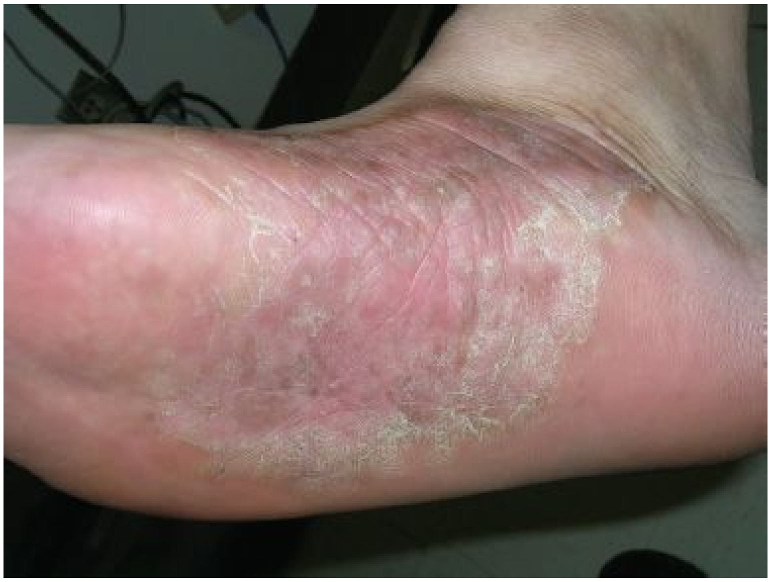

FIGURE 125-12 Plantar psoriasis in a young patient with other areas of psoriasis also present. KOH preparation was negative. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

Table 125-1 discusses management of tinea pedis.

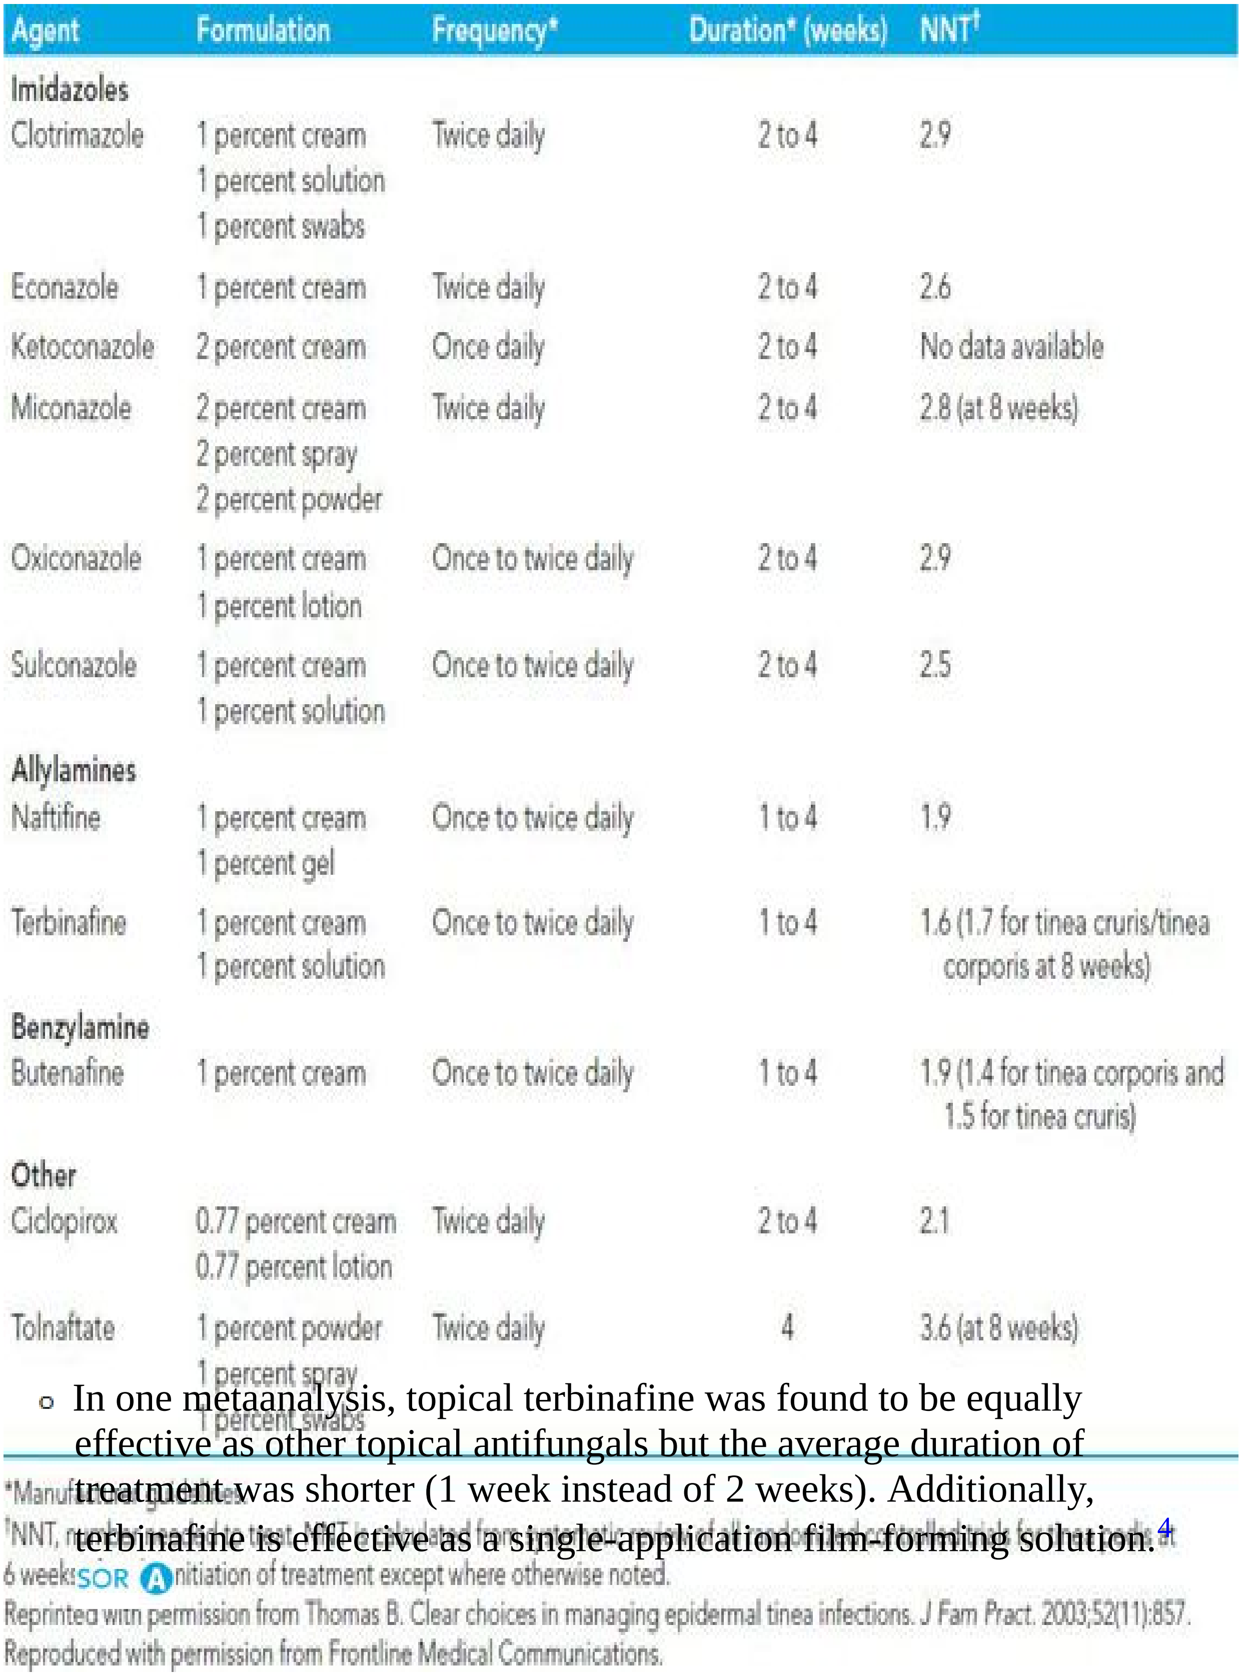
TOPICAL ANTIFUNGALS

- Systematic review of 70 trials of topical antifungals showed good evidence for efficacy compared to placebo for the following:
    - Allylamines (naftifine, terbinafine, butenafine).[3] SOR Ⓐ
    - Azoles (clotrimazole, miconazole, econazole).[3] SOR Ⓐ
    - Allylamines cure slightly more infections than azoles but are more expensive.[3] SOR Ⓐ
    - No differences in efficacy found between individual allylamines or individual azoles (**Table 125-2**). SOR Ⓐ

TABLE 125-2 Topical Antifungal Medications



Agent	Formulation	Frequency*	Duration* (weeks)	NNT†
Imidazoles				
Clotrimazole	1 percent cream 1 percent solution 1 percent swabs	Twice daily	2 to 4	2.9
Econazole	1 percent cream	Twice daily	2 to 4	2.6
Ketoconazole	2 percent cream	Once daily	2 to 4	No data available
Miconazole	2 percent cream 2 percent spray 2 percent powder	Twice daily	2 to 4	2.8 (at 8 weeks)
Oxiconazole	1 percent cream 1 percent lotion	Once to twice daily	2 to 4	2.9
Sulconazole	1 percent cream 1 percent solution	Once to twice daily	2 to 4	2.5
Allylamines				
Naftifine	1 percent cream 1 percent gel	Once to twice daily	1 to 4	1.9
Terbinafine	1 percent cream 1 percent solution	Once to twice daily	1 to 4	1.6 (1.7 for tinea cruris/tinea corporis at 8 weeks)
Benzylamine				
Butenafine	1 percent cream	Once to twice daily	1 to 4	1.9 (1.4 for tinea corporis and 1.5 for tinea cruris)
Other				
Ciclopirox	0.77 percent cream 0.77 percent lotion	Twice daily	2 to 4	2.1
Tolnaftate	1 percent powder 1 percent spray 1 percent swabs	Twice daily	4	3.6 (at 8 weeks)

*Manuf[illegible]

†NNT, n[illegible]

6 week[illegible]nitiation of treatment except where otherwise noted.

Reprinted with permission from Thomas B. Clear choices in managing epidermal tinea infections. *J Fam Pract*. 2003;52(11):857. Reproduced with permission from Frontline Medical Communications.

- In one metaanalysis, topical terbinafine was found to be equally effective as other topical antifungals but the average duration of treatment was shorter (1 week instead of 2 weeks). Additionally, terbinafine is effective as a single-application film-forming solution.[4]

SOR A

ORAL ANTIFUNGALS

- Systematic review of 12 trials, involving 700 participants: oral terbinafine for 2 weeks cures 52 percent more patients than oral griseofulvin.[5] SOR Ⓐ
- Terbinafine is equal to itraconazole in patient outcomes.[5] SOR Ⓐ
- No significant differences in comparisons between a number of oral agents.[5] SOR Ⓐ

Dosing for tinea pedis needing oral therapy:

- Itraconazole two 100 mg tablets daily for 1 week.[6]
- Terbinafine 250 mg PO daily for 1 to 2 weeks.[6]

Patients with onychomycosis may have recurrences of the skin infection related to the fungus that remains in the nails and, therefore, may need oral treatment for 3 months to achieve better results.

Topical urea (Carmol, Keralac), available in 10 to 40 percent concentrations, may be useful to decrease scaling in patients with hyperkeratotic soles.[5]

ALTERNATIVE THERAPY

One small pilot study with 56 participants showed significant improvement or resolution of symptoms in patients treated by wearing socks containing copper-oxide fibers daily for a minimum of 8 to 10 days.[7] SOR Ⓑ

PATIENT EDUCATION

- Do not go barefoot in public showers and locker rooms. SOR Ⓒ
- Keep feet dry and clean, and use clean socks and shoes that allow the feet to get fresh air. SOR Ⓒ

- Use the topical medication beyond the time in which the feet look clear to prevent relapse.

126 TINEA VERSICOLOR

Richard P. Usatine, MD
Melissa M. Chan, MD

PATIENT STORY

A young boy is brought to the office by his parents with a 2-year history of his skin turning white on his trunk (**Figure 126-1**). The boy denies any symptoms. His parents are afraid that he has the same thing that Michael Jackson had (vitiligo). The clinician does a KOH preparation of the white skin and finds the spaghetti and meatball pattern of *Malassezia furfur* under the microscope (**Figure 126-2**). His parents are relieved to receive a prescription for the tinea versicolor and to find out that it is rarely spread to others through contact.

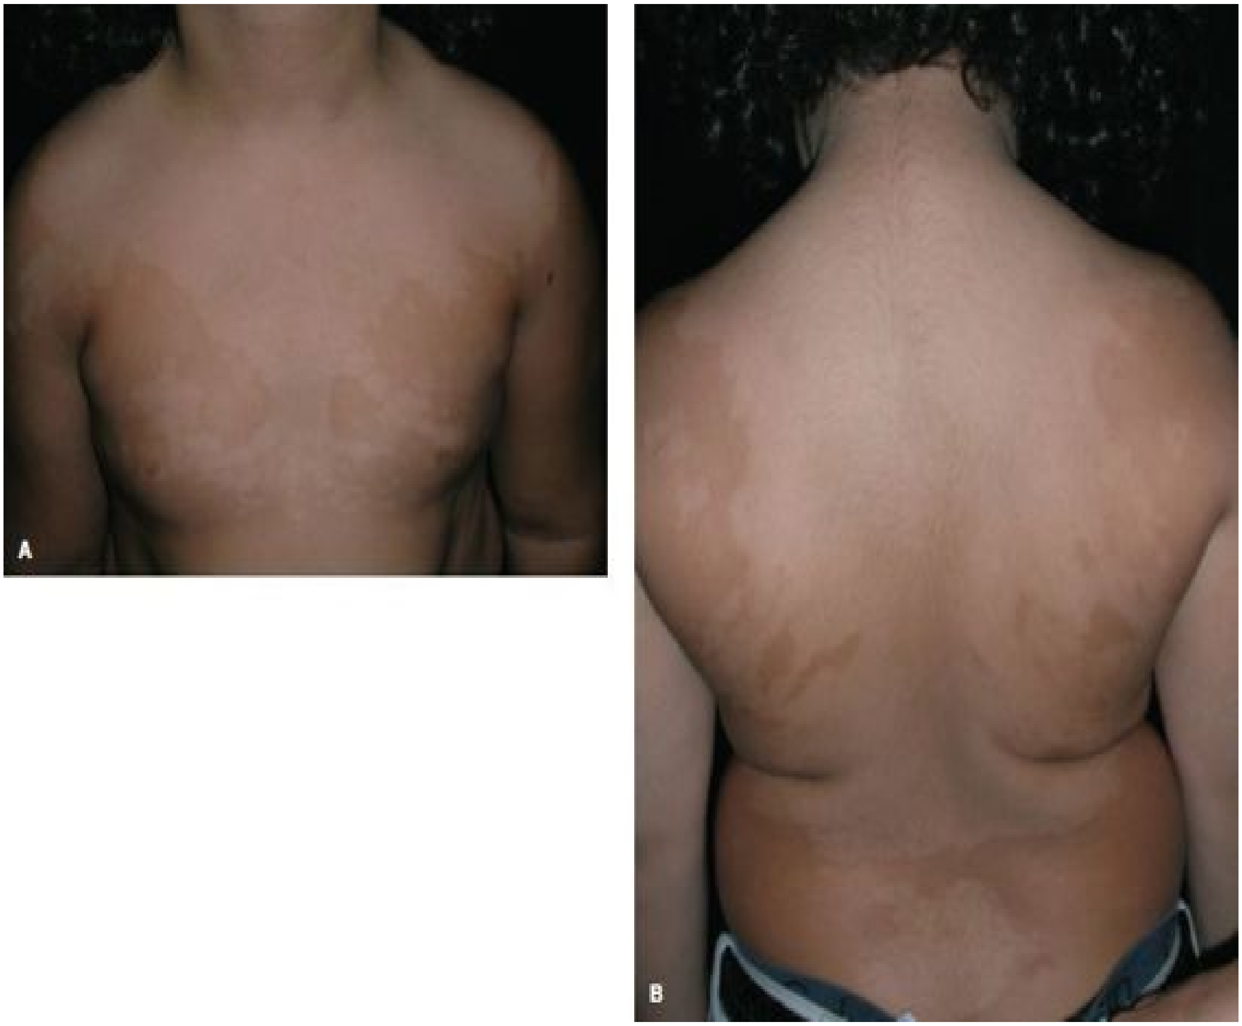

FIGURE 126-1 Tinea versicolor in a young boy showing large areas of hypopigmentation. The darker brown is his normal skin color. The *Malassezia furfur* damages the melanocytes causing the hypopigmentation. The hypopigmentation is reversible with treatment. (*Used with permission from Richard P. Usatine, MD*.)

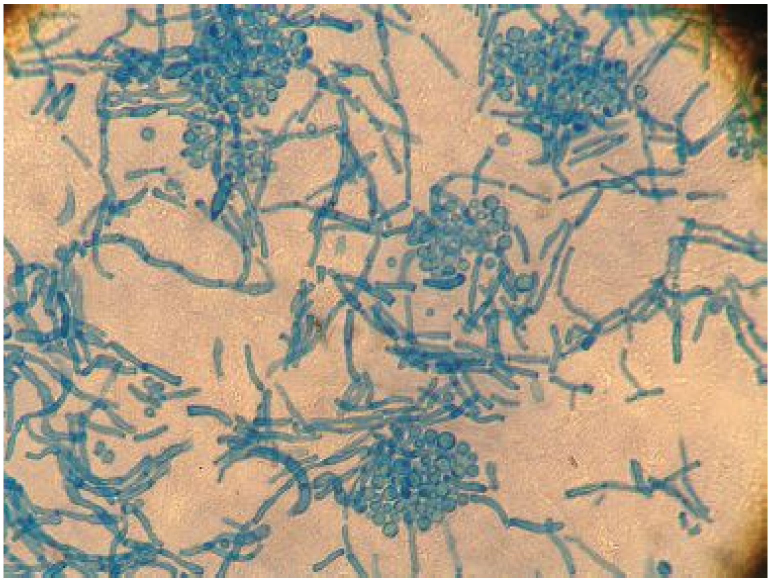

FIGURE 126-2 Positive KOH for tinea versicolor. Microscopic examination of scrapings done from the previous patient showing short mycelial forms and round yeast forms suggestive of spaghetti and meatballs. Swartz-Lamkins stain was used. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Tinea versicolor is a common superficial skin infection caused by the dimorphic lipophilic yeast *Pityrosporum* (*Malassezia furfur*). The most typical presentation is a set of hypopigmented macules and patches with fine scale over the trunk in a cape-like distribution.

SYNONYMS

Pityriasis versicolor is actually a more accurate name as "tinea" implies a dermatophyte infection. Tinea versicolor is caused by *Pityrosporum* and not a dermatophyte.

EPIDEMIOLOGY

- Seen more commonly in men than in women.
- Seen more often during the summer and is especially common in warm and humid climates.

ETIOLOGY AND PATHOPHYSIOLOGY

- Tinea versicolor is caused by *Pityrosporum* (*M. furfur*), which is a lipophilic yeast that can be normal human cutaneous flora.
- *Pityrosporum* exists in two shapes—*Pityrosporum ovale* (oval) and *Pityrosporum orbiculare* (round).
- Tinea versicolor starts when the yeast that normally colonizes the skin changes from the round form to the pathologic mycelial form and then invades the stratum corneum.[1]
- *Pityrosporum* is also associated with seborrhea and *Pityrosporum* folliculitis.
- The white and brown colors are secondary to damage caused by the *Pityrosporum* to the melanocytes, while the pink is an inflammatory reaction to the organism.
- *Pityrosporum* thrive on sebum and moisture; they tend to grow on the skin in areas where there are sebaceous follicles secreting sebum.

DIAGNOSIS

CLINICAL FEATURES

Tinea versicolor consists of hypopigmented, hyperpigmented, or pink macules and patches on the trunk that are finely scaling and well-demarcated. Versicolor means a variety of or variation in colors; tinea versicolor tends to come in white, pink, and brown colors (**Figures 126-1** to **126-5**).

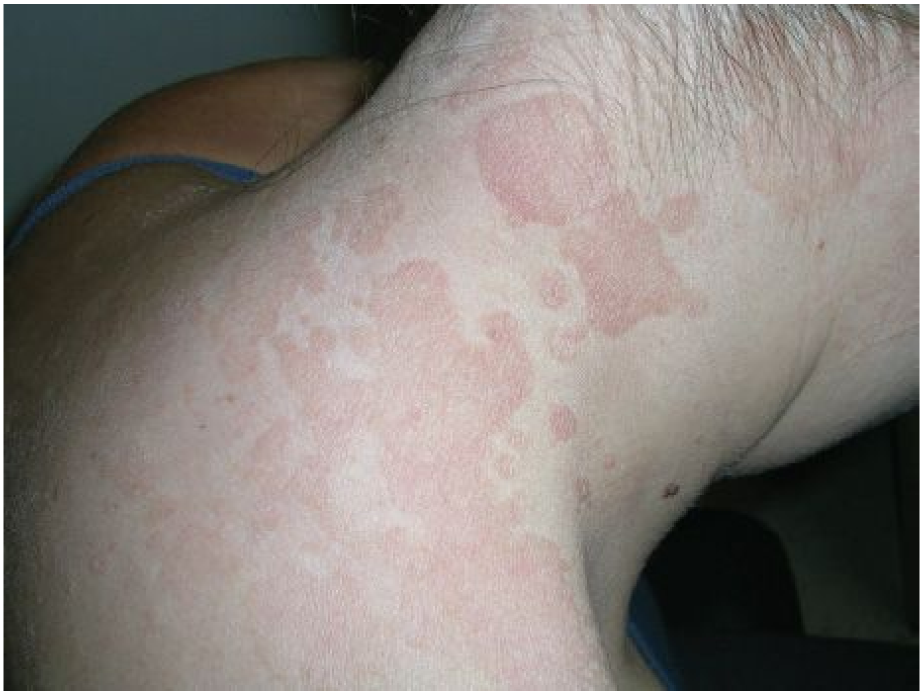

FIGURE 126-3 Pink scaly patches caused by tinea versicolor on the neck of a teenage girl. (*Used with permission from Richard P. Usatine, MD*.)

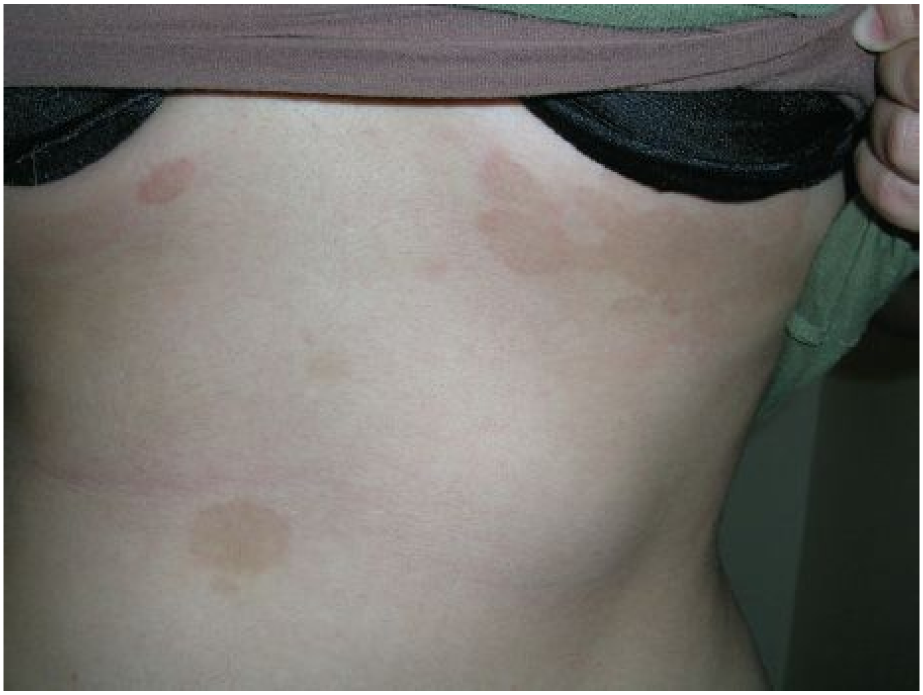

FIGURE 126-4 Brown patches of tinea versicolor on abdomen of this teenage girl. (*Used with permission from Richard P. Usatine, MD.*)

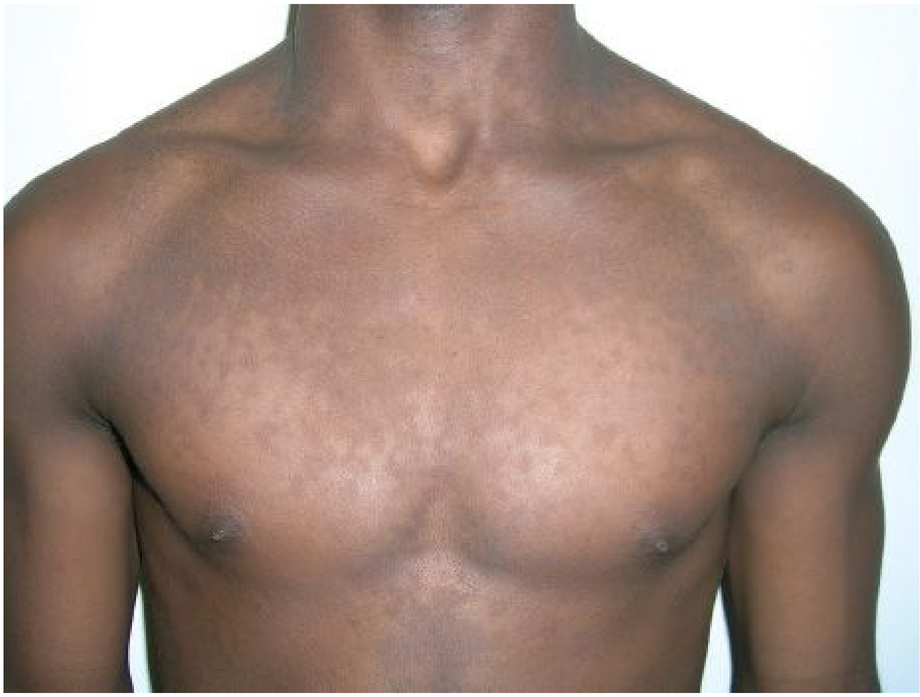

FIGURE 126-5 Hyperpigmented variant of tinea versicolor in a young black man. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

Tinea versicolor is found on the chest, abdomen, upper arms, and back, whereas seborrhea tends to be seen on the scalp, face, and anterior chest.

LABORATORY STUDIES

A scraping of the scaling portions of the skin may be placed onto a slide using the side of another slide or a scalpel. KOH with DMSO (DMSO helps the KOH dissolve the keratinocytes faster and reduces the need for heating the slide) is placed on the slide and covered with a coverslip. Microscopic examination reveals the typical "spaghetti-and-meatballs" pattern of tinea versicolor. The "spaghetti," or more accurately "ziti," is the short mycelial form and the "meatballs" are the round yeast form (**Figures 126-6** and **126-7**). Fungal stains such as the Swartz-Lamkins stain help make the identification of the fungal elements easier.

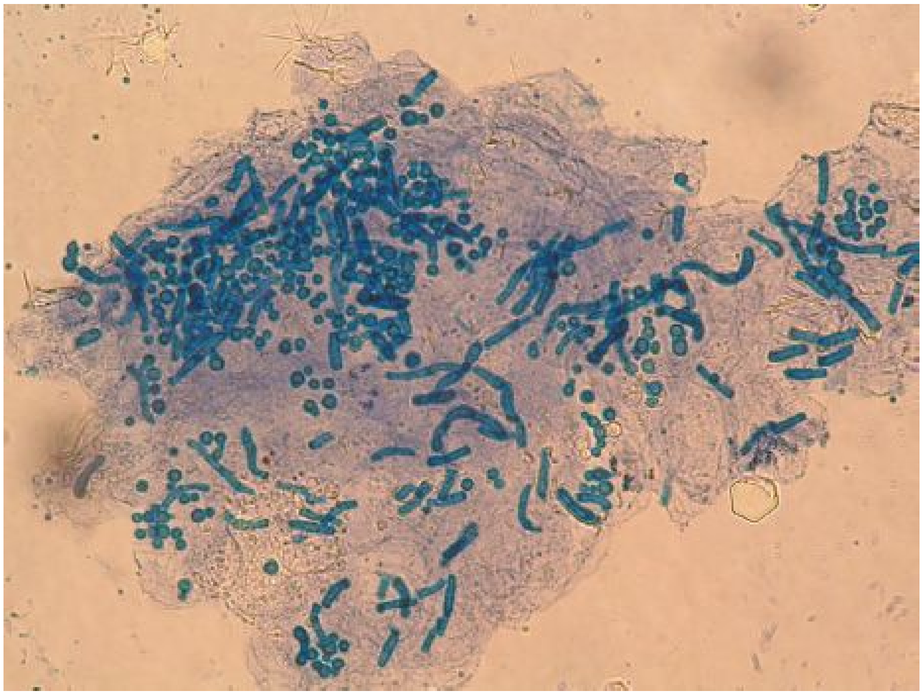

FIGURE 126-6 Positive KOH for tinea versicolor showing short mycelial forms and round yeast forms suggestive of spaghetti (or ziti) and meatballs. Swartz-Lamkins stain was used. (*Used with permission from Richard P. Usatine, MD.*)

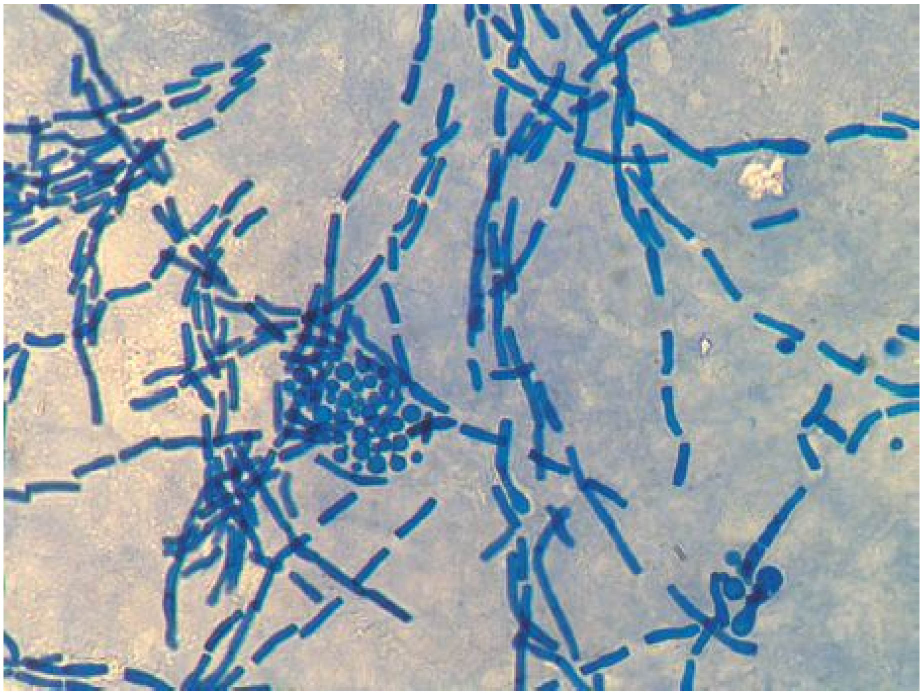

FIGURE 126-7 Close-up of Malassezia furfur (Pityrosporum) showing the ziti-and-meatball appearance after Swartz-Lamkins stain was applied to the scraping of tinea versicolor. (*Used with permission from Richard P. Usatine, MD*.)

DIFFERENTIAL DIAGNOSIS

- Pityriasis rosea has a fine collarette scale around the border of the lesions and is frequently seen with a herald patch. Negative KOH (see Chapter 137, Pityriasis Rosea).
- Secondary syphilis is usually not scaling and tends to have macules on the palms and soles. Negative KOH (see Chapter 181, Syphilis).
- Tinea corporis is rarely as widespread as tinea versicolor and each individual lesion usually has central clearing and a well-defined, raised, scaling border. The KOH preparation in tinea corporis shows hyphae with multiple branch points and not the “ziti-and-meatballs” pattern of tinea versicolor (see Chapter 123, Tinea Corporis).

- Vitiligo—The degree of hypopigmentation is greater and the distribution is frequently different with vitiligo involving the hands and face (see Chapter 167, Vitiligo and Hypopigmentation).
- Pityriasis alba—Lightly hypopigmented areas with slight scale that tend to be found on the face and trunk of children with atopy. These patches are frequently smaller and rounder than tinea versicolor (**Figures 126-8**; see Chapter 130, Atopic Dermatitis).

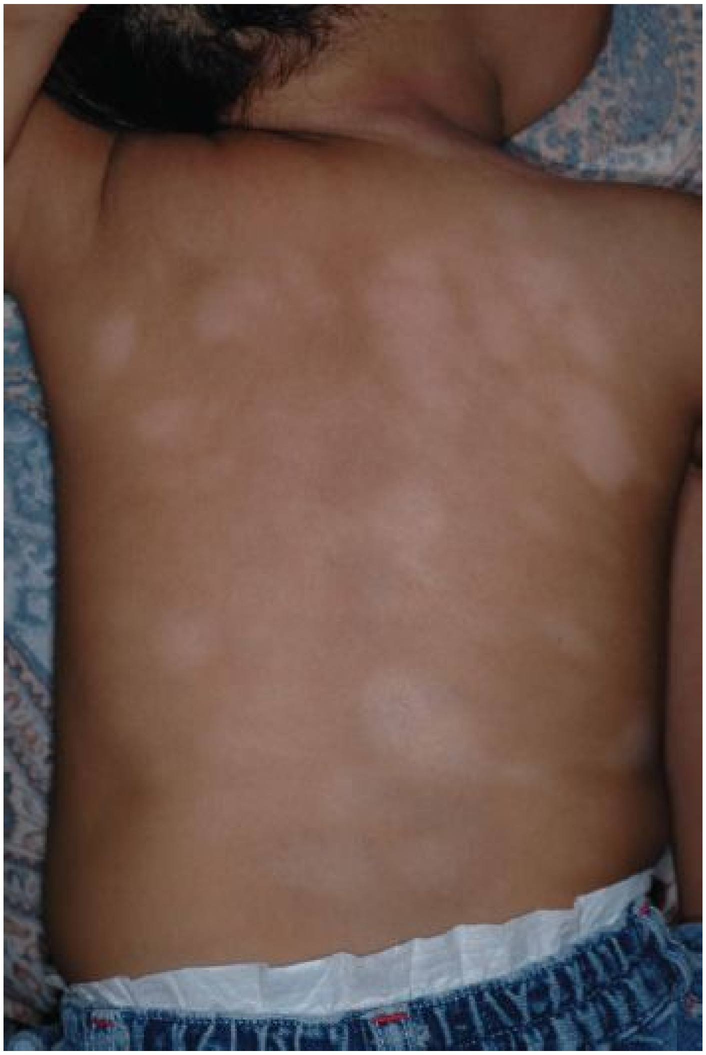

FIGURE 126-8 Pityriasis alba on the back of this young boy that could be mistaken for tinea versicolor. The KOH was negative and the child had other manifestations of atopic dermatitis. (*Used with permission from Richard P. Usatine, MD.*)

- *Pityrosporum* folliculitis is caused by the same organism but presents with pink or brown papules on the back. The patient complains of itchy rough skin and the KOH is positive.

MANAGEMENT

TOPICAL

- Because tinea versicolor is usually asymptomatic, the treatment is mostly for cosmetic reasons.
- The mainstay of treatment has been topical therapy using antidandruff shampoos, because the same *Pityrosporum* species that cause seborrhea and dandruff also cause tinea versicolor.[1,2]
- Patients may apply selenium sulfide 2.5 percent lotion or shampoo, or zinc pyrithione shampoo to the involved areas daily for 1 to 2 weeks. Various amounts of time are suggested to allow the preparations to work, but there are no studies that show a minimum exposure time needed. A typical regimen involves applying the lotion or shampoo to the involved areas for 10 minutes and then washing it off in the shower. SOR Ⓒ
- One study used ketoconazole 2 percent shampoo (Nizoral) as a single application or daily for 3 days and found it safe and highly effective in treating tinea versicolor.[3] SOR Ⓑ
- Topical antifungal creams for smaller areas of involvement can include ketoconazole and clotrimazole. SOR Ⓒ

ORAL TREATMENT AND PREVENTION

- A single-dose 400-mg oral fluconazole provided the best clinical and mycologic cure rate, with no relapse during 12 months of follow-up.[4] SOR Ⓑ

- A single dose of 300 mg of oral fluconazole repeated weekly for 2 weeks was equal to 400 mg of ketoconazole in a single dose repeated weekly for 2 weeks. No significant differences in efficacy, safety, and tolerability between the two treatment regimens were found.[5] SOR Ⓑ
- A single-dose 400-mg oral ketoconazole to treat tinea versicolor is safe and cost-effective compared to using the newer, more expensive, oral antifungal agents, such as itraconazole.[6,7] SOR Ⓑ
- Oral itraconazole 200 mg given twice a day for 1 day a month has been shown to be safe and effective as a prophylactic treatment for tinea versicolor.[8] SOR Ⓑ
- There is no evidence that establishes the need to sweat after taking oral antifungals to treat tinea versicolor.

FOLLOW-UP

None needed unless it is a stubborn or recurrent case. Recurrent cases can be treated with monthly topical or oral therapy.

PATIENT EDUCATION

Patients should be told that the change in skin color will not reverse immediately. The first sign of successful treatment is the lack of scale. The yeast acts like a sunscreen in the hypopigmented macules. Sun exposure will hasten the normalization of the skin color in patients with hypopigmentation.

SECTION 6 INFESTATIONS

127 LICE

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A 12-year-old girl presented to a homeless clinic with her mother for itching on her head. The physical examination revealed multiple nits in her long straight hair (**Figure 127-1**). A live adult louse was also found crawling on the hairs around her neck (**Figure 127-2**). The clinician also examined her mother and found a few nits on the hair behind her ears. There were no other members of the family living at the shelter so both were treated with permethrin now and in one week to kill any remaining live nits before they hatch. The clinician alerted the shelter staff of this infestation and other families were found to be infested. The girl was given permission to return to school if she completed her treatment with the permethrin cream rinse. The clinician recommended that clothes, bed clothes, combs and brushes be washed in hot water.

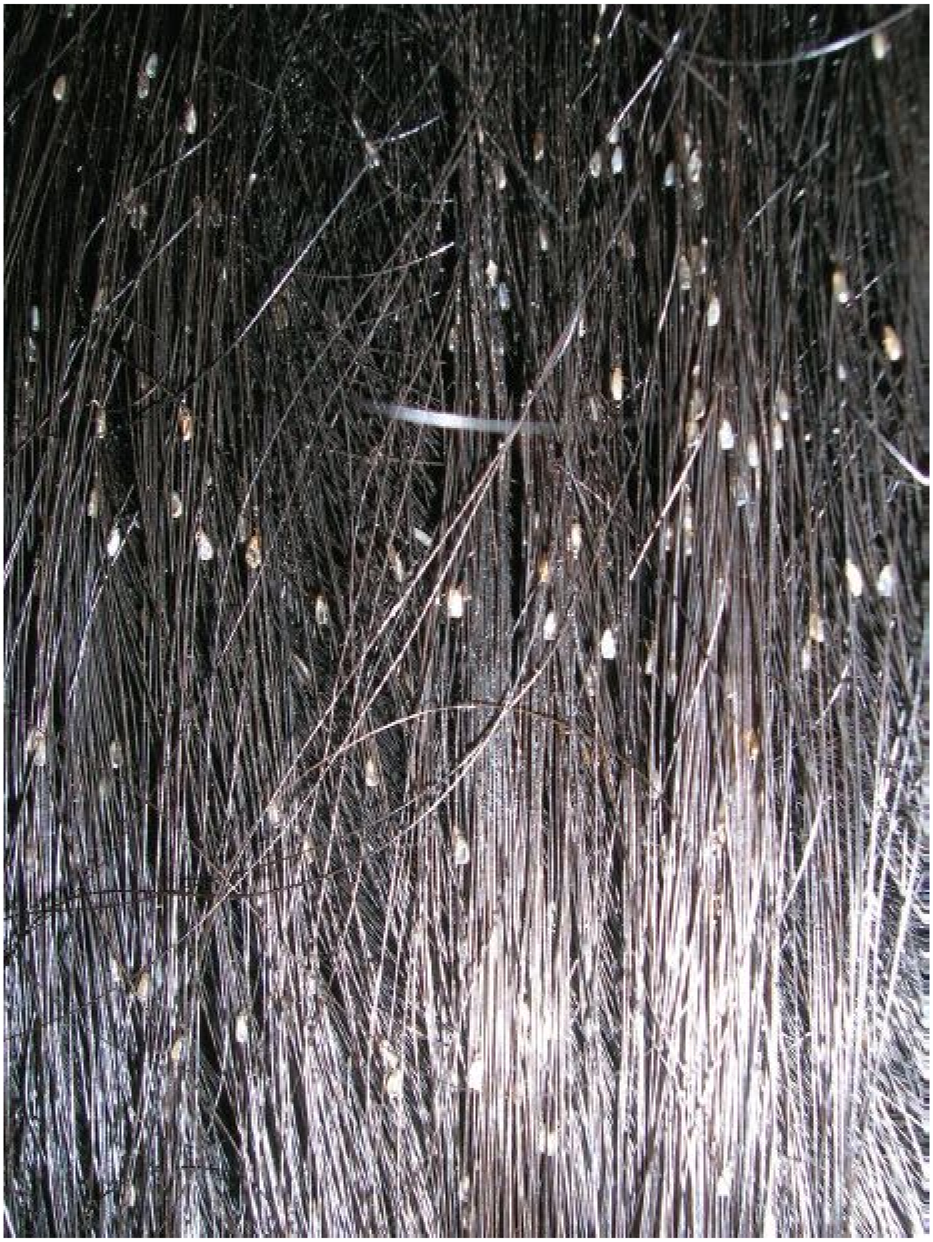

FIGURE 127-1 Pearly nits of the head louse seen in the hair of a 12-year-old girl living in a homeless shelter. (*Used with permission from Richard P. Usatine, MD*.)

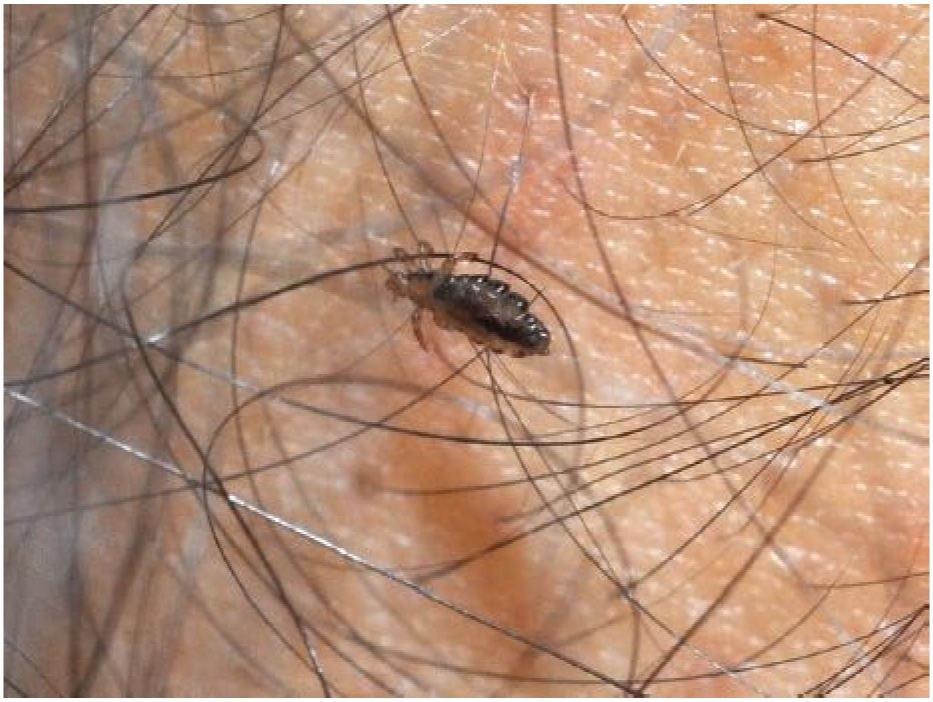

FIGURE 127-2 Adult louse hanging on to the hairs at the nape of the neck. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Lice are ectoparasites that live on or near the body.[1] They will die of starvation within 10 days of removal from their human host. Lice have coexisted with humans for at least 10,000 years.[2] Lice are ubiquitous and remain a major problem throughout the world.[3]

SYNONYMS

Pediculosis, crabs (pubic lice).

EPIDEMIOLOGY

- Human lice (pediculosis corporis, pediculosis pubis, and pediculosis capitis) are found in all countries and climates.[3]
- Head lice are most common among school-age children. Each year, approximately 6 to 12 million children, ages 3 to 12 years, are infested.[4]
- Head lice infestation is seen across all socioeconomic groups and is not a sign of poor hygiene.[5]
- In the US, black children are affected less often as a result of their oval-shaped hair shafts that are difficult for lice to grasp.[4]
- Body lice infest the seams of clothing (**Figure 127-3**) and bed linen. Infestations are associated with poor hygiene and conditions of crowding.

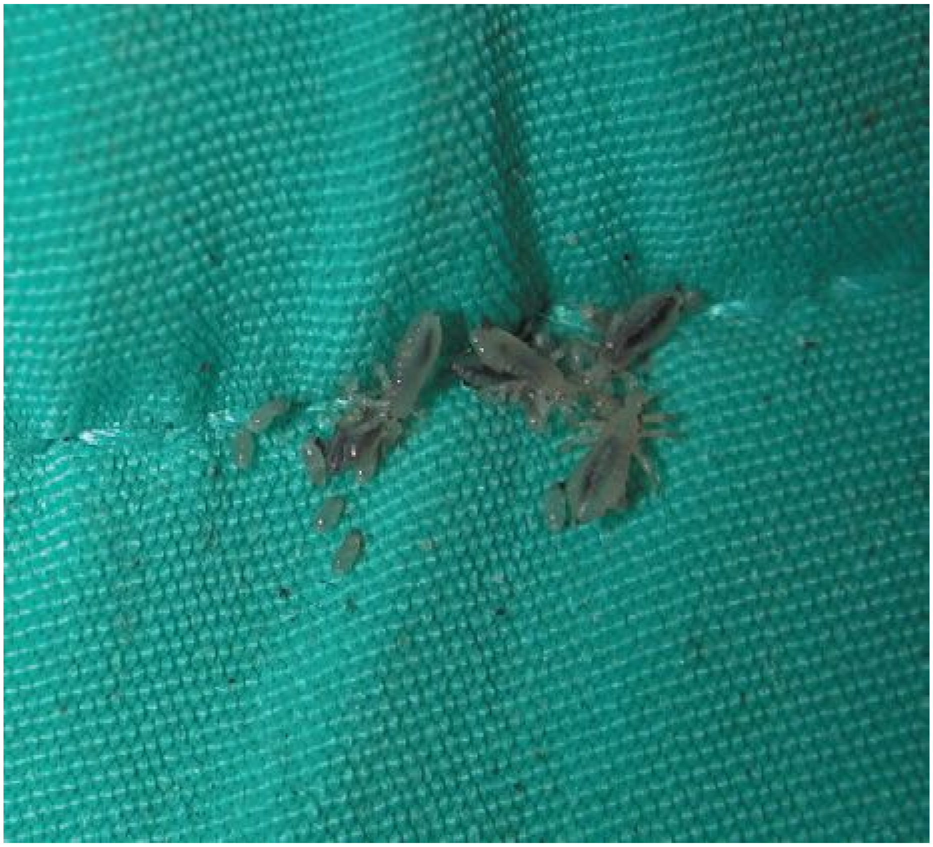

FIGURE 127-3 Adult body lice and nymphs visible along the pant seams of a patient with body lice. (*Used with permission from Richard P. Usatine, MD*.)

- Pubic lice are most common in sexually active adolescents and adults. Young children with pubic lice typically have infestations of the eyelashes. Although infestations in this age group may be an indication of sexual abuse, children generally acquire the crab lice from their parents.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

- Lice are parasites that have six legs with terminal claws that enable them to attach to hair and clothing. There are three types of lice responsible for human infestation. All three kinds of lice must feed daily on human blood and can only survive 1 to 2 days away from the host. The three types of lice are as follows:
    - Head lice (*Pediculus humanus capitis*)—Measure 2 to 4 mm in length (**Figures 127-2** and **127-4**).

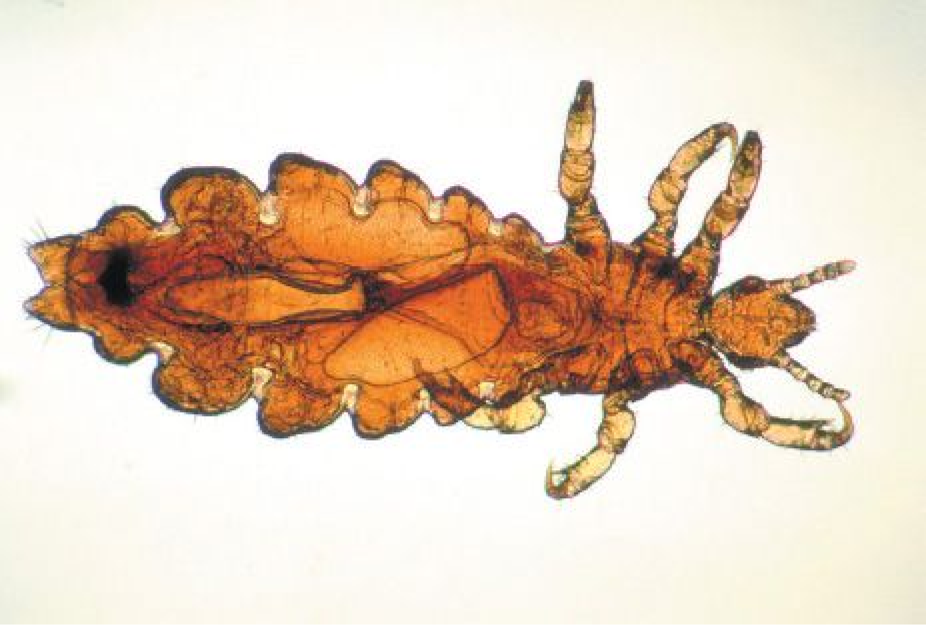

FIGURE 127-4 Adult head louse with elongated body. (*Used with permission from Centers for Disease Control and Prevention and Dennis D. Juranek*.)

- Body lice (*Pediculus humanus corporis*)—Body lice similarly measure 2 to 4 mm in length (**Figure 127-5**).

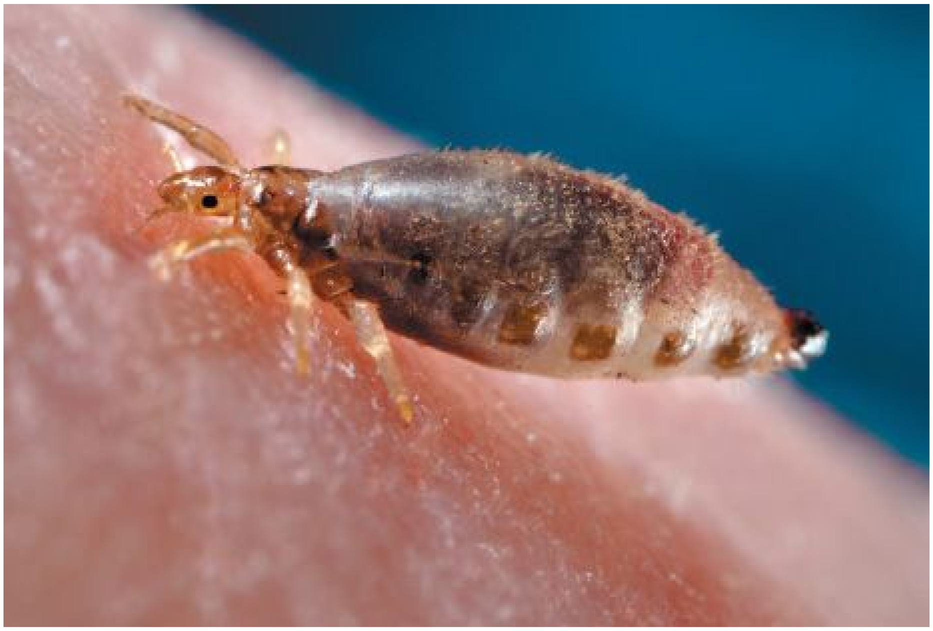

FIGURE 127-5 A body louse feeding on the blood of the photographer. The dark mass inside the abdomen is a previously ingested blood meal. (*Used with permission from Centers for Disease Control and Prevention and Frank Collins, PhD*.)

- Pubic or crab lice (*Phthirus pubis*)—Pubic lice are shorter, with a broader body and have an average length of 1 to 2 mm (**Figure 127-6**).

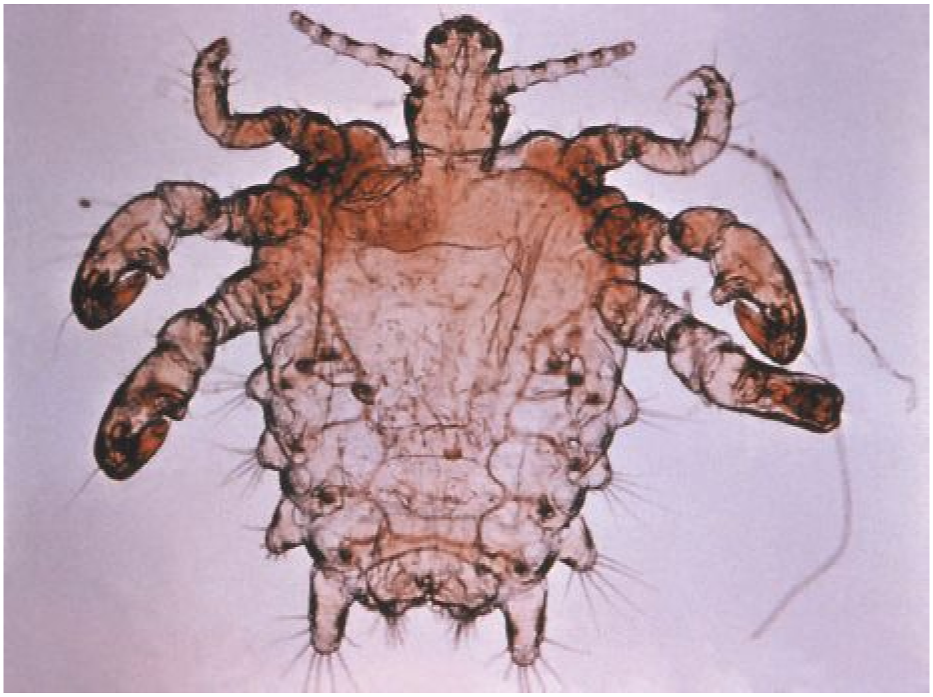

FIGURE 127-6 The crab louse has a short body and its large claws are responsible for the “crab” in its name. (*Used with permission from Centers for Disease Control and Prevention and World Health Organization*.)

- Female lice have a lifespan of approximately 30 days and can lay approximately 10 eggs (nits) a day.[4]
- Nits are firmly attached to the hair shaft or clothing seams by a glue-like substance produced by the louse (**Figure 127-7**).

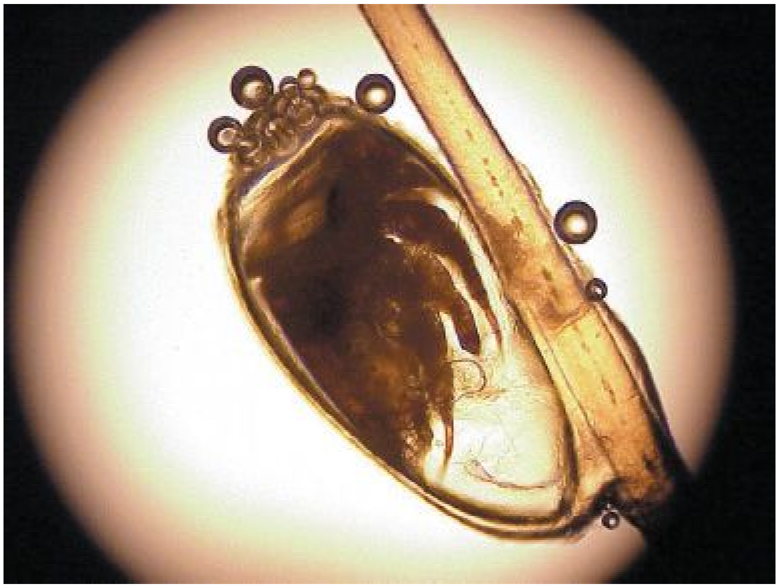

FIGURE 127-7 Microscopic view of a nit cemented to the hair and about to hatch. (*Used with permission from Dan Stulberg, MD*.)

- Nits are incubated by the host's body heat.
- The incubation period from laying eggs to hatching of the first nymph is 7 to 14 days.
- Mature adult lice capable of reproducing appear 2 to 3 weeks later.[5]
- Transmission of head lice occurs through direct contact with the hair of infested individuals. The role of fomites (e.g., hats, combs, brushes) in transmission is negligible.[6] Head lice do not serve as vectors for transmission of disease among humans.
- Transmission of body lice occurs through direct human contact or contact with infested material. Unlike head lice, body lice are well-recognized vectors for transmission of the pathogens responsible for epidemic typhus, trench fever, and relapsing fever.[5]
- Pubic or crab lice are transmitted primarily through sexual contact. In addition to pubic hair (**Figure 127-8**), infestations of eyelashes, eyebrows, beard, upper thighs, abdominal, and axillary hairs may also occur.

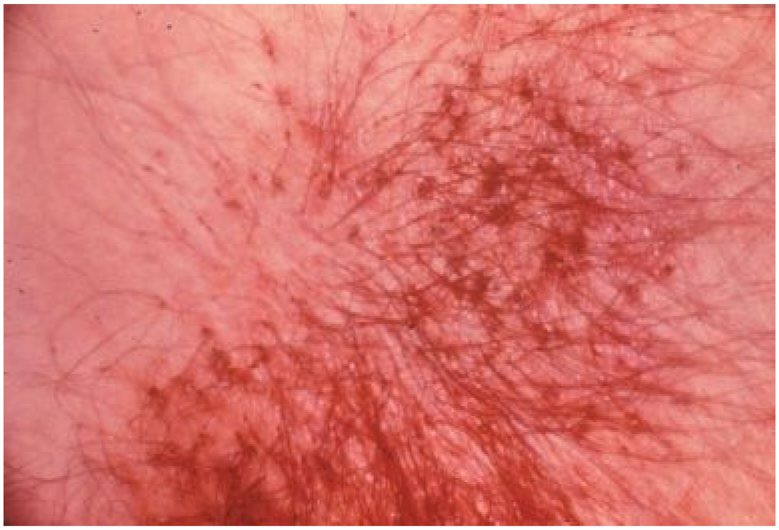

FIGURE 127-8 Crab lice infesting pubic hair. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

RISK FACTORS

- Contact with an infected individual. This commonly occurs in schools or between siblings at home.
- Living in crowded quarters such as homeless shelters.
- Poor hygiene and mental illness.

DIAGNOSIS

CLINICAL FEATURES

- Nits can be seen in active disease or treated disease. Nits closer to the base of the hairs are generally newer and more likely to be live and unhatched. Unfortunately, nits that were not killed by pediculicides can hatch and start the infestation cycle over again. Note that nits are glued to the hairs and are hard to remove, whereas flakes of dandruff can be easily brushed off.

- Pruritus is the hallmark of lice infestation. It is the result of an allergic response to louse saliva.[7] Head lice are associated with excoriated lesions that appear on the scalp, ears, neck, and back.
- Occipital and cervical adenopathy may develop, especially when lesions become superinfected.
- Body lice result in small maculopapular eruptions that are predominantly found on the trunk and in the seams of the clothing (**Figure 127-3**).
- Chronic infestations often result in hyperpigmented, lichenified plaques known as “vagabond’s skin.”[8]
- Pubic lice produce bluish-gray spots (macula cerulea) that can be found on the chest, abdomen, and thighs.[8]

TYPICAL DISTRIBUTION

- Head lice—Look for nits and lice in the hair especially above the ears, behind the ears, and at the nape of the neck. There are many more nits present than live adults. Finding nits without an adult louse does not mean that the infestation has resolved (**Figures 127-1** and **127-6**). Systematically combing wet or dry hair with a fine toothed nit comb (teeth of comb are 0.2 mm apart) better detects active louse infestation than visual inspection of the hair and scalp alone.[9]
- Body lice—Look for the lice and larvae in the seams of the clothing (**Figure 127-3**).
- Pubic lice—Look for nits and lice on the pubic hairs (**Figure 127-8**). These lice and their nits may also be seen on the hairs of the upper thighs, abdomen, axilla, beard, eyebrows, and eyelashes. Little specks of dried blood may be seen in the underwear as a clue to the infestation. The diagnosis of pubic lice in a child (under age 18) should prompt the clinician to inquire about sexual abuse.

LABORATORY TESTING

- Direct visualization and identification of live lice or nits are sufficient to make a diagnosis (**Figures 127-1** to **127-9**).

FIGURE 127-9 A group of medical students is helping children in Ethiopia to apply permethrin to their lice infested hair. (*Used with permission from Richard P. Usatine, MD.*)

- The use of a magnification lens may aid in the detection or confirmation of lice infestation.
- Under Wood light the head lice nits fluoresce a pale blue.
- If you find an adult louse put it on a slide with a cover slip loosely above it. Look at it under the microscope on the lowest power (**Figures 127-4** and **127-5**). You will see the internal workings of the live organs. If the louse was not found in a typical location, you can use the morphology of the body and legs to determine the type of louse causing the infestation.
- In cases of pubic lice infestations, individuals should be screened for other sexually transmitted diseases.[5]

DIFFERENTIAL DIAGNOSIS

- Dandruff, hair casts, and debris should be ruled out in cases of suspected lice infestations. Unlike nits, these particles are easily removed from the hair shaft. In addition, adult lice are absent.
- Scabies is also characterized by intense pruritus and papular eruptions. Unlike lice infestations, scabies may be associated with vesicles, and the presence of burrows is pathognomonic. Diagnosis is confirmed by microscopic examination of the scrapings from lesions for the presence of mites or eggs (see Chapter 128, Scabies).

MANAGEMENT

NONPHARMACOLOGIC

- In young children or others who wish to avoid topical pediculicides for head lice, mechanical removal of lice by wet combing is an alternative therapy. A 1:1 vinegar: water rinse (left under a conditioning cap or towel for 15 to 20 minutes) or 8 percent formic acid crème rinse may enhance removal of tenacious nits.[8] Combing is performed until no lice are found for 2 weeks.SOR Ⓑ
    - Nits are also removed with a fine-toothed comb following the application of all treatments. This step is critical in achieving resolution.
    - Combs and hairbrushes should be discarded, soaked in hot water (at a temperature of at least 55°C [130°F]) for 5 minutes, or treated with pediculicides.[10]

MEDICATIONS

- *Pediculus humanus capitis* (head lice):

- Nonprescription 1 percent permethrin cream rinse (Nix), pyrethrins with piperonyl butoxide (which inhibits pyrethrin catabolism; RID) shampoo, or permethrin 1 percent is applied to the hair and scalp and left on for 10 minutes then rinsed out.[11] SOR A In **Figure 127-9**, a group of medical students is helping children in Ethiopia to apply permethrin to their lice infested hair.
- Pyrethrins are only pediculicidal, whereas permethrin is both pediculicidal and ovicidal. It is important to note that treatment failure is common with these agents owing to the emergence of resistant strains of lice.
- After 7 to 10 days repeating the application is optional when permethrin is used, but is a necessary for pyrethrin. Lice persisting after treatment with a pyrethroid may be an indication of resistance.
- Malathion 0.5 percent (Ovide) is available by prescription only, and is a highly effective pediculicidal and ovicidal agent for resistant lice. Malathion may have greater efficacy than pyrethrins.[12] It is approved for use in children age 6 years and older. The lotion is applied to dry hair for 8 to 12 hours and then washed. Repeat application is recommended after 7 to 10 days if live lice are still present. When used appropriately, malathion is 78 percent to 95 percent effective.[12] SOR A
- Benzyl alcohol 5 percent lotion (Ulesfia) is a newer treatment option in patients 6 months of age and older. It works by asphyxiating the parasite. It is applied for 10 minutes with saturation of the scalp and hair, and then rinsed off with water. The treatment is repeated after 7 days.[13] SOR A
- Spinosad (Natroba) is a new topical prescription medication approved by the FDA in 2011 for the treatment of lice. Spinosad is a fermentation product of the soil bacterium *Saccharopolyspora spinosa* that compromises the central nervous system of lice. It is approximately 85 percent effective in lice eradication, usually after one application. It is applied to completely cover the dry scalp and hair, and rinsed off after 10 minutes. Treatment should be repeated if live lice remain 7 days after the initial application.[14] SOR A
- In February 2012, the US FDA approved ivermectin 0.5 percent lotion for the treatment of head lice for people above 6 months of age. It is applied as a single 10-minute topical application. The safety of

  ivermectin in infants younger than age 6 months has not been established.[15] SOR Ⓐ
  - Hair conditioners should not be used prior to the application of pediculicides; these products may result in reduced efficacy.[16]
  - A Cochrane review found no evidence that any one pediculicide was better than another; permethrin, synergized pyrethrin, and malathion were all effective in the treatment of head lice.[17] SOR Ⓐ
  - Other therapeutic options include permethrin 5 percent cream and lindane 1 percent shampoo. Permethrin 5 percent is conventionally used to treat scabies; however, it is anecdotally recommended for treatment of recalcitrant head lice.[5] SOR Ⓒ
  - Lindane is considered a second-line treatment option owing to the possibility of central nervous system toxicity, which is most severe in children.
  - Oral therapy options include a 10-day course of trimethoprim-sulfamethoxazole or 2 doses of ivermectin (200 mcg/kg) 7 to 10 days apart. SOR Ⓒ Trimethoprim-sulfamethoxazole is postulated to kill the symbiotic bacteria in the gut of the louse.[4] Combination therapy with 1 percent permethrin and trimethoprim-sulfamethoxazole is recommended in cases of multiple treatment failure or suspected cases of resistance to therapy.[5,10] SOR Ⓒ

- *Pediculus humanus corporis* (body lice):
  - Improving hygiene, and laundering clothing and bed linen at temperatures of 65°C (149°F) for 15 to 30 minutes will eliminate body lice.[8]
  - In settings where individuals cannot change clothing (e.g., indigent population), a monthly application of 10 percent lindane powder can be used to dust the lining of all clothing.[8]
  - Additionally, permethrin cream may be applied to the body for 8 to 12 hours to eradicate body lice.

- *Phthirus pubis* (pubic lice):
  - Pubic lice infestations are treated with a 10-minute application of the same topical pediculicides used to treat head lice.
  - Retreatment is recommended 7 to 10 days later.

  - Petroleum ointment applied 2 to 4 times a day for 8 to 10 days will eradicate eyelash infestations.
  - Clothing, towels, and bed linen should also be laundered to eliminate nit-bearing hairs.[8]

PREVENTION

- Washing clothing and linen used by the head or pubic lice-infested person during the 2 days prior to therapy in hot water and/or drying the items on a high-heat dryer cycle (54.5°C [130°F]). Items that cannot be washed may be dry cleaned or stored in a sealed plastic bag for 2 weeks.

FOLLOW-UP

- Patients should be reexamined upon completion of therapy to confirm eradication of lice.

PATIENT EDUCATION

- Patients should be instructed to wash potentially contaminated articles of clothing, bed linen, combs, brushes, and hats.
- Nit removal is important in preventing continued infestation as a result of new progeny. Careful examination of close contacts, with appropriate treatment for infested individuals is important in avoiding recurrence.
- In cases of pubic lice, all sexual contacts should be treated.

128 SCABIES

Richard P. Usatine, MD
Pierre Chanoine, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 2-year-old boy is seen with severe itching and crusting of his hands (**Figures 128-1** and **128-2**). He also has a pruritic rash over the rest of his body. The child has had this problem since 2 months of age and has had a number of treatments for scabies. Other adults and children in the house have itching and rash. Various attempts at treatment have only included topical preparations. A scraping was done and scabies mites and scybala (feces) were seen (**Figures 128-3** and **128-4**). The child and all the family members were put on ivermectin simultaneously and the Norwegian scabies cleared from the child. The family cleared as well and the child was given a repeat dose of ivermectin to avoid relapse.

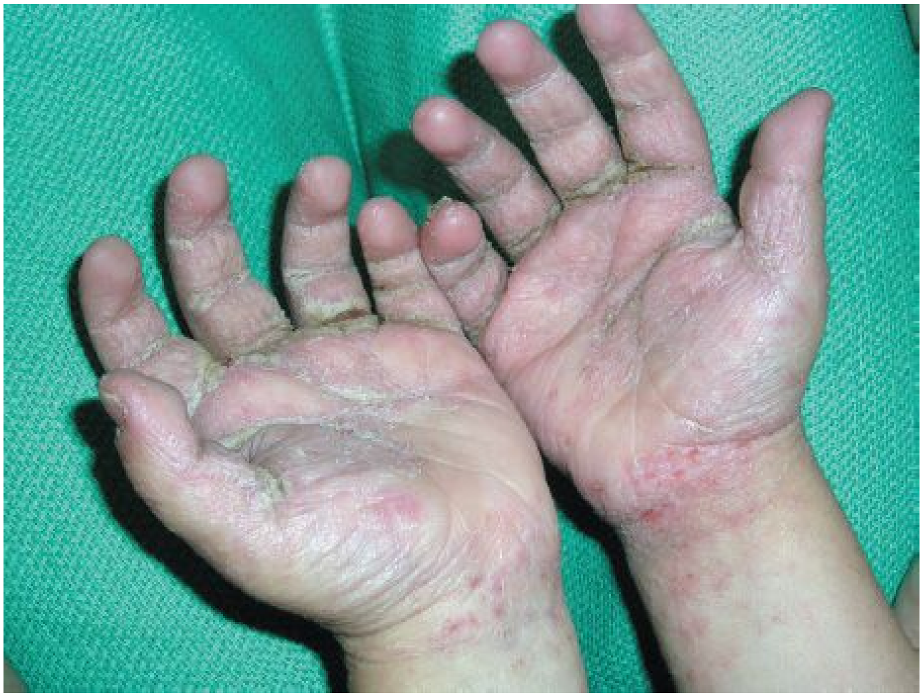

FIGURE 128-1 Crusted scabies (Norwegian scabies) in a 2-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

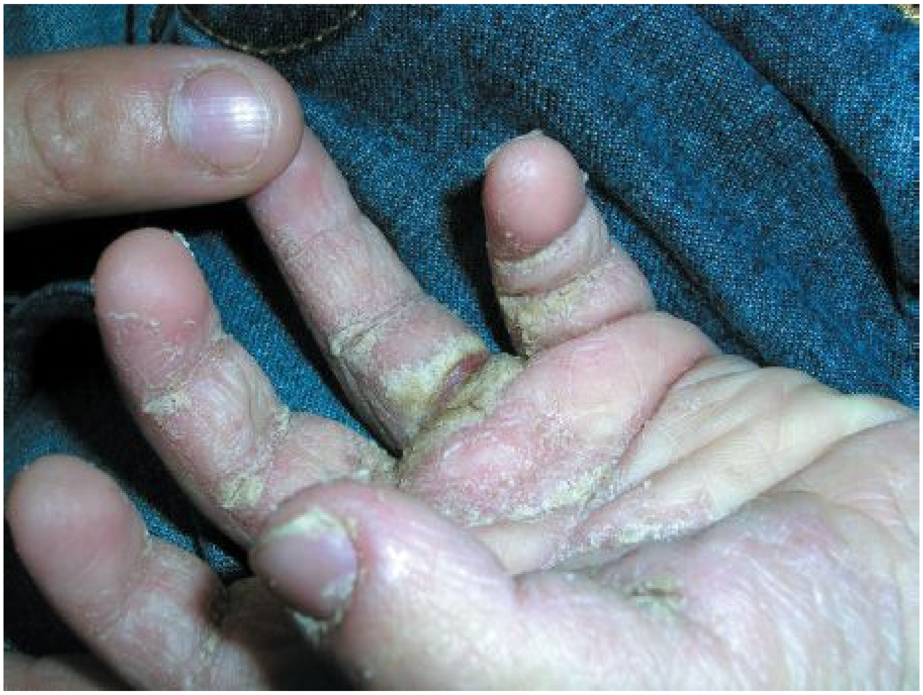

FIGURE 128-2 The boy in **Figure 128-1** with a close-up of his hand showing crusting and a fissure. (*Used with permission from Richard P. Usatine, MD*.)

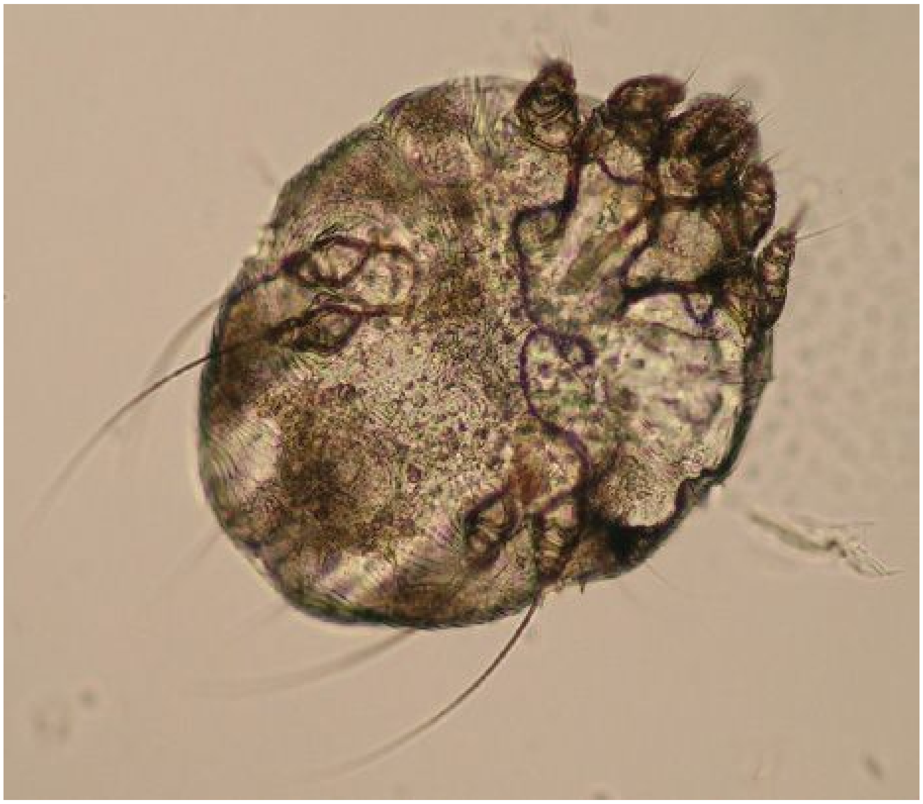

FIGURE 128-3 Microscopic view of the scabies mite from a patient with crusted scabies. (*Used with permission from Richard P. Usatine, MD*.)

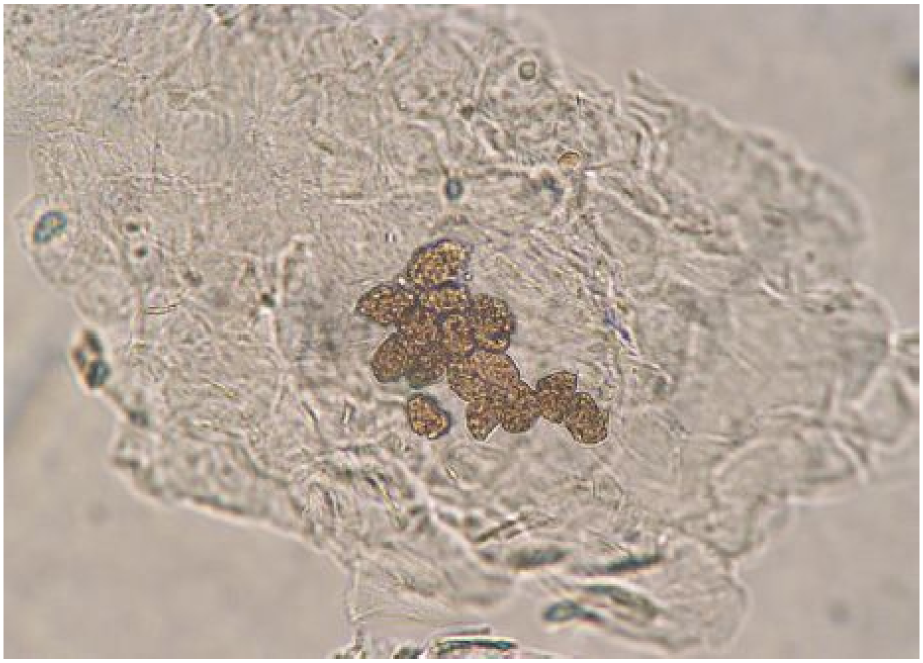

FIGURE 128-4 Scraping of the patient’s hand produced a good view of the scybala (the mites’ feces). (*Used with permission from Richard P. Usatine, MD*.)

SYNONYMS

Seven-year itch.

EPIDEMIOLOGY

- Three hundred million cases per year are estimated worldwide.[1] In some tropical countries, scabies is endemic.
- The prevalence of scabies among school children in Nigeria was reported to be 4.7 percent in 2005.[2]
- The prevalence of scabies among boarding school children in Malaysia in 2009 was found to be 8.1 percent.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Human scabies is caused by the mite *Sarcoptes scabei*, an obligate human parasite (**Figure 128-3**).[1,4]
- Adult mites spend their entire life cycle, around 30 days, within the epidermis. After copulation the male mite dies and the female mite burrows through the superficial layers of the skin excreting feces (**Figure 128-4**) and laying eggs (**Figure 128-5**).

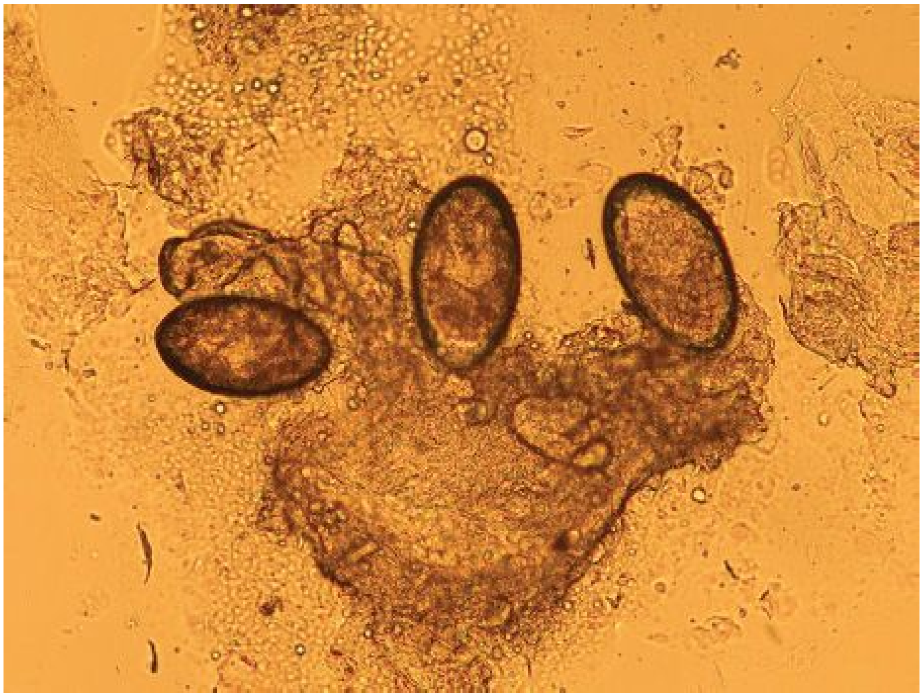

FIGURE 128-5 Scabies eggs from a scraping. (*Used with permission from Richard P. Usatine, MD*.)

- Mites move through the superficial layers of skin by secreting proteases that degrade the stratum corneum.
- Infected individuals usually have less than 100 mites. In contrast, immunocompromised hosts can have up to 1 million mites, and are susceptible to crusted scabies also called Norwegian scabies (**Figures 128-1** and **128-2**, and **128-6** to **128-8**).[1]

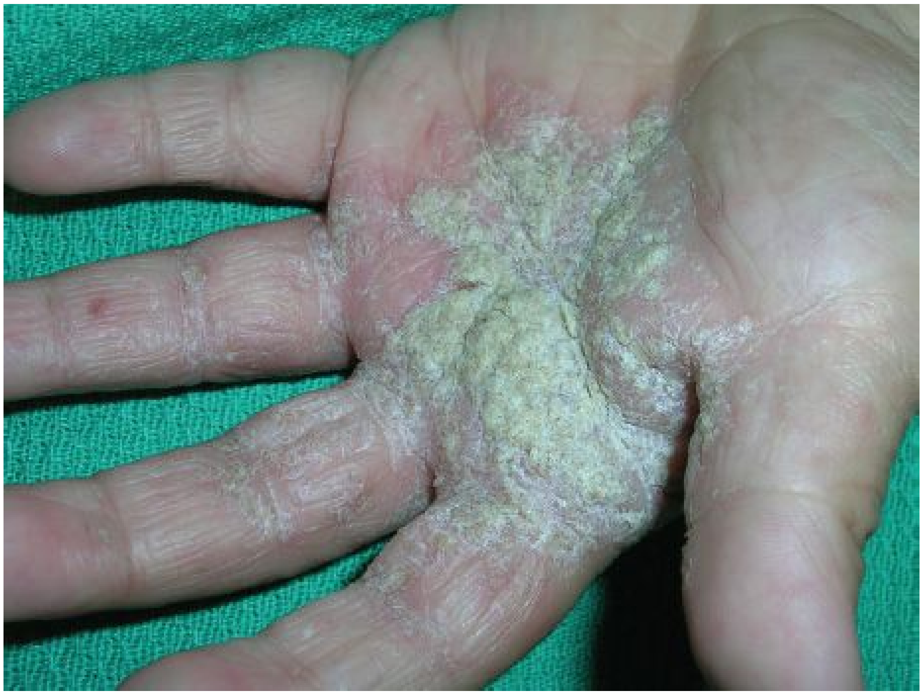

FIGURE 128-6 Norwegian scabies with crusting on the hand of a 3-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

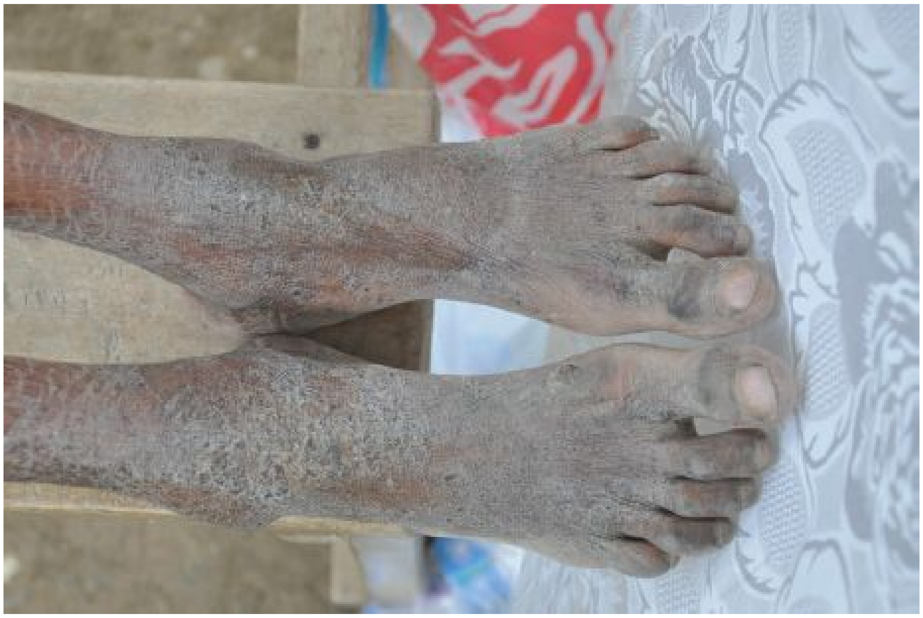

FIGURE 128-7 Crusted scabies on the feet of a malnourished girl in Haiti. (*Used with permission from Richard P. Usatine, MD*.)

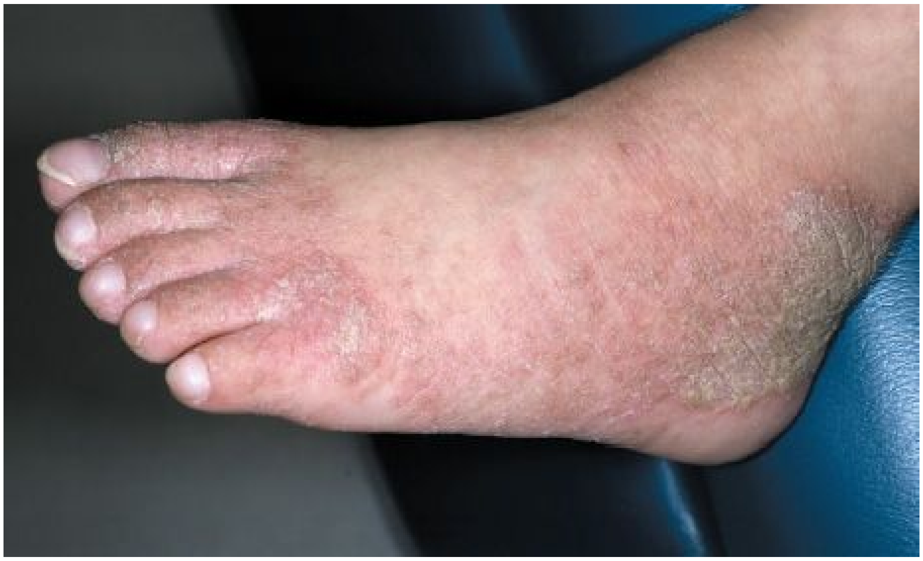

FIGURE 128-8 Crusted scabies on the foot of a 5-year-old boy with Down syndrome. (*Used with permission from Richard P. Usatine, MD*.)

- Transmission usually occurs via direct skin contact (**Figures 128-9**). Scabies in adults is frequently sexually transmitted.[5] Scabies mites can also be transmitted from animals to humans.[1]

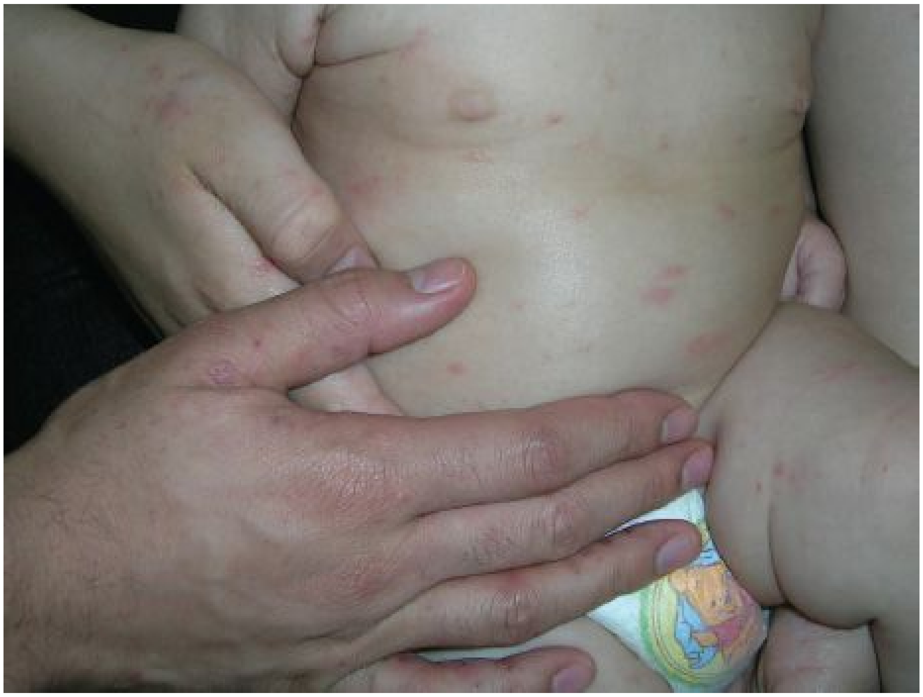

FIGURE 128-9 Scabies has been transmitted by skin to skin contact in this family. The photograph shows the active infection on the skin of the infant

and the hands of the mother and father. (*Used with permission from Richard P. Usatine, MD.*)

- Mites can also survive for 3 days outside of the human epidermis allowing for infrequent transmission through bedding and clothing.
- The incubation period is on average 3 to 4 weeks for an initial infestation. Sensitized individuals can have symptoms within hours of reexposure.

RISK FACTORS

- Scabies is more common in young children, health care workers, homeless and impoverished persons, and individuals who are immunocompromised or suffering from dementia.[1]
- Institutionalized individuals and those living in crowded conditions also have a higher incidence of the infestation.[1]

DIAGNOSIS

CLINICAL FEATURES

- Pruritus is a hallmark of the disease.[1]
- Skin findings include papules (**Figure 128-10**), burrows (**Figures 128-11** and **128-12**) nodules (**Figures 128-13**), and vesiculopustules (**Figure 128-14**).

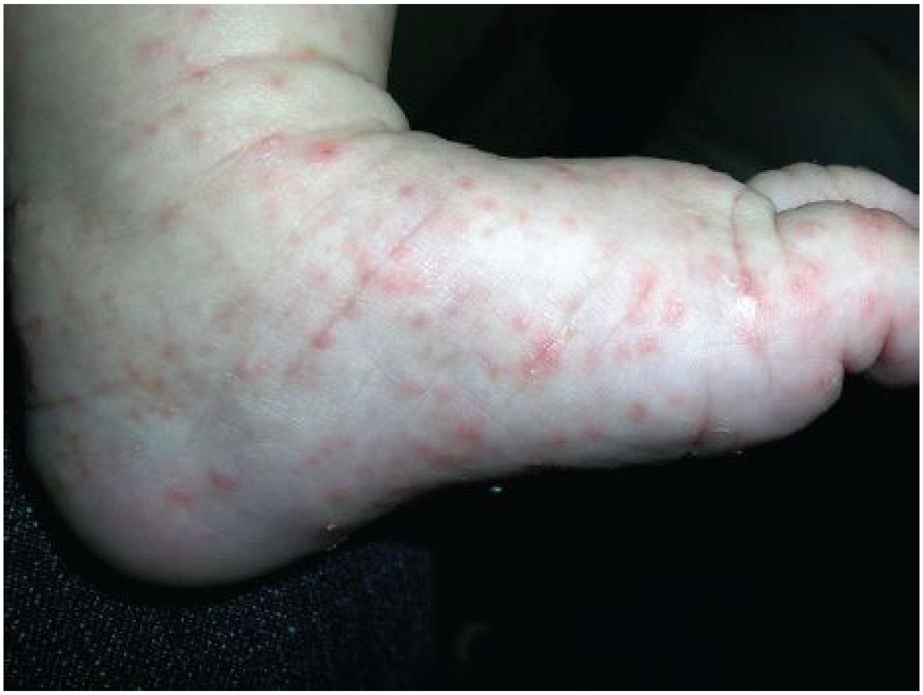

FIGURE 128-10 Scabies papules on the foot of a 3-month-old child. (*Used with permission from Richard P. Usatine, MD*.)

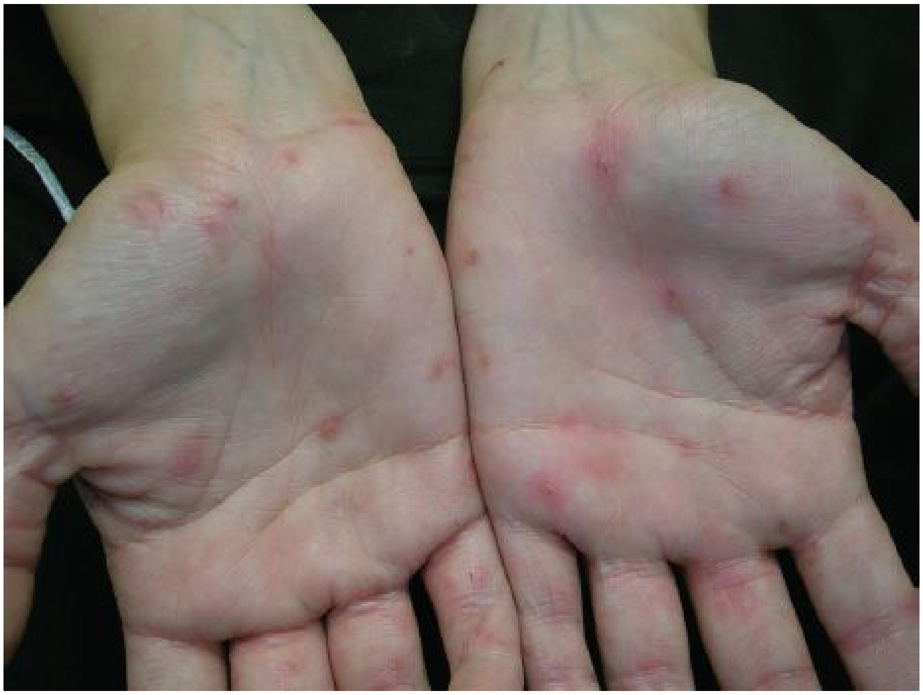

FIGURE 128-11 Scabies infestation on the hand of a 17-year-old teenager with visible burrows and papules. Dermoscopy revealed scabies mites within burrows. (*Used with permission from Richard P. Usatine, MD*.)

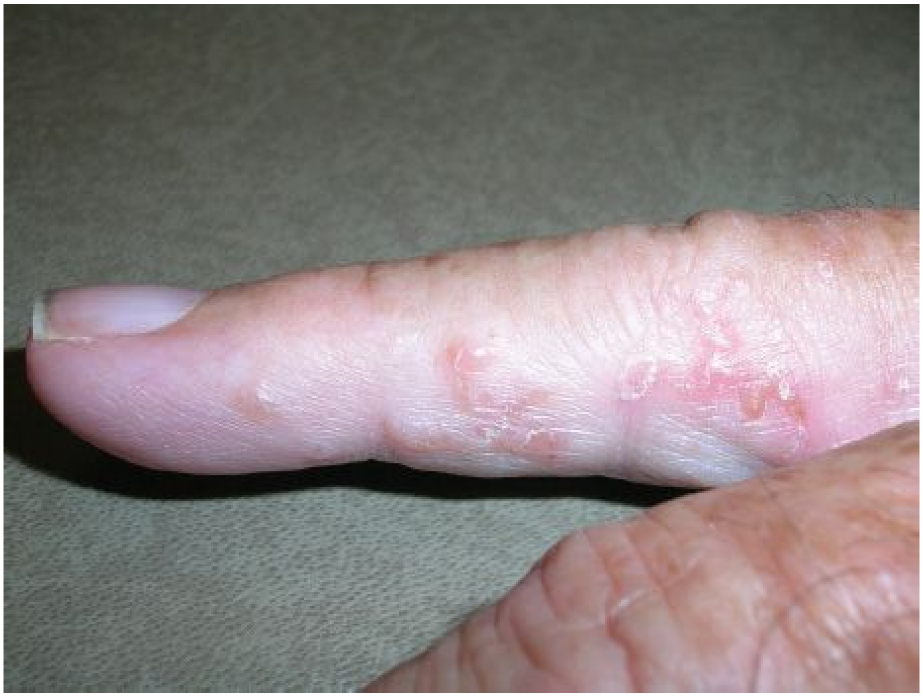

FIGURE 128-12 Burrows prominently visible between the fingers. Burrows are a classic manifestation of scabies. (*Used with permission from Richard P. Usatine, MD*.)

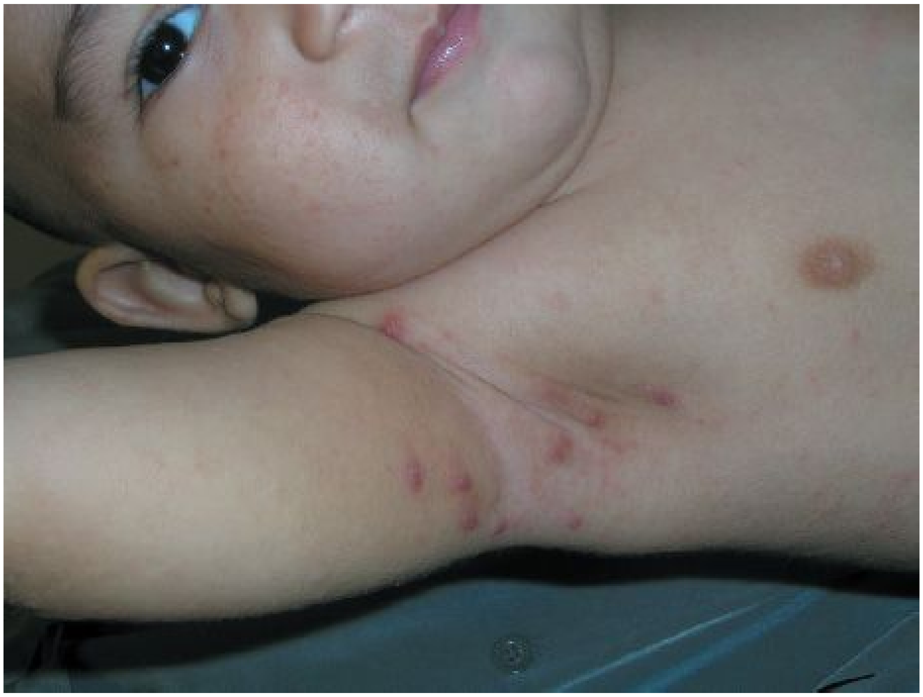

FIGURE 128-13 Scabetic nodules in the axilla of a toddler with scabies. (*Used with permission from Richard P. Usatine, MD*.)

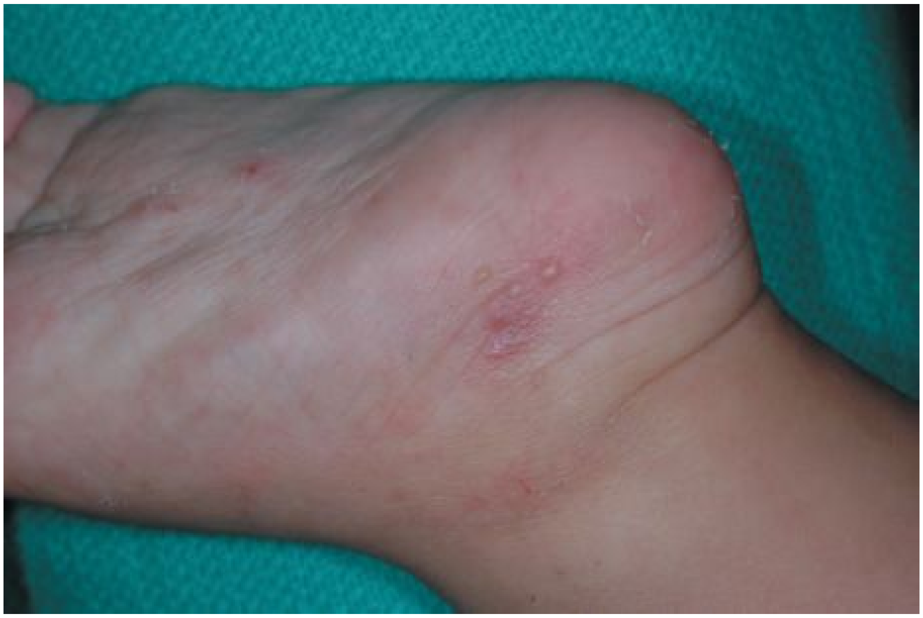

FIGURE 128-14 Scabies on the foot of a 9-month-old infant with pustules. Although this also looks like acropustulosis, the mother also had scabies. (*Used with permission from Richard P. Usatine, MD*.)

- Burrows are the classic morphologic finding in scabies and the best location to find the mite (**Figures 128-11** and **128-12**).
- Infants and young children can also exhibit irritability and poor feeding.
- Pruritic papules/nodules around the axillae (**Figure 128-13**), umbilicus, or on the penis (**Figures 128-15** and **128-16**) and scrotum are highly suggestive of scabies.

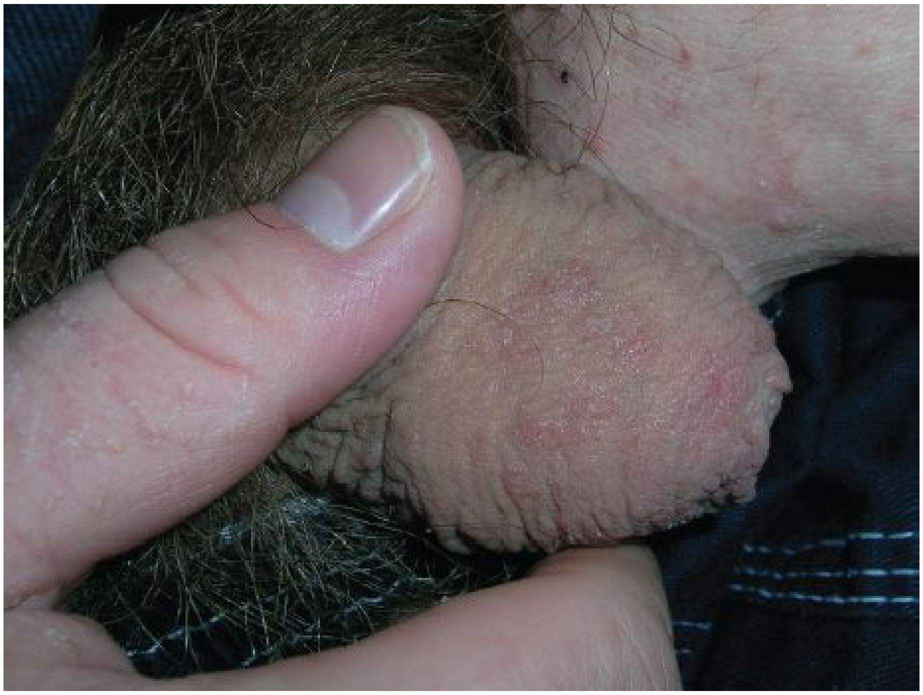

FIGURE 128-15 Pruritic papules of scabies on the foreskin of the penis, hands, and groin acquired as a sexually transmitted disease. (*Used with permission from Richard P. Usatine, MD*.)

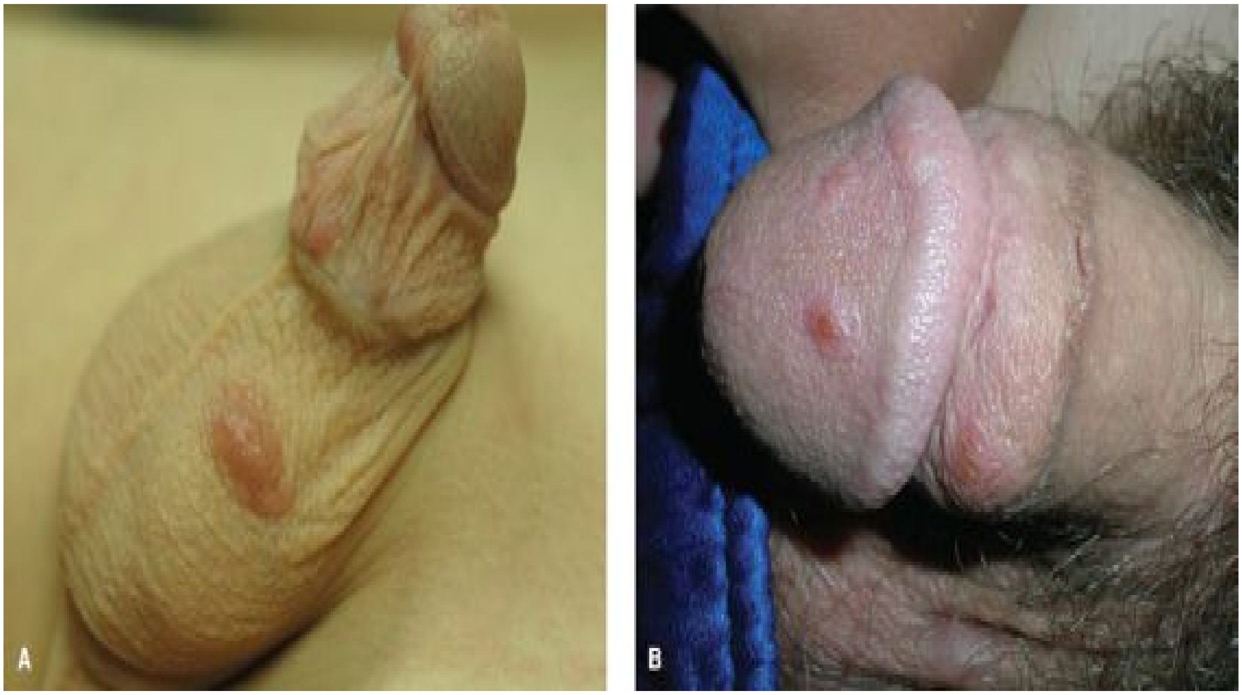

FIGURE 128-16 Papules and nodules on the glans penis, penile shaft and scrotum are typical of scabies. **A.** Nodular scabies in a 6-year-old boy. (*Used*

with permission from Robert Brodell, MD.) **B.** Pruritic papules of scabies on the glans of this teenager. (*Used with permission from Richard P. Usatine, MD*.)

TYPICAL DISTRIBUTION

- Classic distribution in scabies includes the interdigital spaces (**Figure 128-17**), wrists (**Figure 128-18**), ankles (**Figure 128-19**), waist (**Figure 128-20**), groin, axillae (**Figure 128-13**), palms, and soles (**Figures 128-1**, **128-2**, **128-6**, and **128-7**).

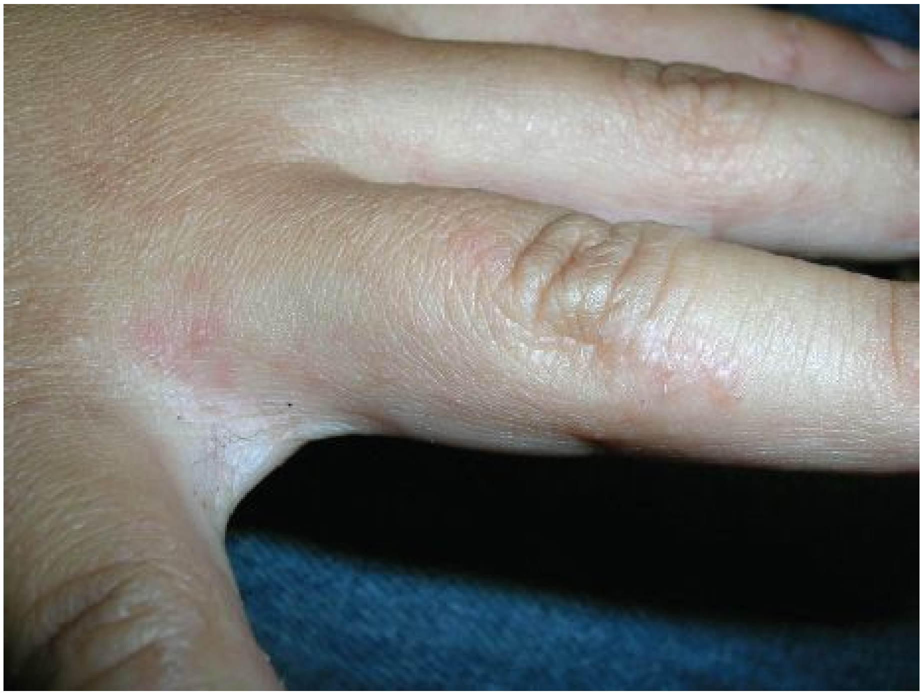

FIGURE 128-17 Scabies found in the classic location between the fingers in this interdigital webspace. (*Used with permission from Richard P. Usatine, MD*.)

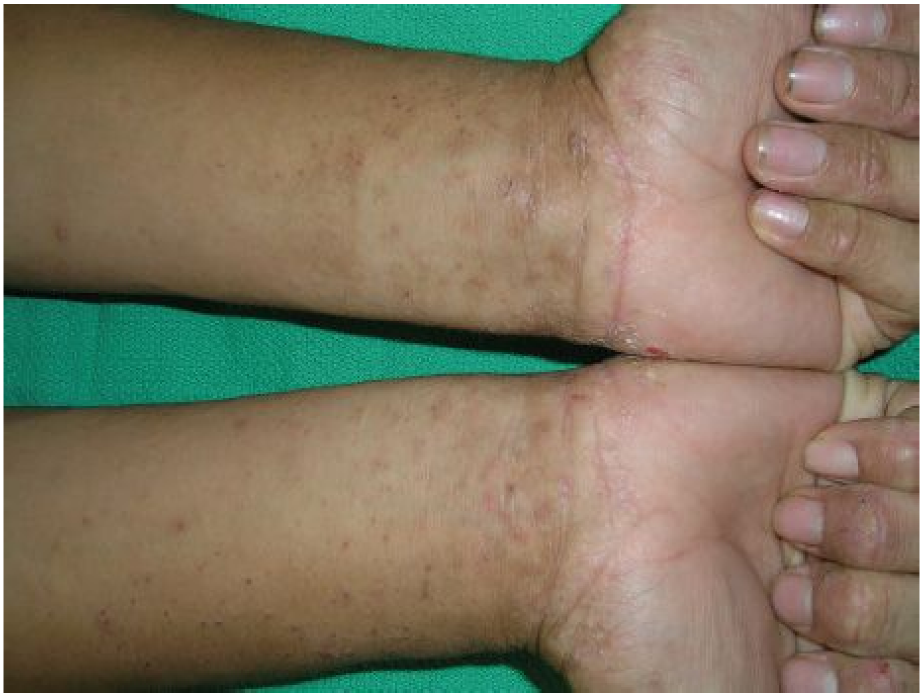

FIGURE 128-18 Scabies papules found prominently around the wrists of this 15-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

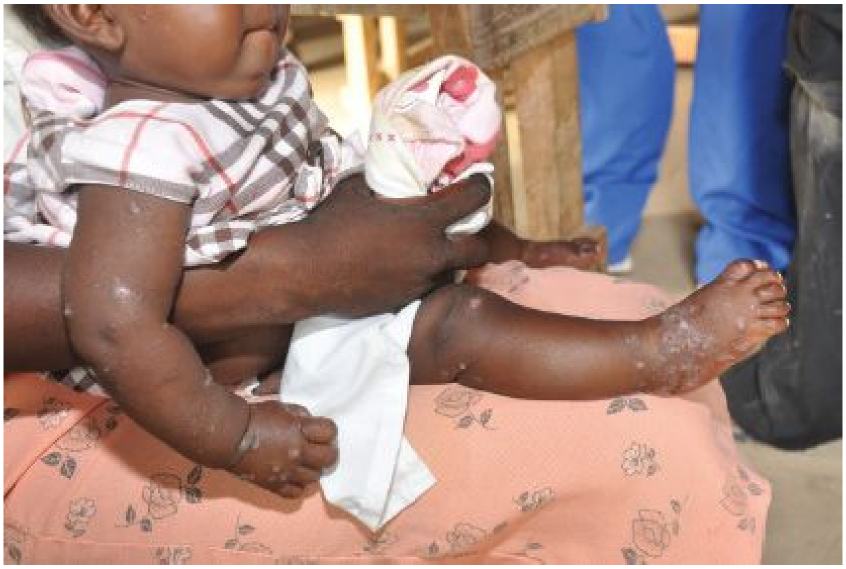

FIGURE 128-19 Ethiopian child with widely distributed scabies seen prominently on the wrists and ankles. (*Used with permission from Richard P. Usatine, MD.*)

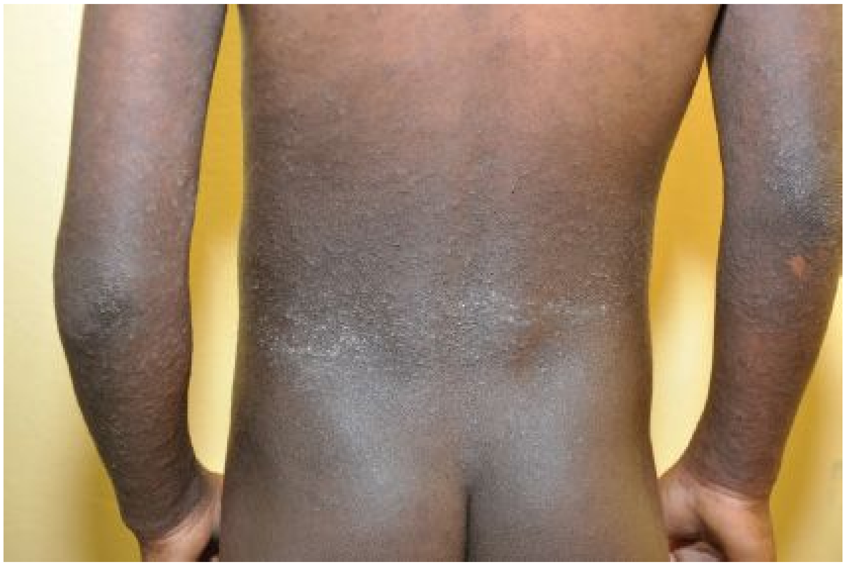

FIGURE 128-20 Scabies around the waist showing postinflammatory hyperpigmentation along with multiple papules and some crusting. (*Used with permission from Richard P. Usatine, MD*.)

- Genital involvement can also occur (**Figures 128-15** and **128-16**).
- In children, the head can also be involved (**Figure 128-21**).

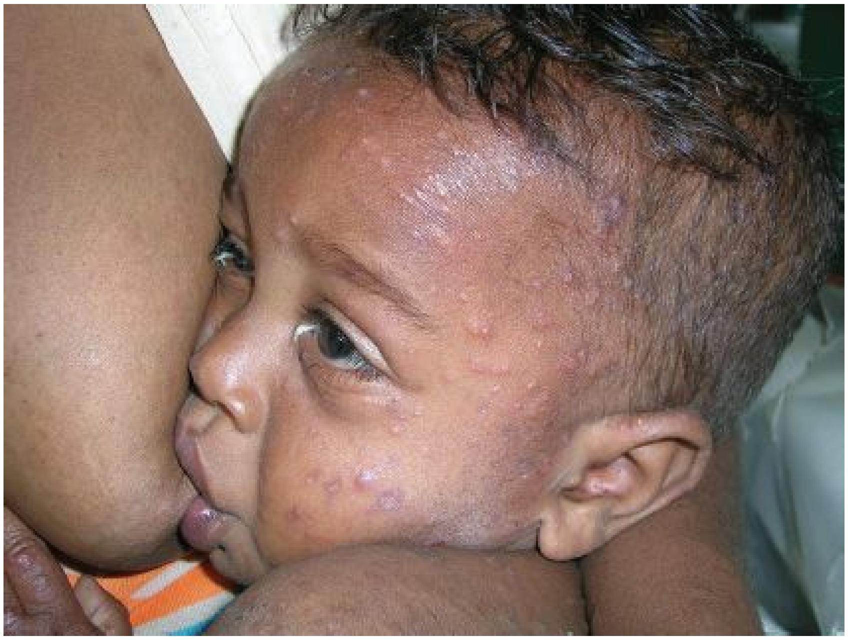

FIGURE 128-21 Scabies on the head and face of a young breastfeeding boy. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY STUDIES AND IMAGING

- Light microscopy of skin scrapings provides a definitive diagnosis when mites, eggs, or feces are identified (**Figures 128-3** to **128-5**). This can be challenging and time-consuming, even when mites, eggs, or feces are present. Packing tape stripping of skin has also been used instead of a scalpel to find mites for examination under the microscope.[6] The inability to find these items should not be used to rule out scabies in a clinically suspicious case. In what is believed to be a recurrent case, it is helpful to find definitive evidence that your diagnosis is correct.
- Dermoscopy is a useful and rapid technique for identifying a scabies mite at the end of a burrow (see Appendix 3: Dermoscopy).[7] The mite has been described as an arrowhead or a jet plane in its appearance (**Figure 128-22**). The advantage of the dermoscope is that multiple burrows can be examined quickly without causing any pain to the patient. Children are more likely to stay still for this than scraping with a scalpel or skin stripping with tape.

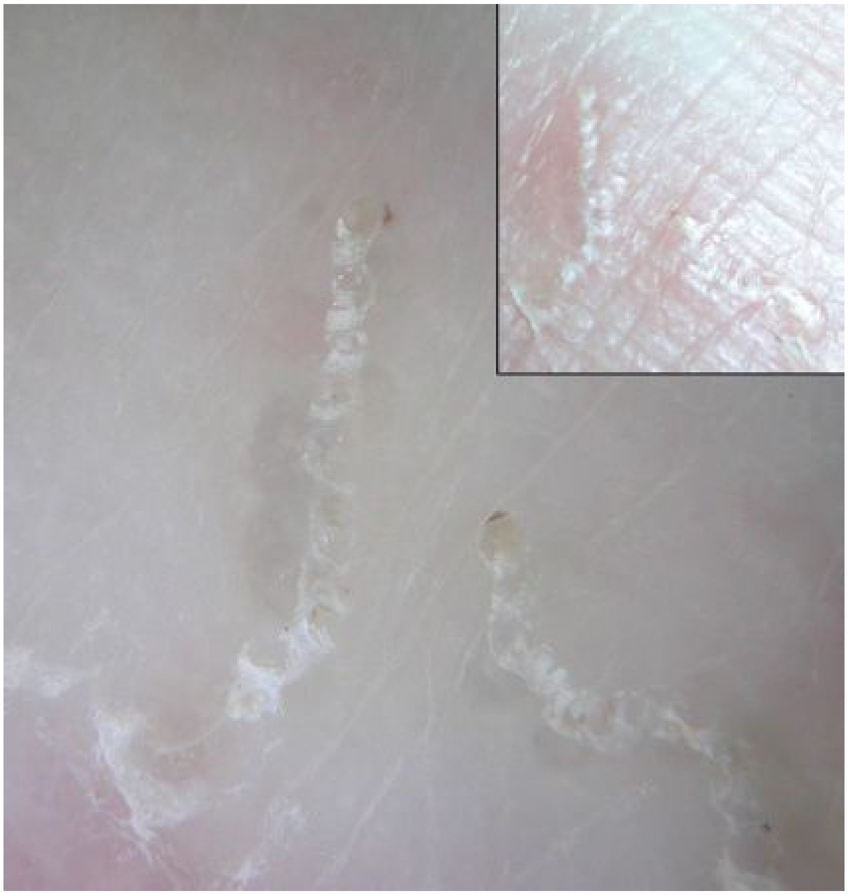

FIGURE 128-22 Two scabies mites visible with dermoscopy. Note how the darkest most visible aspect of the mite looks like an arrowhead or jet plane. In this case the oval bodies of the mites are also visible. The *upper right inset* shows the same burrows without dermoscopy. (*Used with permission from Richard P. Usatine, MD*.)

- If a dermoscope is available, start with this noninvasive examination. If the findings are typical, then a microscopic examination is not needed. If the findings are not convincing, or a dermoscope is not available, perform a scraping. It is best to scrape the skin at the end of a burrow. Use a #15 scalpel that has been dipped into mineral oil or microscope immersion oil. Scrape holding the blade perpendicular to the skin until the burrow (or papule) is opened (some slight bleeding is usual; **Figure 128-23**). Transfer the material to a slide and add a cover slip.

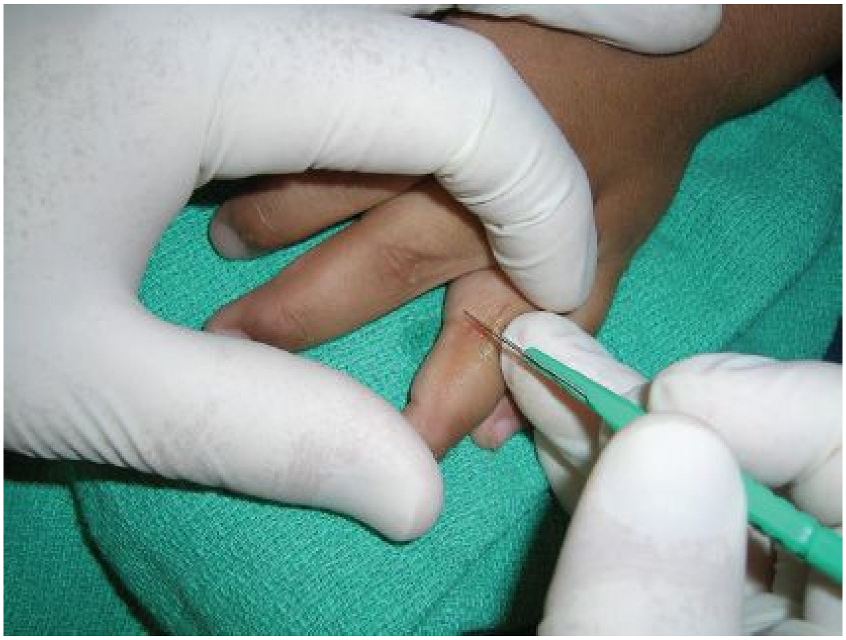

FIGURE 128-23 Using a #15 scalpel held perpendicular to the skin to scrape a suspicious burrow for scabies. Some mineral oil was applied to the scalpel and the scraping must be deep enough to get some tissue. (*Used with permission from Richard P. Usatine, MD*.)

- Tips for microscopic examination—Start by examining the slide with the lowest power available as mites may be seen under 4 power and the slide can be scanned most quickly with the lowest power. If no mites are seen, switch to 10 power and scan the slide again looking for mites, eggs, and feces. Forty power may be used to confirm findings under 10 power.

- In one study comparing dermoscopic mite identification with microscopic examination of skin scrapings, found the former technique to be of comparable sensitivity (91% and 90%, respectively) with specificity of 86 percent (versus 100% by definition), even in inexperienced hands.[8] Another study reported sensitivity of dermoscopy at 83 percent (95% confidence interval, 0.70 to 0.94).[9] In this study, the negative predictive value was identical for dermoscopy and the adhesive tape test (0.85), making the latter a good screening test in resource-poor areas.
- Videodermatoscopy can also be used to diagnose scabies.[10] Videodermatoscopy allows for skin magnification with incidental lighting at high magnifications for viewing mites and eggs. The technique is noninvasive and does not cause pain.
- *S. scabiei* recombinant antigens have diagnostic potential and are under investigation for identifying antibodies in individuals with active scabies.[11]

BIOPSY

Rarely necessary unless there are reasons to suspect another diagnosis.

DIFFERENTIAL DIAGNOSIS

- Atopic dermatitis—Itching is a prominent symptom in atopic dermatitis and scabies. The distribution of involved skin can help to differentiate the 2 diagnoses. Look for burrows in scabies and a history of involved family members. In children, atopic dermatitis is often confined to the flexural and extensor surfaces of the body. In adults, the hands are a primary site of involvement (see Chapter 130, Atopic Dermatitis).
- Contact dermatitis—Characterized by vesicles and papules on bright red skin, which are rare in scabies. Chronic contact dermatitis often leads to

scaling and lichenification and may not be as pruritic as scabies (see Chapter 131, Contact Dermatitis).

- Seborrheic dermatitis—A papulosquamous eruption with scales and crusts that is limited to the sebum rich areas of the body; namely, the scalp, the face the postauricular areas, and the intertriginous areas. Pruritus is usually mild or absent (see Chapter 135, Seborrheic Dermatitis).
- Impetigo—Honey-crusted plaques are a hallmark of impetigo. Scabies can become secondarily infected, so consider that both diagnoses can occur concomitantly with papules and pustules present (**Figure 128-24**) (see Chapter 99, Impetigo).

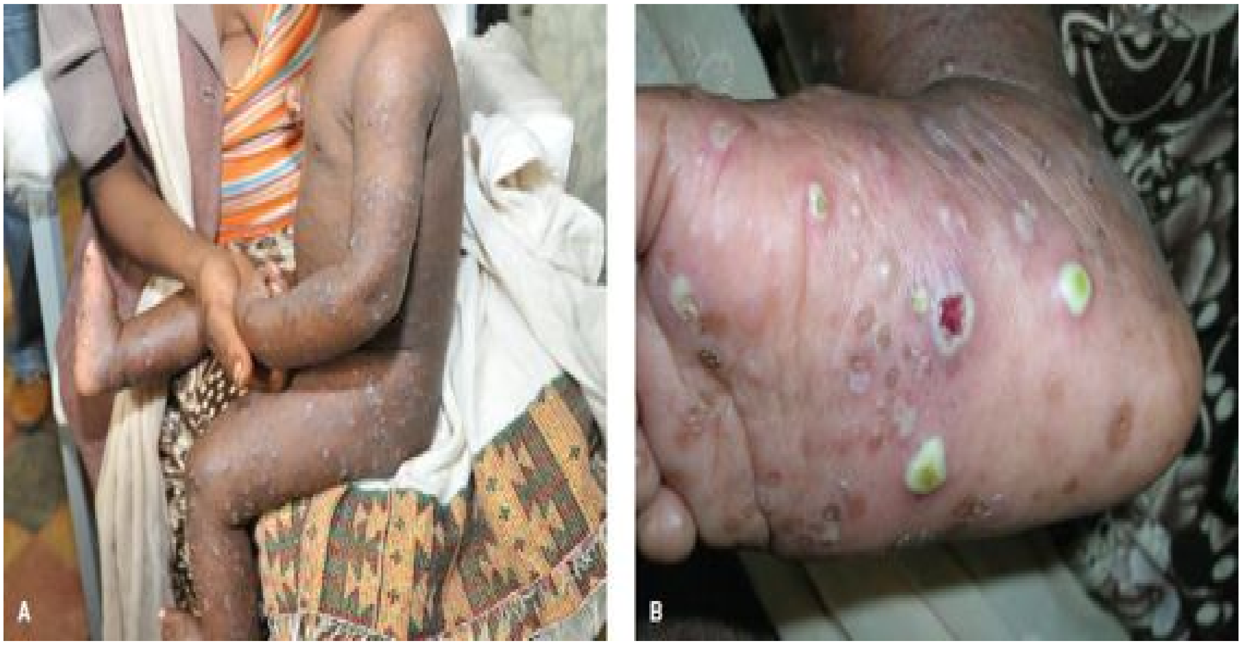

FIGURE 128-24 A. Superinfected scabies from head to toe in this young boy. **B.** Note the large pustules on the foot of this boy demonstrating the bacterial superinfection. (*Used with permission from Richard P. Usatine, MD.*)

- Arthropod bites—Bites may exhibit puncta that allow for differentiation from scabies.
- Acropustulosis of infancy (**Figure 128-25**)—A vesicopustular recurrent eruption limited to the hands, wrists, feet, and ankles. It is rare after 2 years of age (see Chapter 94, Pustular Diseases of Childhood).

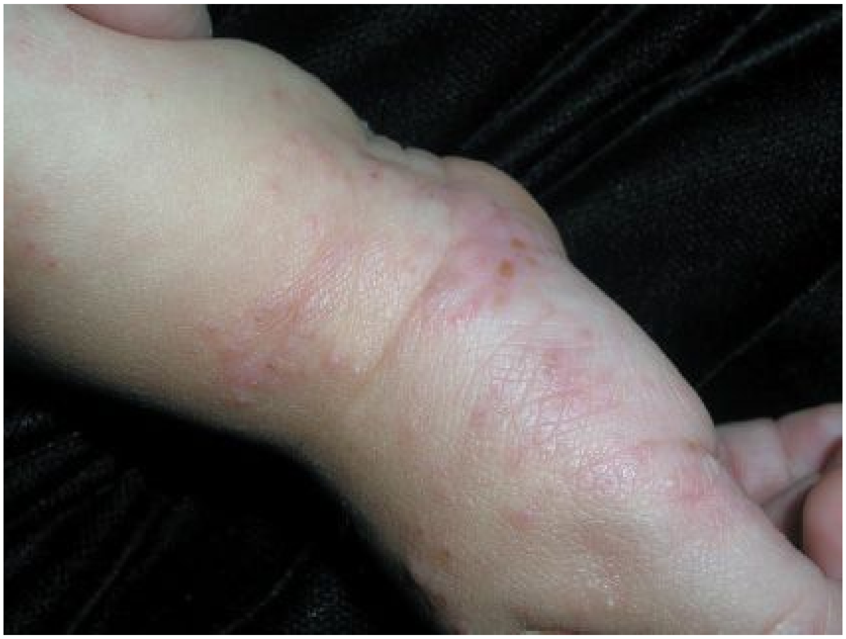

FIGURE 128-25 Infantile acropustulosis in a 9-month-old child that was mistakenly treated for scabies. No one else in the household had lesions and the scabies treatment did not lead to resolution of the pustules and vesicles. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

NONPHARMACOLOGIC

- Environmental decontamination is a standard component of all therapies. SOR Ⓑ Clothing, bed linens, and towels should be machine washed in hot water. Clothing or other items (e.g., stuffed animals) that cannot be washed may be dry cleaned or stored in sealed bags for at least 72 hours.[12]

MEDICATIONS

Treatment includes administration of an antiscabicide and an antipruritic.[1,13]

- Permethrin 5 percent cream (Elimite, Acticin) is the most effective treatment based upon a systematic review in the Cochrane Database.[13] SOR Ⓐ The cream is applied from the neck down (include the head when it is involved) and rinsed off 8 to 14 hours later. Usually, this is done overnight. Repeating the treatment in 1 to 2 weeks may be more effective. SOR Ⓒ In patients with crusted scabies, use of a keratolytic cream may facilitate the breakdown of skin crusts and improve penetration of the cream.[14] Unfortunately, scabies resistance to permethrin is increasing.
- Ivermectin is an oral treatment for resistant or crusted scabies. Studies have demonstrated its safety and efficacy. Most studies used a single dose of ivermectin at 200 mcg/kg.[13] SOR Ⓐ Taking the drug with food may enhance drug penetration into the epidermis.[14] Some experts advocate repeating a dose 1 week later. It is worth noting that the FDA has not labeled this drug for use in children weighing less than 15 kg. Ivermectin is currently available only in 3- and 6-mg tablets, so dosing often needs to be rounded up to accommodate the use of whichever tablets are available. As there is no oral suspension available, tablets may need to be cut and given with food for use in children.
- Diphenhydramine, hydroxyzine, and mid-potency steroid creams can be used for symptomatic relief of itching. SOR Ⓒ. It is important to note that pruritus may persist for 1 to 2 weeks after successful treatment because the dead scabies mites and eggs still have antigenic qualities that may cause persistent inflammation.
- All household or family members living in the infested home and sexual contacts should be treated. SOR Ⓒ Failure to treat all involved individuals often results in recurrences within the family. Use of insecticide sprays and fumigants is not recommended.
- Other less-effective medications include topical benzyl benzoate, crotamiton, lindane (no longer used in the US because of concerns regarding neurotoxicity), and synergized natural pyrethrins.[9] SOR Ⓐ Topical agents used more commonly in other countries include 5 to 10 percent sulfur in paraffin (widely in Africa and South America), 10 to 25 percent benzyl benzoate (often used in Europe and Australia), and malathion.[14] In infants younger than 2 months of age, crotamiton or a sulfur preparation is

recommended by one author instead of permethrin because of theoretical concerns of systemic absorption of permethrin.[14]

- Antibiotics are needed if there is evidence of a bacterial superinfection (**Figure 128-23**). SOR C

COMPLEMENTARY/ALTERNATIVE THERAPY

- Tea tree oil contains oxygenetic terpenoids, found to have rapid scabicidal activity.[15]

PREVENTION

- Avoid direct skin-to-skin contact with an infested person or with items such as clothing or bedding used by an infested person.
- Treat members of the same household and other potentially exposed persons at the same time as the infested person to prevent possible reexposure and reinfestation.

PROGNOSIS

- The prognosis with proper diagnosis and treatment is excellent unless the patient is immunocompromised; reinfestation, however, often occurs if environmental risk factors continue.[1]
- Postinflammatory hyper- or hypopigmentation can occur.[1]

FOLLOW-UP

- Routine follow-up is indicated when symptoms do not resolve.
- Consider an immunologic work-up for individuals with crusted scabies.

PATIENT EDUCATION

- Patients should avoid direct contact including sleeping with others until they have completed the first application of the medicine.
- Patients may return to school and work 24 hours after first treatment.
- Patients should be warned that itching may persist for 1 to 2 weeks after successful treatment but that if symptoms are still present by the third week, the patient should return for further evaluation.

129 CUTANEOUS LARVA MIGRANS

Jennifer A. Keehbauch, MD

PATIENT STORY

A mother brought her 18-month-old son to the physician’s office for an itchy rash on his feet and buttocks (**Figures 129-1** and **129-2**).[1] The first physician examined the child and made the incorrect diagnosis of tinea corporis. The topical clotrimazole cream failed. The child was unable to sleep because of the intense itching and was losing weight secondary to his poor appetite. He was taken to an urgent care clinic where the physician learned that the family had returned from a trip to the Caribbean prior to the visit to the first physician. The child had played on beaches that were frequented by local dogs. The physician recognized the serpiginous pattern of cutaneous larva migrans (CLM) and successfully treated the child with oral ivermectin. The child was 15 kg so the dose was 3 mg (0.2 mg/kg), and the tablet was ground up and placed in applesauce.

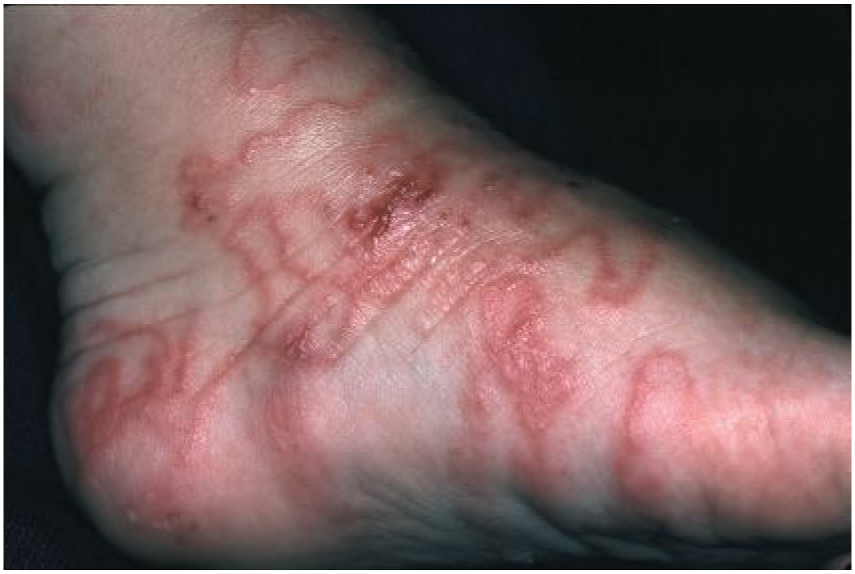

FIGURE 129-1 The serpiginous rash of cutaneous larva migrans on the foot of an 18-month-old boy after a family trip to the beaches of the Caribbean. (*Used with permission from Richard P. Usatine, MD. Usatine RP. A rash on the feet and buttocks. West J Med. 1999;170(6):344-335*.)

SYNONYMS

Creeping eruption, Plumber’s itch.

EPIDEMIOLOGY

- Endemic in developing countries, particularly Brazil, India, South Africa, Somalia, Malaysia, Indonesia, and Thailand.[2,3]
- Peak incidence in the rainy seasons.[3]
- During peak rainy seasons, the prevalence in children is as high as 15 percent in resource poor areas, but much less common in affluent communities in these same countries with only 1 to 2 per 10,000 individuals per year.[4]

- In the US, it is found predominantly in Florida, southeastern Atlantic states, and the Gulf Coast.[2]
- Children are more frequently affected than adults.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Caused most commonly by dog and cat hookworms (i.e., *Ancylostoma braziliense*, *Ancylostoma caninum*, or *Uncinaria stenocephala*).[4]
- Eggs are passed in cat or dog feces.[2]
- Larvae are hatched in moist, warm sand or soil.[2]
- Infective stage larvae penetrate the skin.[2]

DIAGNOSIS

The diagnosis is based on history and clinical findings.

CLINICAL FEATURES

- Elevated, serpiginous, or linear reddish-brown tracks 1 to 5 cm long (**Figures 129-1** to **129-3**).[2,5]

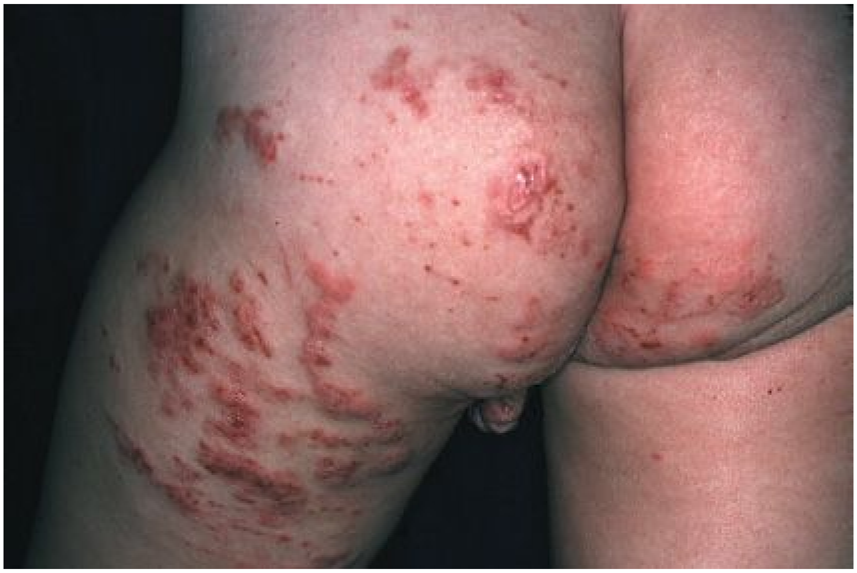

FIGURE 129-2 Cutaneous larva migrans on the buttocks and thigh of the same boy showing significant excoriations. (*Used with permission from Richard P. Usatine, MD. Usatine RP. A rash on the feet and buttocks. West J Med. 1999;170(6):344-335*.)

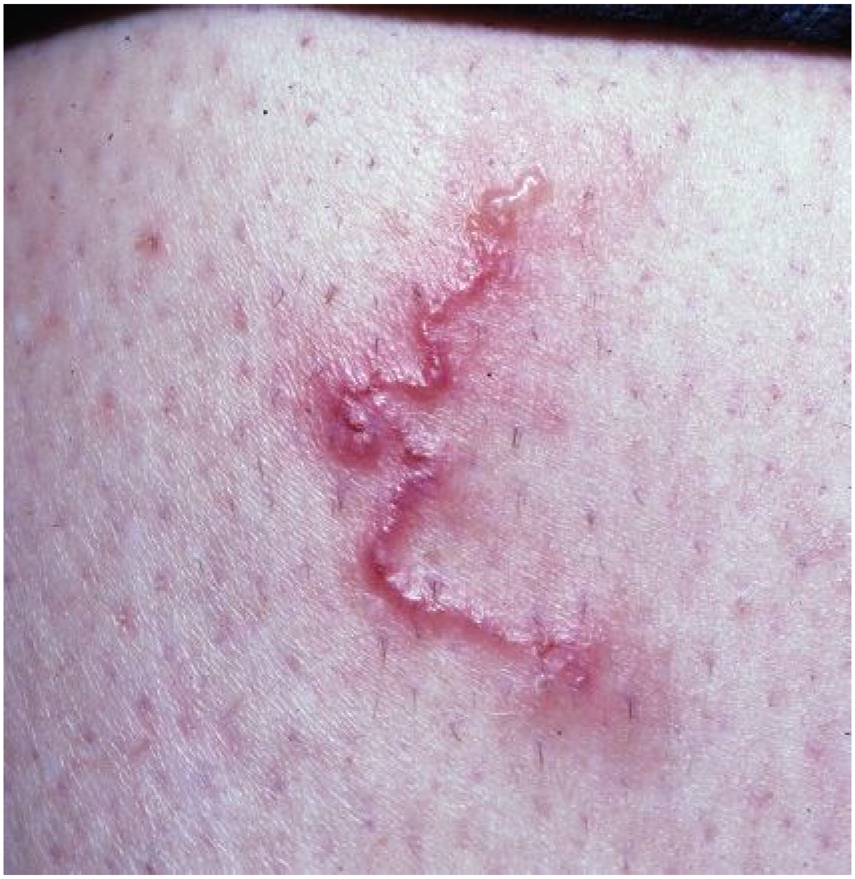

FIGURE 129-3 Close-up of a serpiginous burrow from cutaneous larva migrans on the leg. The actual larva is 2 to 3 cm beyond the visible tracks. (*Used with permission from John Gonzalez, MD.*)

- Intense pruritus, which often disrupts sleep.[3]
- Symptoms last for weeks to months, and, rarely, years. Most cases are self-limiting.[5]

TYPICAL DISTRIBUTION

- Feet and lower extremities (73%), buttocks (13% to 18%), and abdomen (16%) (**Figure 129-4**).[6,7]

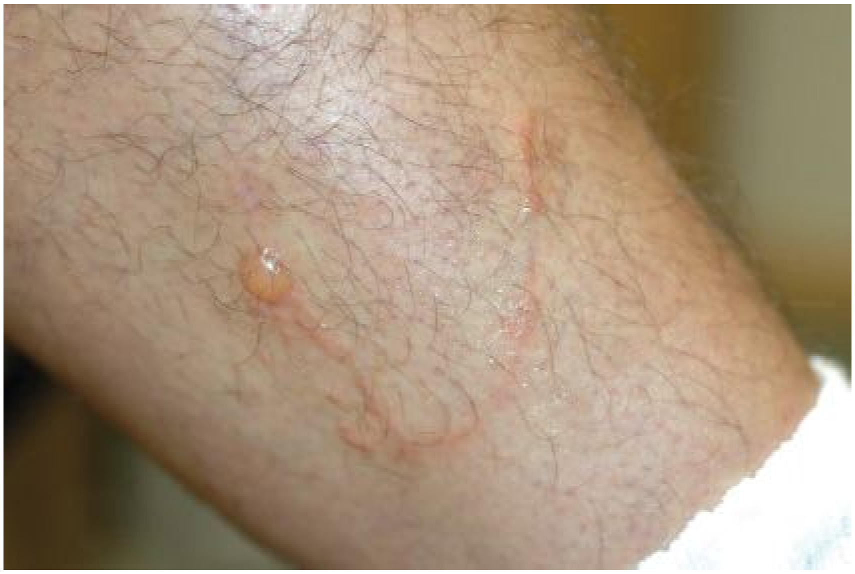

FIGURE 129-4 Cutaneous larva migrans on the leg of a teenager. He developed this pruritic serpiginous rash several days after returning from the beach. It extended several mm in length each day and a blister developed at the distal point of the burrow in the past 24 hours. (*Used with permission from Robert T. Brodell, MD.*)

- Areas that come in contact with contaminated sand or soil.
  - Most commonly the feet, buttocks, and thigh.[3]

LABORATORY AND IMAGING

- Not indicated, but rarely blood tests shows Eosinophilia or elevated immunoglobulin E levels.[5]

DIFFERENTIAL DIAGNOSIS

May be confused with the following conditions:

- Cutaneous fungal infections—Lesions are typically scaling plaques and annular macules with central clearing. If the serpiginous track of CLM is circular, this can lead to the incorrect diagnosis of “ringworm.” The irony is that ringworm is a dermatophyte fungus whereas CLM really is a worm (see Chapter 123, Tinea Corporis).
- Contact dermatitis—Differentiate by distribution of lesions, presence of vesicles, and absence of classical serpiginous tracks (see Chapter 131, Contact Dermatitis).
- Erythema migrans of Lyme disease—Lesions are usually annular macules or patches and are not raised and serpiginous (see Chapter 183, Lyme Disease).
- Phytophotodermatitis—The acute phase of phytophotodermatitis is erythematous with vesicles; this later develops into postinflammatory hyperpigmented lesions. This may be acquired while preparing drinks with lime on the beach and not from the sandy beach infested with larvae.

MANAGEMENT

- Oral thiabendazole was the first proven therapy with FDA approval. It was removed from the market in 2010.
- Albendazole has been successfully prescribed for more than 25 years, and is the Centers for Disease Control and Prevention (CDC) drug of

choice.[3,5] Albendazole lacks FDA approval for this indication.
  - The recommended dose is 400 mg daily for 3 days.[3,5] SOR Ⓑ
  - Cure rates with albendazole exceed 92 percent, but are less with single dosage.[3]
- Ivermectin (Stromectol) has been well studied and is an appropriate alternative as per the CDC with dosing of 0.2 mg/kg daily for 1 to 2 days.[3,5] It also lacks FDA approval for this indication.
  - A single dose of ivermectin 0.2 mg/kg is also recommended.[3] SOR Ⓑ
  - Cure rates of 77 to 100 percent with a single dose.[3]
  - Ivermectin has been used worldwide on millions with an excellent safety profile.[3]
  - Ivermectin is contraindicated in pregnancy, breastfeeding mothers, and in children weighing less than 15 kg.[3]
  - Studies on compounded ivermectin and albendazole for topical use are limited, but promising for use in children.[3]
- Cryotherapy is ineffective and harmful and should be avoided.[3] SOR Ⓑ

ADJUNCT THERAPY

- Antihistamines may relieve itching.
- Antibiotics may be used if secondary infection occurs.

FOLLOW-UP

- Follow-up if lesions persist.

PATIENT EDUCATION

- Wear shoes on beaches where animals are allowed.

- Keep covers on sand boxes.
- Pet owners should keep pets off the beaches, deworm pets, and dispose of feces properly.

SECTION 7 DERMATITIS/ALLERGIC

130 ATOPIC DERMATITIS

Richard P. Usatine, MD
Lindsey B. Finklea, MD

PATIENT STORYX

A 1-year-old Asian American girl is brought to her family physician for a new rash on her face and legs (**Figures 130-1** and **130-2**). The child is scratching both areas but is otherwise healthy. There is a family history of asthma, allergic rhinitis, and atopic dermatitis (AD) on the father's side. The child responded well to low-dose topical corticosteroids and emollients.

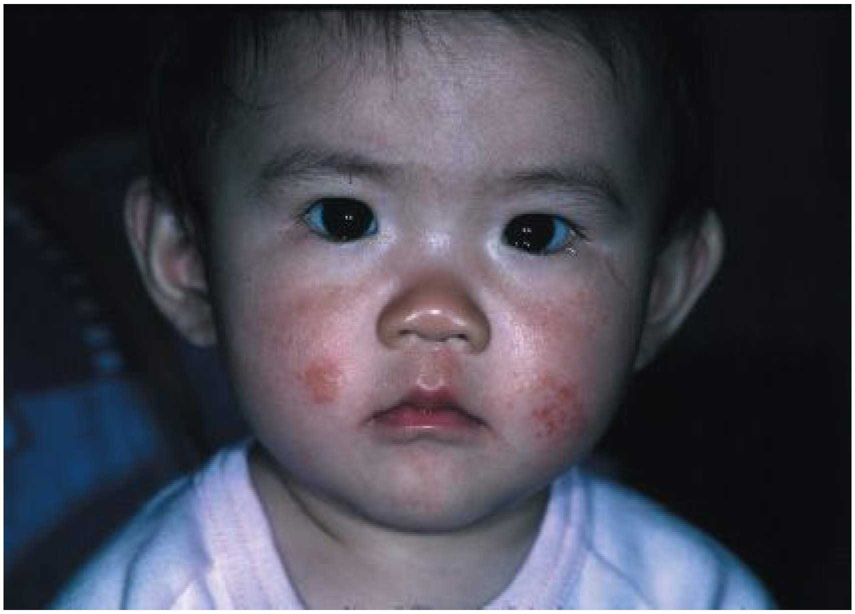

FIGURE 130-1 Atopic dermatitis on the cheeks of an infant. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier; 2004.*)

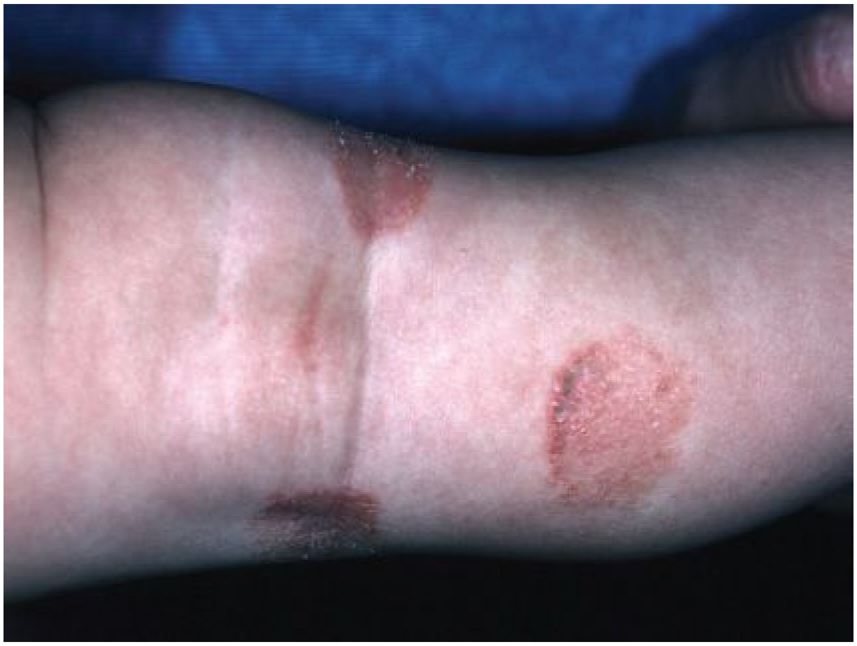

FIGURE 130-2 Atopic dermatitis on the leg of the infant in Figure 130-1. The coin-like pattern is that of nummular eczema. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier; 2004.*)

INTRODUCTION

AD is a chronic and relapsing inflammatory skin disorder characterized by itching and inflamed skin that is triggered by the interplay of genetic, immunologic, and environmental factors.

SYNONYMS

Eczema, atopic eczema.

EPIDEMIOLOGY

- AD is the most frequent inflammatory skin disorder in the US and the most common skin condition in children.[1]
- Worldwide prevalence in children is 15 to 20 percent and is increasing in industrialized nations.[2]
- Sixty percent of cases begin during the first year of life and 90 percent by 5 years of age.[1] 1/3 will persist into adulthood.[2]
- Sixty percent of adults with AD have children with AD (**Figure 130-3**).[1]

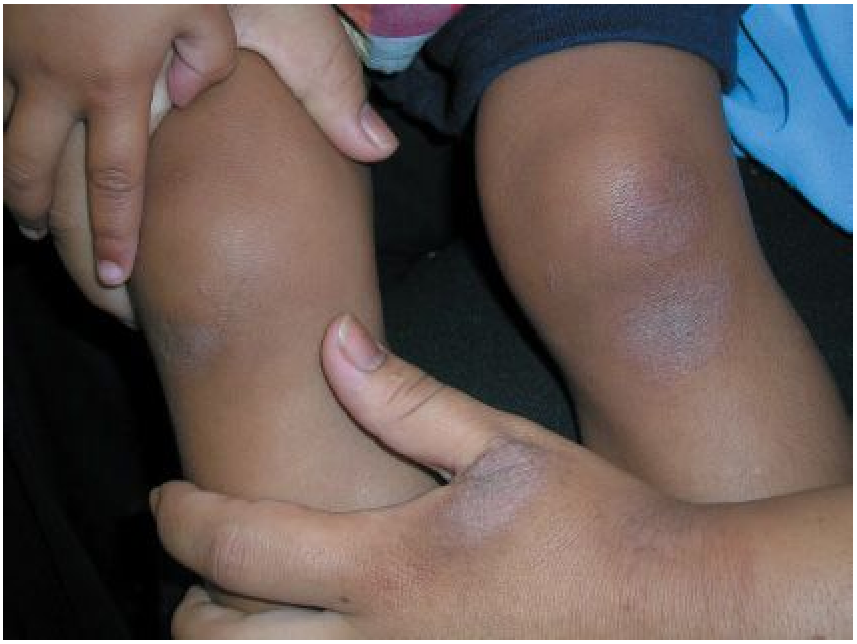

FIGURE 130-3 The child and his mother both have atopic dermatitis but not in the most typical distribution. (*Used with permission from Richard P. Usatine, MD.*)

ETIOLOGY AND PATHOPHYSIOLOGY

- Strong familial tendency, especially if atopy is inherited from the maternal side.

- Associated with elevated T-helper (Th) 2 cytokine response, elevated serum immunoglobulin (Ig) E, hyperstimulatory Langerhans cells, defective cell-mediated immunity, and loss of function mutation in filaggrin, an epidermal barrier protein.
- Exotoxins of *Staphylococcus aureus* act as superantigens and stimulate activation of T-cells and macrophages, worsening AD without actually showing signs of superinfection.
- Patients may have a primary T-cell defect. This may be why they can get more severe skin infections caused by herpes simplex virus (eczema herpeticum as seen in **Figure 130-4**) or bacteria (widespread impetigo). They are also at risk of a bad reaction to the smallpox vaccine with dissemination of the attenuated virus beyond the vaccination site. Eczema vaccinatum is a potentially deadly complication of smallpox vaccination (**Figure 130-5**).

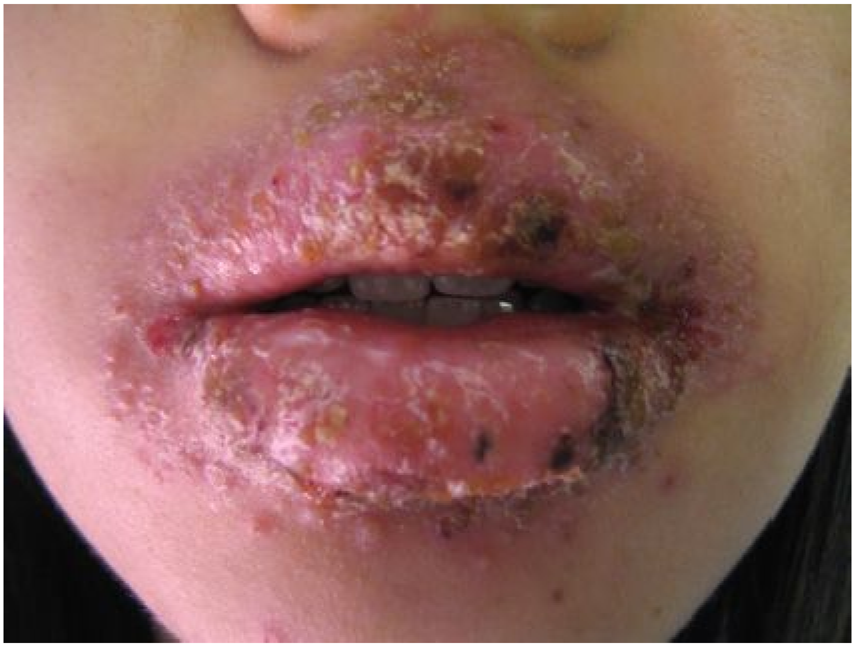

FIGURE 130-4 A teenager with atopic dermatitis superinfected by herpes (eczema herpeticum). (*Used with permission from Richard P. Usatine, MD.*)

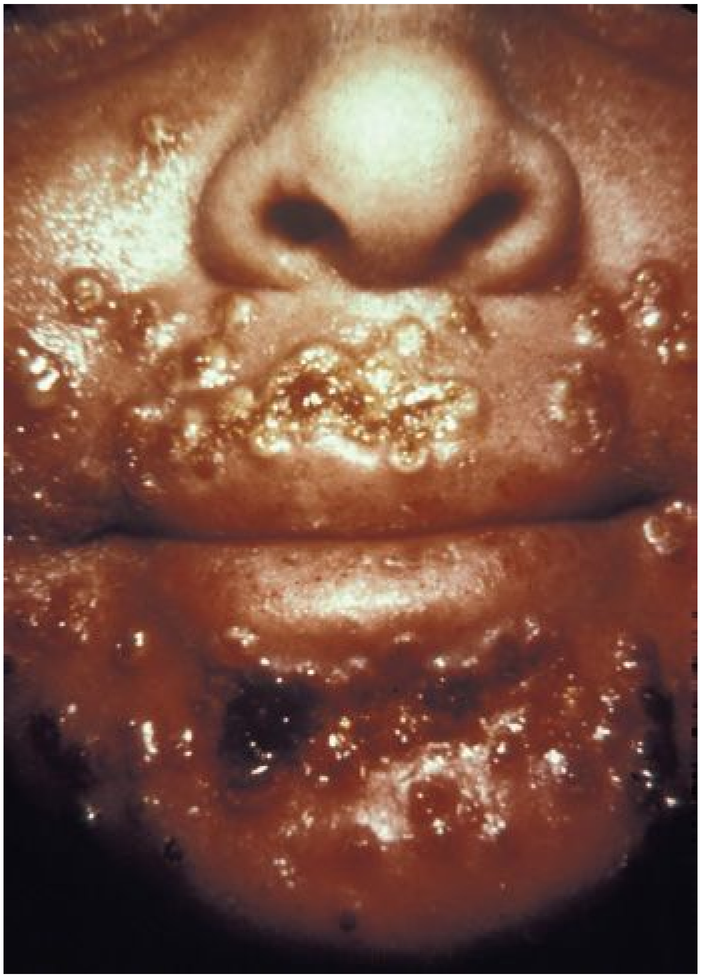

FIGURE 130-5 Eczema vaccinatum in a 17-year-old woman with atopic dermatitis who was given the smallpox vaccine. This eruption became this severe 8 days after her vaccination. (*Used with permission from CDC and Arthur E. Kaye*.)

DIAGNOSIS

- History—Pruritus is the hallmark symptom of AD. It is referred to as “the itch that rashes” as patients will often feel the need to scratch before a primary lesion appears. If it does not itch, it is not AD. Persons with AD often have a personal or family history of other allergic conditions, namely asthma and allergic rhinitis.

- The atopic triad is AD, allergic rhinitis, and asthma. Atopic persons have an exaggerated inflammatory response to factors that irritate the skin.
- Physical examination—Primary lesions include vesicles, scale, papules, and plaques.
- Secondary (or sequential) lesions include linear excoriations from scratching or rubbing, which may result in lichenification (thickened skin with accentuation of skin lines), fissuring, and prurigo nodularis. Crust may indicate that a secondary infection has occurred. Postinflammatory hyperpigmentation and follicular hyperaccentuation (more prominent hyperkeratotic follicles; **Figure 130-6**) may also be identified.

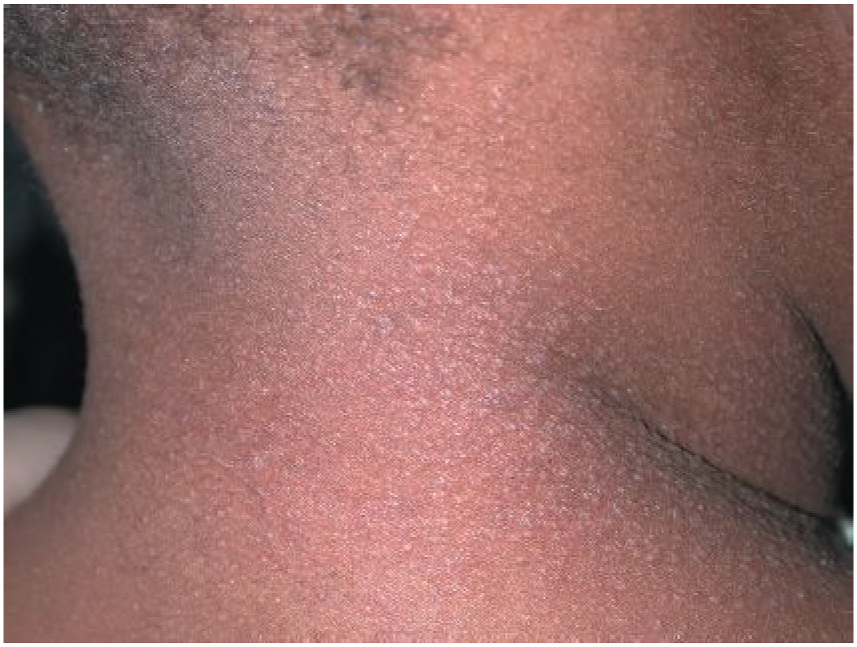

FIGURE 130-6 A young black girl with atopic dermatitis showing follicular hyperaccentuation on the neck. This pattern of atopic dermatitis is more common in persons of color. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

- AD often starts on the face in infancy and childhood (**Figures 130-1** and **130-7**) and then appears in the flexural folds, especially the antecubital and popliteal fossa (**Figures 130-8** to **130-10**).

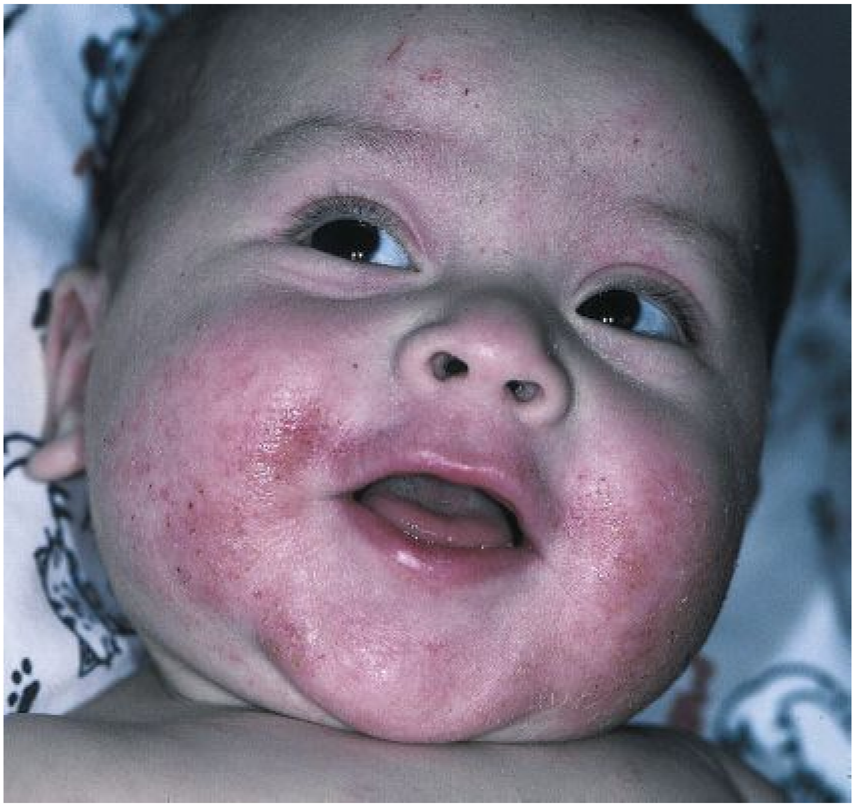

FIGURE 130-7 An infant with atopic dermatitis on the face that has become superinfected. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier; 2004*.)

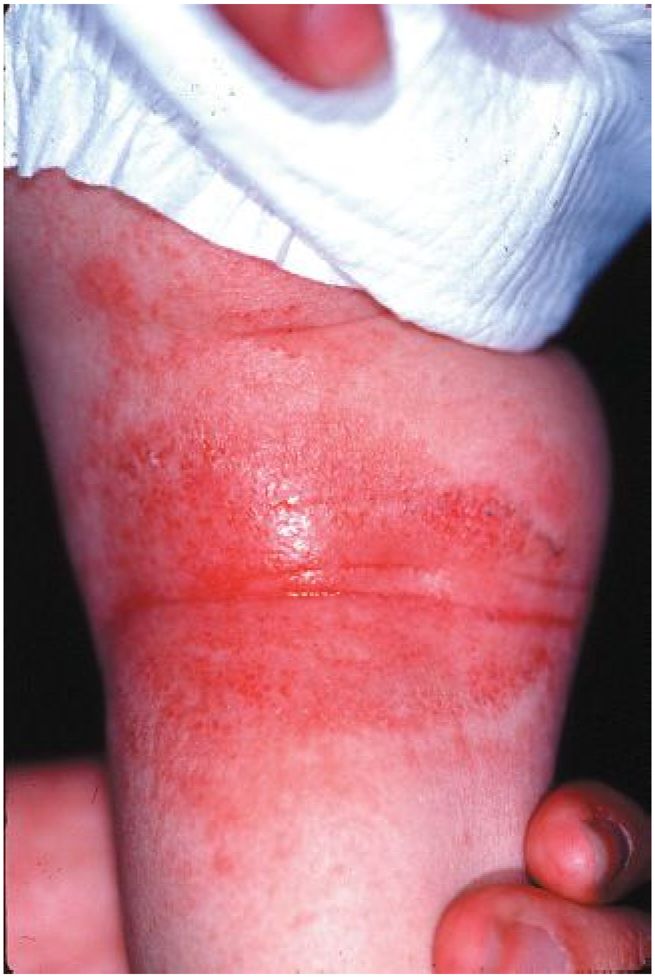

FIGURE 130-8 The same infant with superinfected atopic dermatitis of the popliteal fossa. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier; 2004*.)

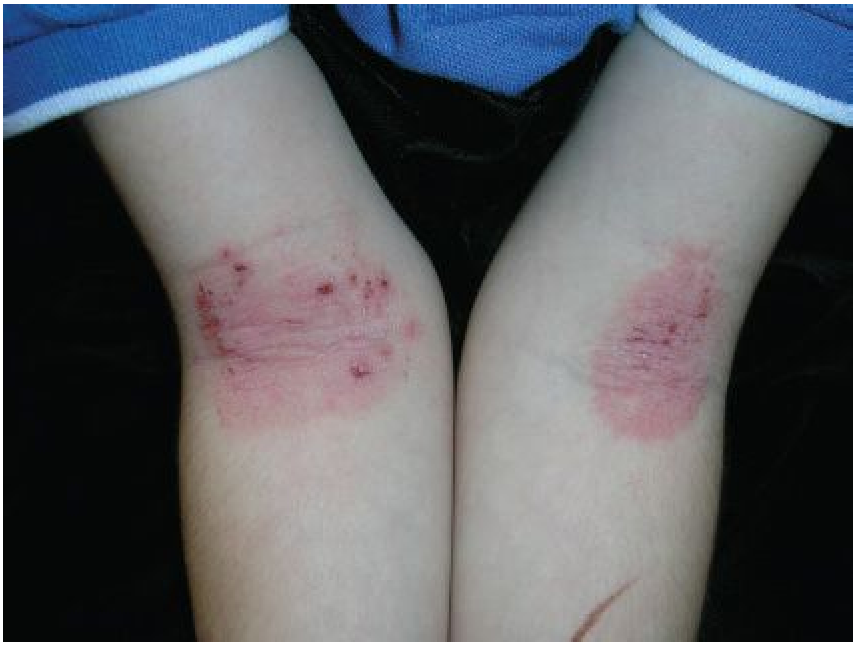

FIGURE 130-9 Atopic dermatitis in the antecubital fossae of a 6-year-old boy. Note the erythematous plaques with excoriations. (*Used with permission from Richard P. Usatine, MD*.)

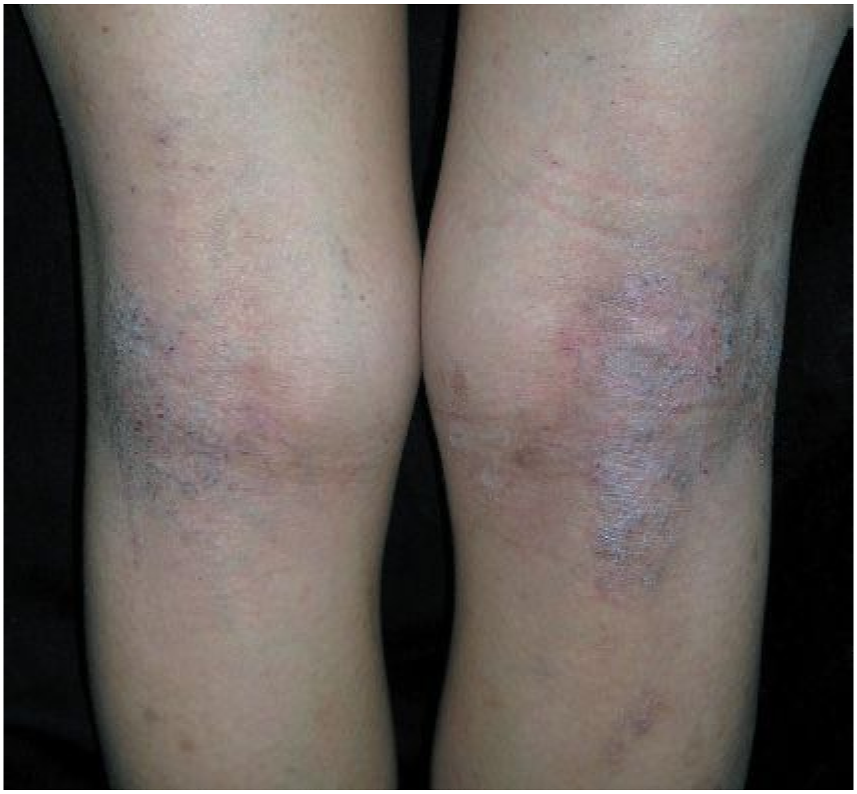

FIGURE 130-10 A 20-year-old young woman with severe chronic atopic dermatitis showing lichenification and hyperpigmentation in the popliteal fossa. (*Used with permission from Richard P. Usatine, MD.*)

- Involvement of the neck, wrists, and ankles also may occur (**Figures 130-11** and **130-12**).

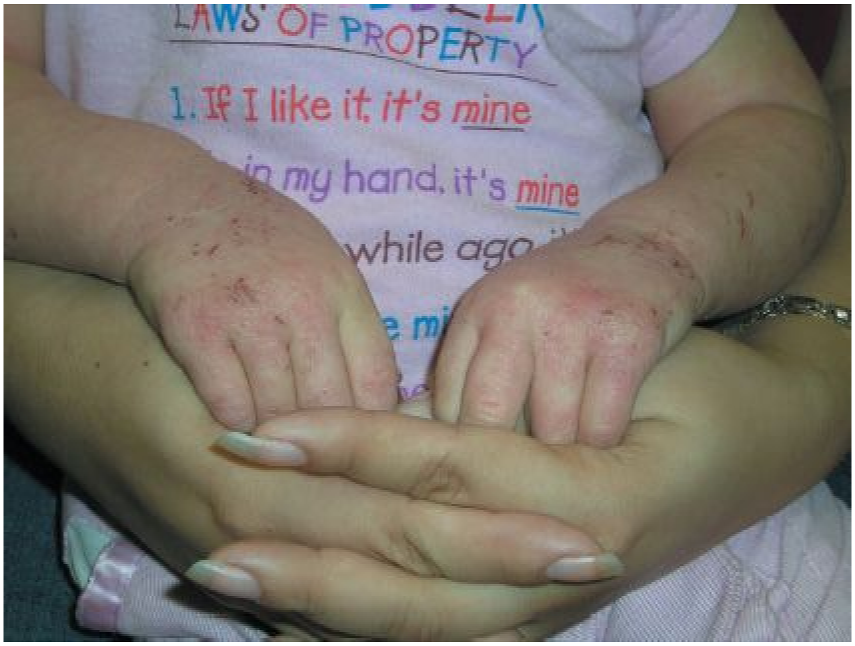

FIGURE 130-11 A 2-year-old girl with atopic dermatitis visible on her hands, wrists, and arms. (*Used with permission from Richard P. Usatine, MD.*)

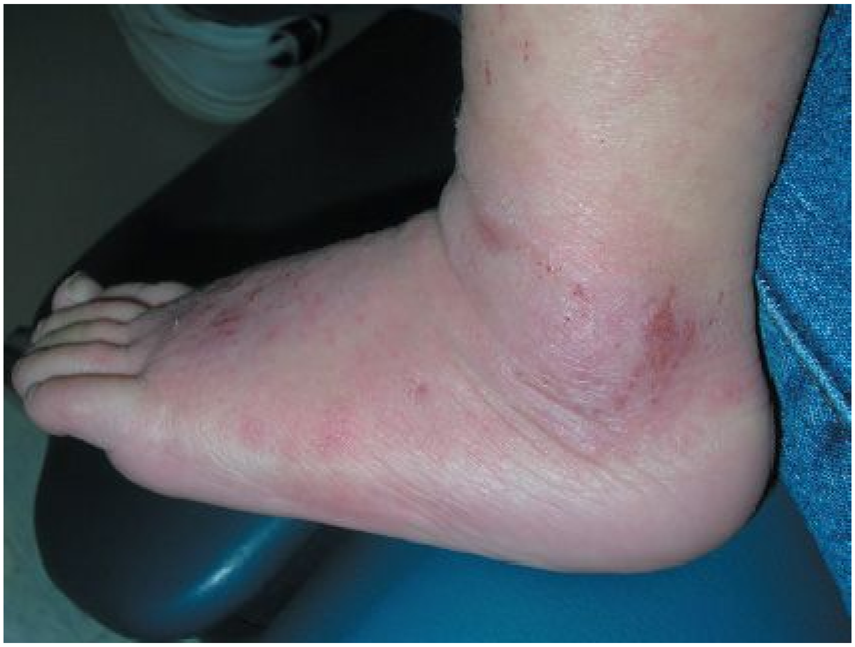

FIGURE 130-12 The girl in **Figure 130-11** with an exacerbation of her atopic dermatitis on the ankle showing many excoriations. (*Used with permission from Richard P. Usatine, MD*.)

- AD in adults can occur on the hands, around the mouth, or eyelids as well as all the other areas (**Figures 130-13** and **130-14**).

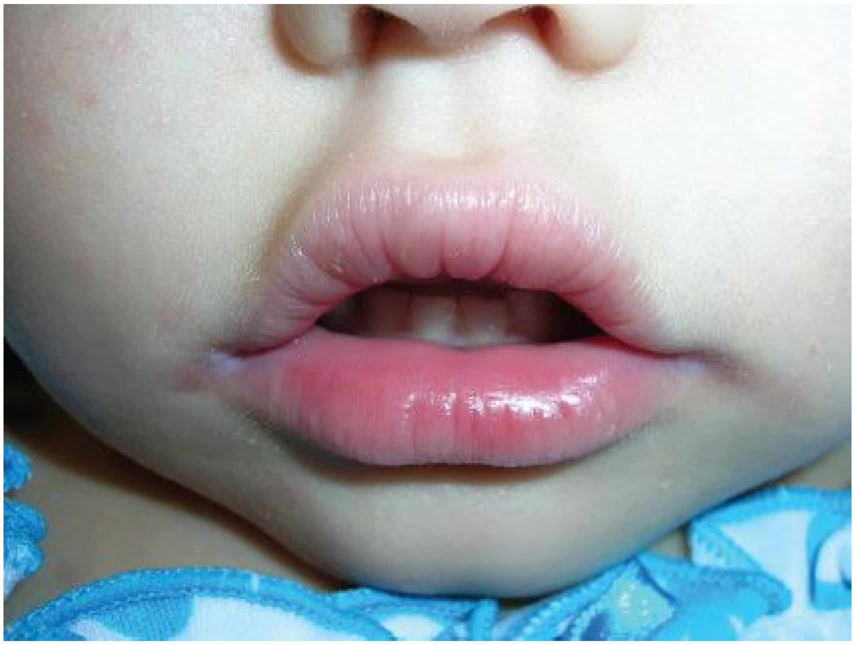

FIGURE 130-13 Angular cheilitis in an infant with atopic dermatitis. (*Used with permission from Richard P. Usatine, MD.*)

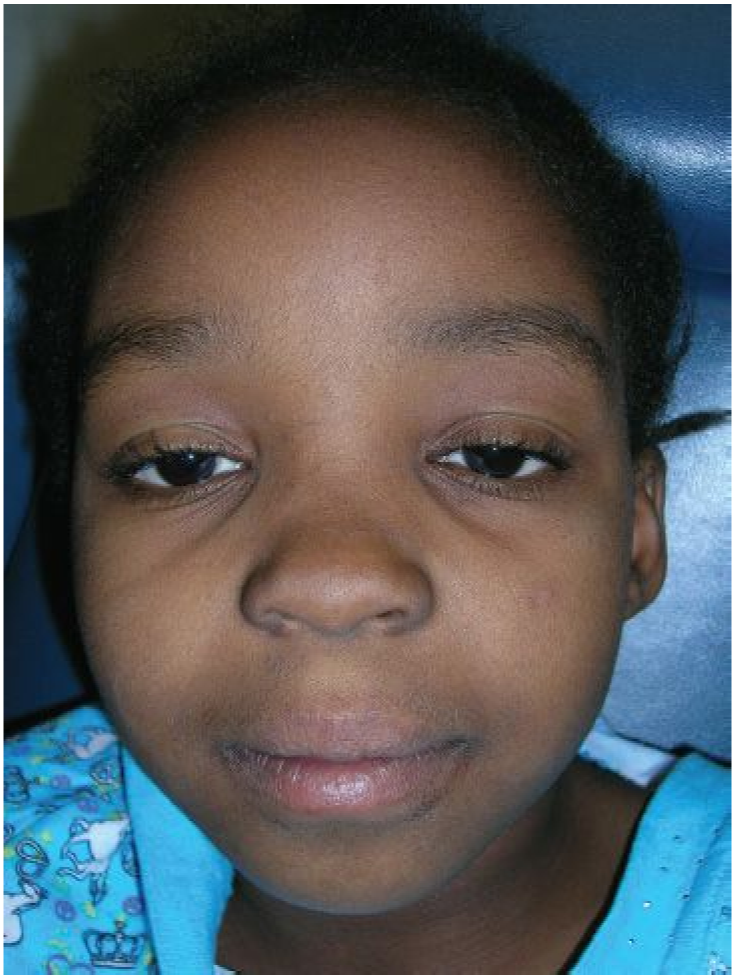

FIGURE 130-14 A young girl with the atopic triad. The patient has Denny Morgan lines visible on the lower eyelids. She was observed doing the allergic salute many times during her office visit. (*Used with permission from Richard P. Usatine, MD.*)

- In one series, the prevalence of hand involvement in patients with active AD was 58.9 percent. There was a significant trend toward an increasing prevalence of hand involvement with increasing age.[3]

OTHER FEATURES OR CONDITIONS ASSOCIATED WITH ATOPIC DERMATITIS

- Keratosis pilaris (**Figure 130-15**).

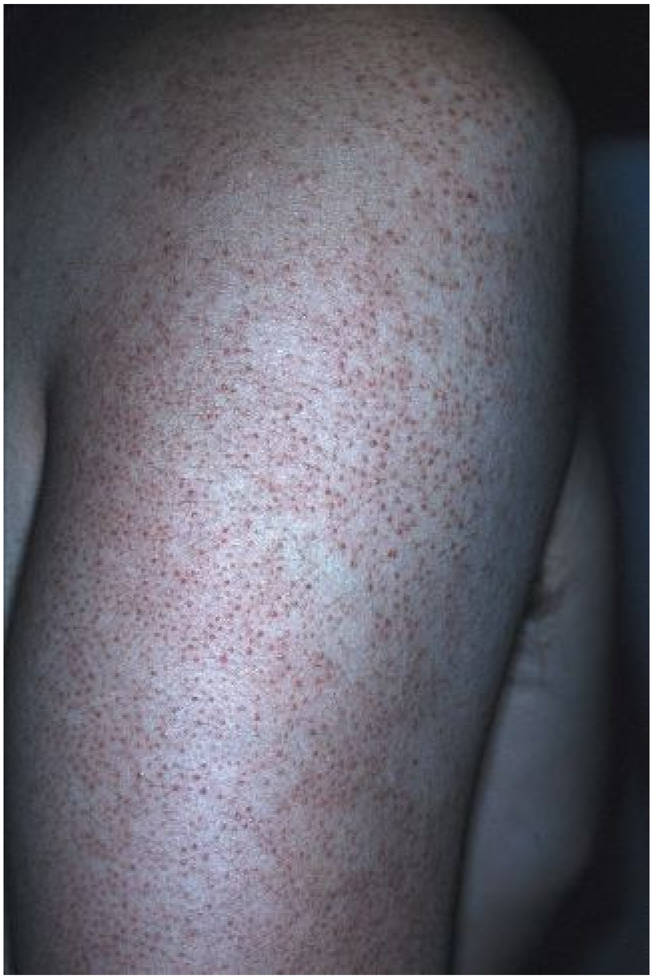

FIGURE 130-15 Keratosis pilaris on the lateral upper arm. The papules can vary in color from pink to brown to white depending upon the skin color of the person. (*Used with permission from Richard P. Usatine, MD.*)

- Ichthyosis (**Figure 130-16**).

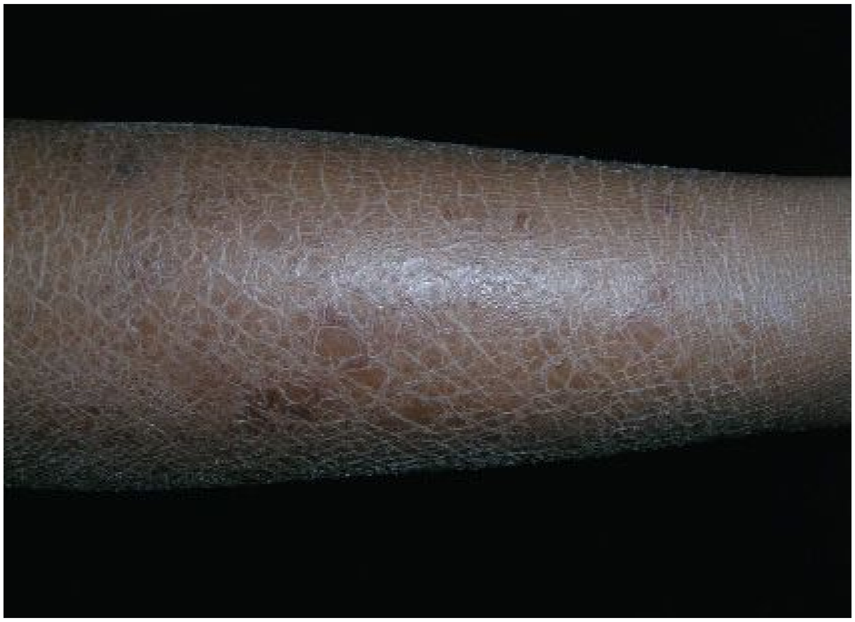

FIGURE 130-16 Acquired ichthyosis on the leg of a 9-year-old boy with atopic dermatitis. Note the fish-scale appearance along with the dry skin. (*Used with permission from Richard P. Usatine, MD*.)

- Pityriasis alba (**Figures 130-17** and **130-18**).

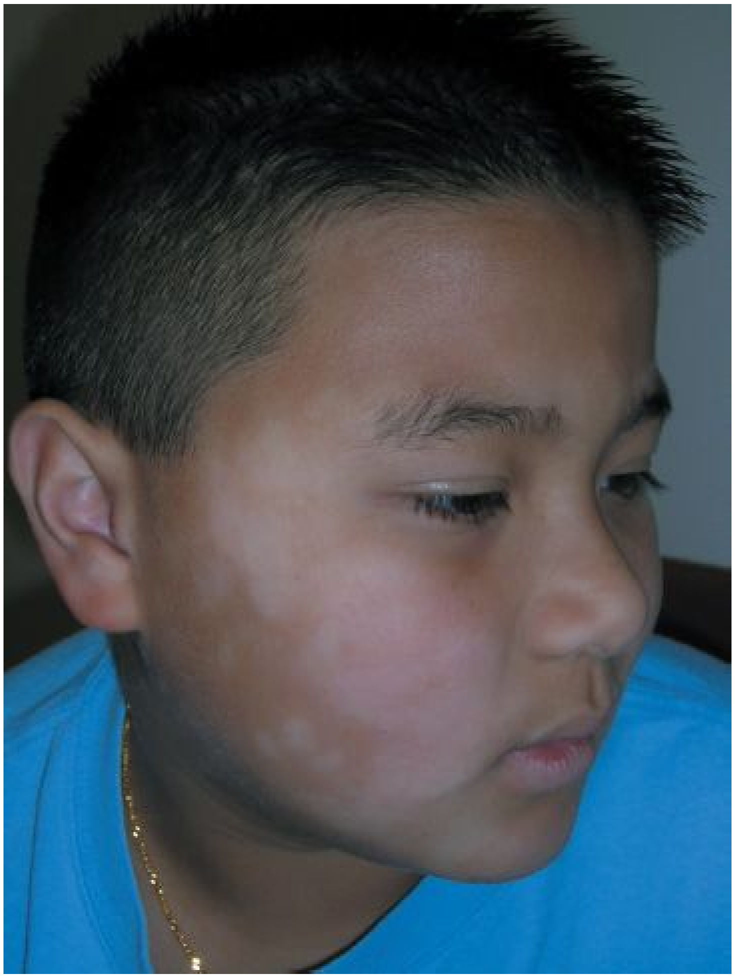

FIGURE 130-17 Pityriasis alba on the face of a young boy. (*Used with permission from Richard P. Usatine, MD*.)

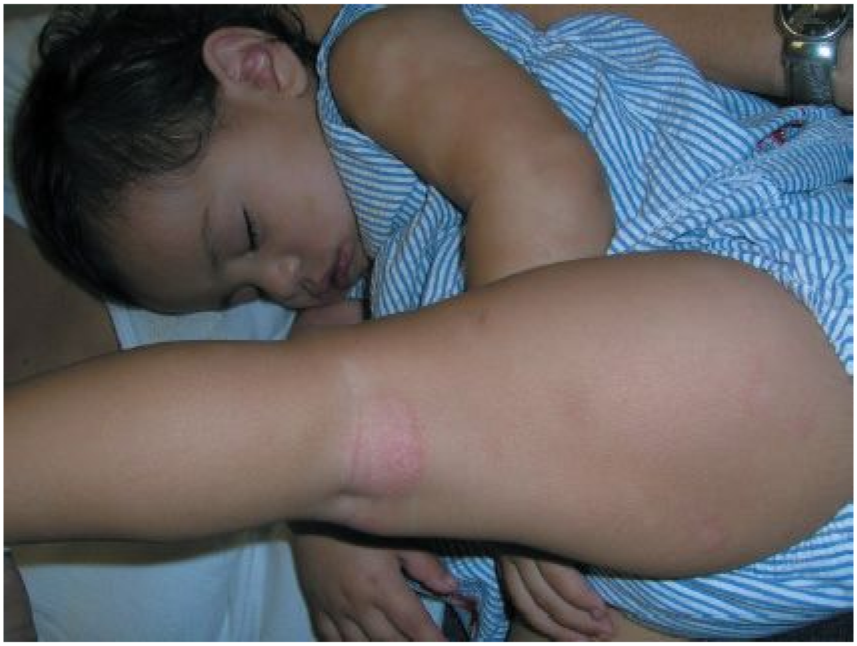

FIGURE 130-18 An 18-month-old girl with atopic dermatitis visible in her popliteal fossa and pityriasis alba on her arm (*Used with permission from Richard P. Usatine, MD*.)

- Palmar or plantar hyperlinearity.
- Angular Cheilitis (**Figure 130-13**).
- Dennie-Morgan lines (infraorbital fold) (**Figure 130-14**).
- Hand or foot dermatitis
- Susceptibility to cutaneous infections (**Figures 130-4** and **130-5**).
- Xerosis (dry skin) (**Figure 130-19**).

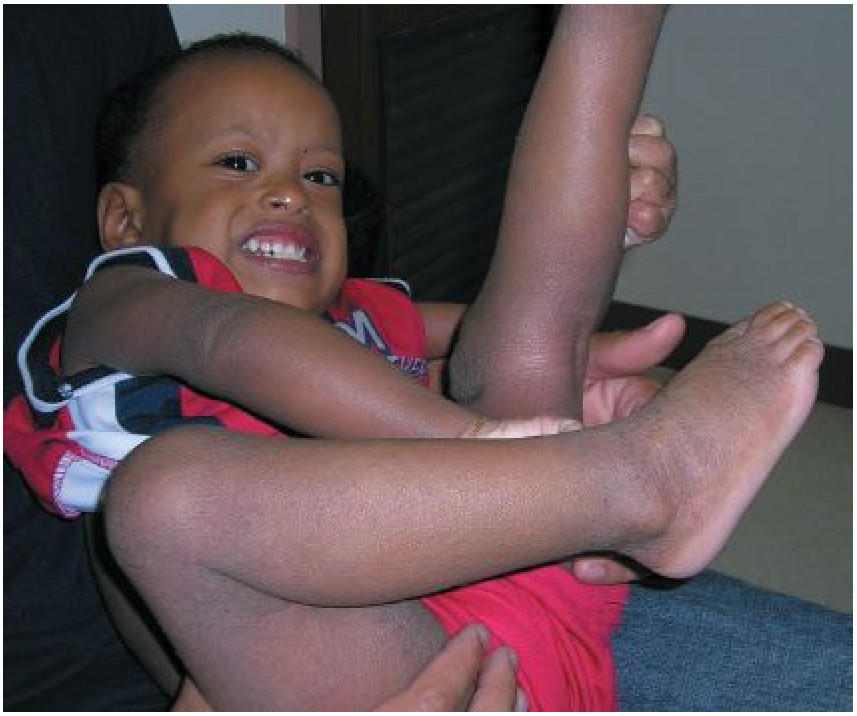

FIGURE 130-19 Severe atopic dermatitis in a 2-year-old black boy with very dry (xerotic) skin. He is spontaneously scratching and crying out in discomfort. (*Used with permission from Richard P. Usatine, MD*.)

- Eye findings—Recurrent conjunctivitis, keratoconus (**Figure 130-20**), cataracts, and orbital darkening.

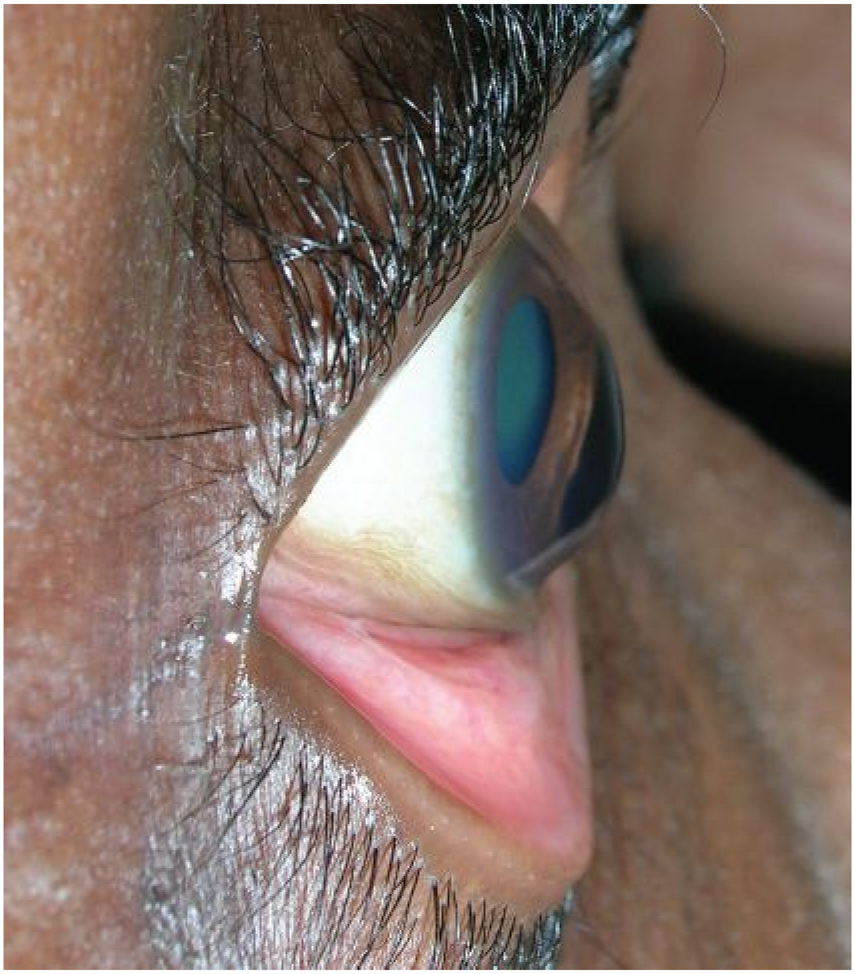

FIGURE 130-20 Keratoconus in a young woman with severe atopic dermatitis. She admits to rubbing her eyes frequently. In keratoconus the cornea bulges out in the middle like a cone and can adversely affect the health of the eye. (*Used with permission from Richard P. Usatine, MD.*)

- A horizontal nasal crease may be seen over the bridge of the nose in a patient with allergic rhinitis prone to performing the allergic salute. In some patients, this crease may become hyperpigmented (**Figure 130-21**).

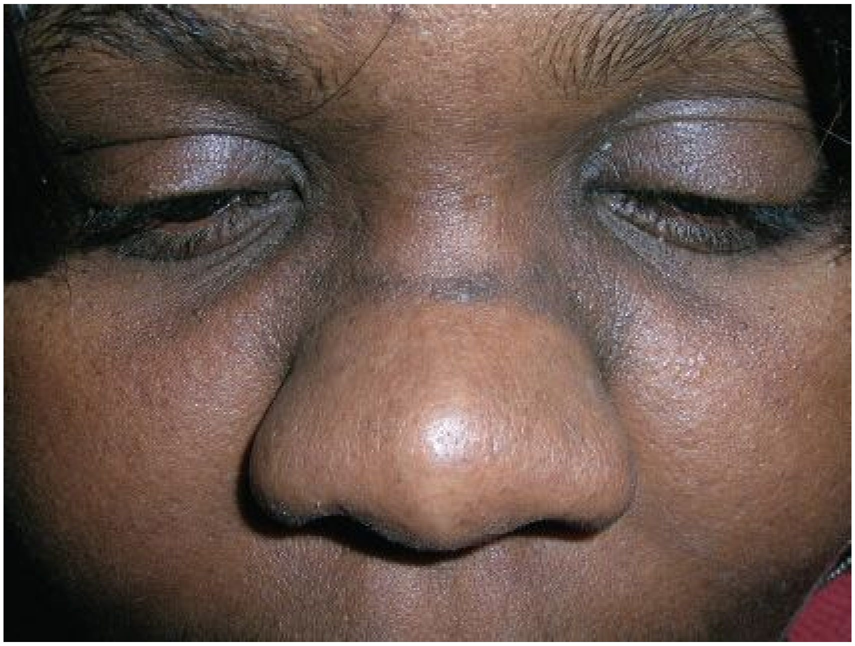

FIGURE 130-21 Hyperpigmented horizontal nasal crease in a patient with the atopic triad who repeatedly performs the allergic salute when her nose is feeling itchy. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY STUDIES

Labs are rarely needed if the history and physical examination support the diagnosis. Occasionally, a KOH preparation may be needed to rule out tinea or a skin scraping to rule out scabies. Of course, both of these conditions can occur on top of AD. A Radioallergosorbent test (RAST) for food allergies and serum IgE levels are not of proven benefit.

DIFFERENTIAL DIAGNOSIS

- Dyshidrotic eczema—Dry inflamed scaling skin on the hands and feet with tapioca-like vesicles, especially seen between the fingers.
- Seborrheic dermatitis—Greasy, scaly lesions on scalp, face, and chest (see Chapter 135, Seborrheic Dermatitis).

- Psoriasis—Thickened plaques on extensor surfaces, scalp, and buttocks; pitted nails (see Chapter 136, Psoriasis).
- Lichen simplex chronicus (sometimes called neurodermatitis)—Usually, a single patch in an area accessible to scratching such as the ankle, wrist, and neck.
- Contact dermatitis—Positive exposure history, rash in area of exposure; absence of family history. Patch testing may be helpful in distinguishing from AD (see Chapter 131, Contact Dermatitis).
- Scabies—Papules, burrows, finger web involvement, positive skin scraping (see Chapter 128, Scabies).
- Dermatophyte infection—On the hands or feet can look just like hand or foot dermatitis; a positive KOH preparation for hyphae can help make the diagnosis (see Chapter 125, Tinea Pedis).

MANAGEMENT

- There is some evidence suggesting that controlling house dust mites reduces severity of symptoms in patients with the atopic triad. Bedding covers were found to be the most effective method to control dust mites and AD symptoms in this subgroup of AD patients. Unfortunately, dust mite interventions are not proven to be effective for patients with AD that do not have the full atopic triad.[1] SOR Ⓑ
- Dietary restriction is controversial but may be useful for infants with proven egg allergies. SOR Ⓑ There is insufficient evidence that dietary manipulation in children or adults reduces symptom severity and may cause iatrogenic malnourishment.
- Patient education, avoidance of possible triggers (enzyme-rich detergents, wool clothing), and dry skin care should be optimized.
- Dilute bleach baths (0.5 cup of 6 percent bleach in tub of bath water) lower the *S. aureus* burden on the skin, decreasing severity of AD.[4] SOR Ⓑ

- There is some evidence suggesting probiotic treatment of pregnant mother and prolonged nursing of child may delay onset of AD.[1] SOR Ⓑ

TOPICAL THERAPIES

- Topical steroids and emollients have been proven to work for AD and are the mainstay of treatment.[1] SOR Ⓐ
- Vehicle selection and steroid strength area based on age, body location, and lesion morphology. The ointments are best for dry and cracked skin and are more potent. Creams are easier to apply and are better tolerated by some patients.
- Use stronger steroids for thicker skin, severe outbreaks, or lesions that have not responded to weaker steroids. Avoid strong steroids on face, genitals, and armpits and in infants and small children.
- To avoid adverse effects, the highest potency steroids (e.g., clobetasol) should not be used for longer than 2 weeks continuously. However, they can be used intermittently for recurring AD in a pulse-therapy mode (e.g., apply every weekend, with no application on weekdays).
- Topical calcineurin inhibitors (immunomodulators, such as pimecrolimus and tacrolimus) reduce the rash severity and symptoms in children and adults.[1] SOR Ⓐ These work by suppressing antigen-specific T-cell activation and inhibiting inflammatory cytokine release. These are steroid-sparing medications that are helpful for eyelid eczema and in other areas when steroids may thin the skin (**Figure 130-22**). These agents are now only approved for persons older than 2 years of age and the FDA states that they should not be used as first-line agents because of a possible risk of causing cancer. The American Academy of Dermatology (AAD) has released a statement that the “data does not prove that the proper topical use of pimecrolimus and tacrolimus is dangerous.”

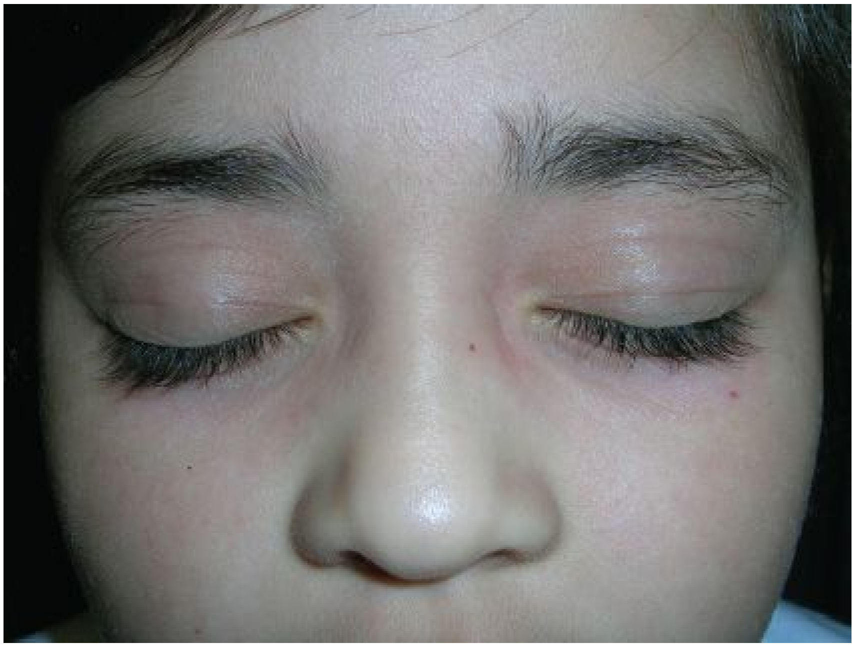

FIGURE 130-22 Atopic dermatitis involving the eyelids in this 8-year-old girl with atopic dermatitis since infancy. A topical calcineurin inhibitor helped to get the eyelid eczema under control. (*Used with permission from Richard P. Usatine, MD*.)

- Short-term adjunctive use of topical doxepin may aid in the reduction of pruritus.[1] SOR Ⓐ
- Topical and systemic antibiotics are used for AD that has become secondarily infected with bacteria. The most common infecting organism is *S. aureus*. Weeping fluid and crusting during an exacerbation should prompt consideration of antibiotic use[1] (**Figures 130-7**, **130-8**, and **130-23**). SOR Ⓐ

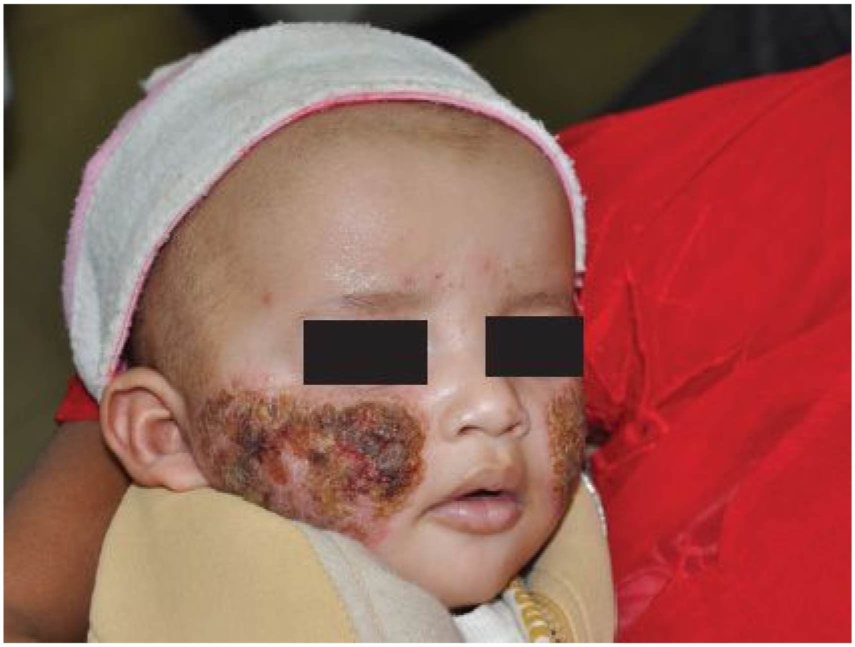

FIGURE 130-23 Superinfected atopic dermatitis on the cheeks. The crusting is a sign of secondary infection usually caused by Staph. aureus or Strep. pyogenes. (*Used with permission from Richard P. Usatine, MD*.)

ORAL/SYSTEMIC THERAPIES

- For extensive flares, consider oral prednisone or an IM shot of triamcinolone (40 mg in 1 mL of 40 mg/mL suspension for adults).[1] SOR Ⓒ
- The value of antihistamines in AD is controversial. If antihistamines are to be used, the sedating agents are most effective and can be given at night.[1] SOR Ⓑ
- Cyclosporine for severe refractory AD can be used in long-term maintenance therapy to treat and avoid relapse.[1] SOR Ⓐ Cyclosporine is approved for 1 year of lifetime therapy for skin diseases in the US and 2 years in Europe (**Figure 130-24**). A short course with careful monitoring can be very helpful.

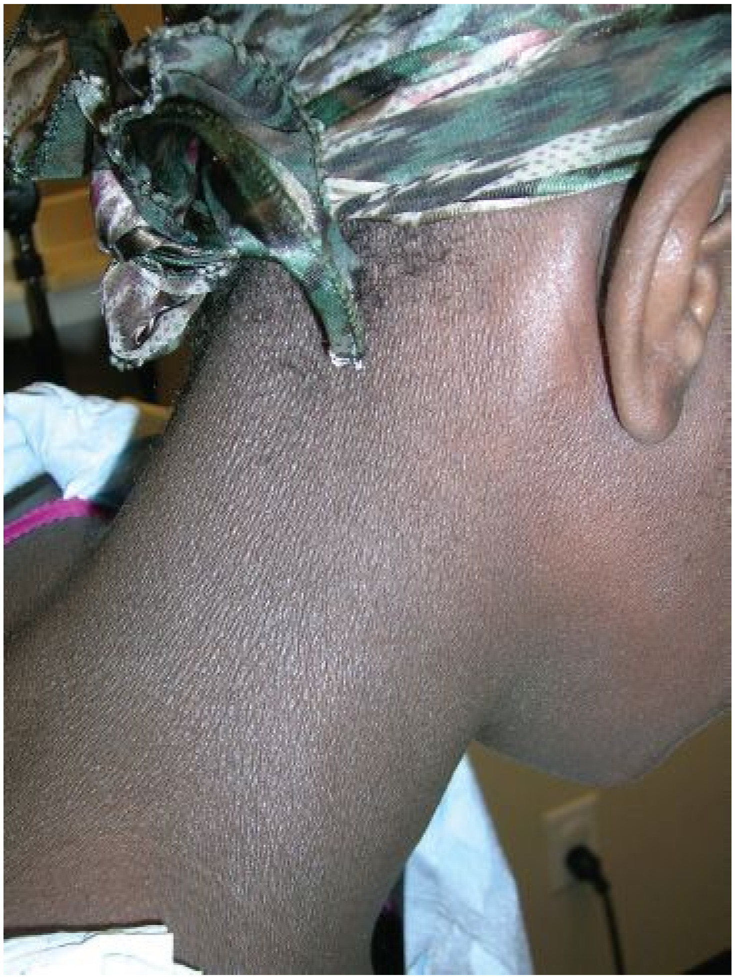

FIGURE 130-24 Atopic dermatitis so flared up from head to ankles that this 17-year-old teen was started on oral cyclosporine. Her response to cyclosporine over the next 2 months was so excellent that she was able to go off the cyclosporine and keep her skin clear with emollients and occasional topical steroids. (*Used with permission from Richard P. Usatine, MD*.)

- UV phototherapy may also be used in severe refractory AD with some success.[1] SOR Ⓐ
- Azathioprine, methotrexate, and mycophenolate mofetil are of possible benefit, but there is less evidence for their effectiveness.[1] SOR Ⓒ

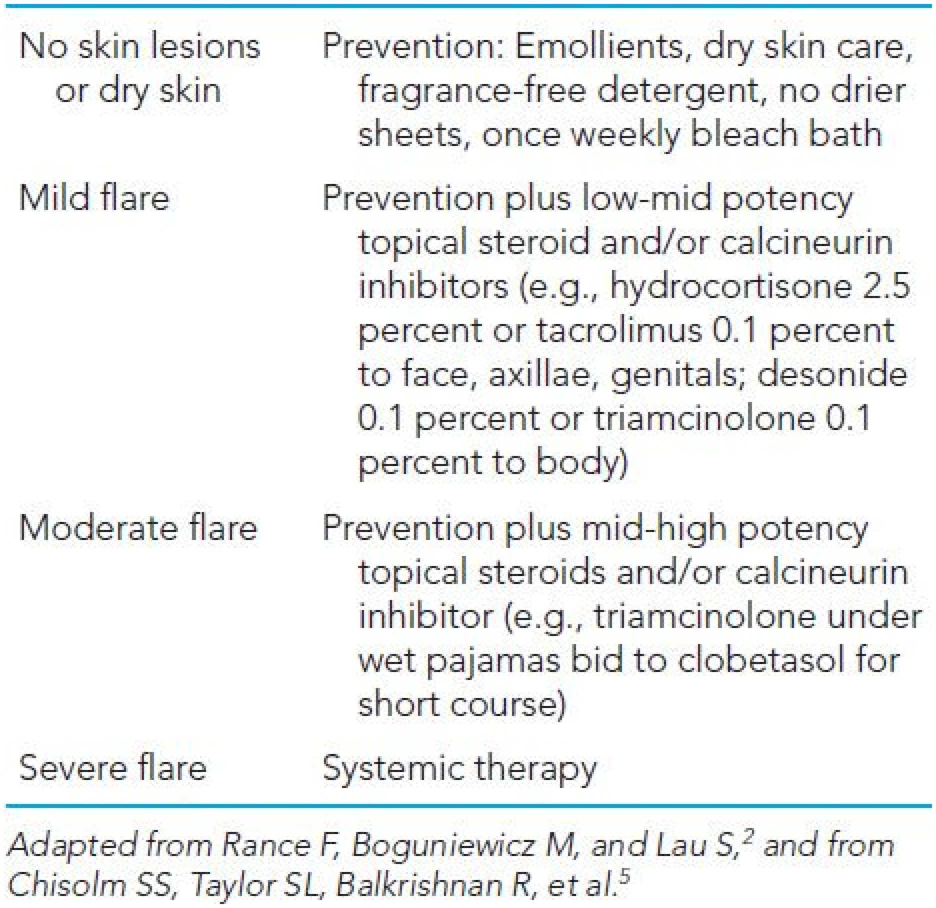
FOLLOW-UP

Regular follow-up should be given to patients with chronic and difficult-to-control AD. Establishing a good regimen is crucial to good control and then visits may be adjusted to longer intervals between visits.

PATIENT EDUCATION

Patients need to know that scratching their AD makes it worse. Behavior modification is especially challenging in young children and may involve cutting fingernails short and occluding hands/body at night with cotton gloves or clothing. Because of its chronicity and cyclic nature, AD patients may have poor adherence. In one recent study, overall adherence was 32 percent. A written action plan may be employed to improve adherence (**Table 130-1**).

TABLE 130-1 Written Action Plan to Be Given to Patients (or Their Parents)



No skin lesions or dry skin	Prevention: Emollients, dry skin care, fragrance-free detergent, no drier sheets, once weekly bleach bath
Mild flare	Prevention plus low-mid potency topical steroid and/or calcineurin inhibitors (e.g., hydrocortisone 2.5 percent or tacrolimus 0.1 percent to face, axillae, genitals; desonide 0.1 percent or triamcinolone 0.1 percent to body)
Moderate flare	Prevention plus mid-high potency topical steroids and/or calcineurin inhibitor (e.g., triamcinolone under wet pajamas bid to clobetasol for short course)
Severe flare	Systemic therapy

131 CONTACT DERMATITIS

Richard P. Usatine, MD

PATIENT STORY

An 11-year-old girl presents with a rash on her abdomen for the past month (**Figure 131-1**).

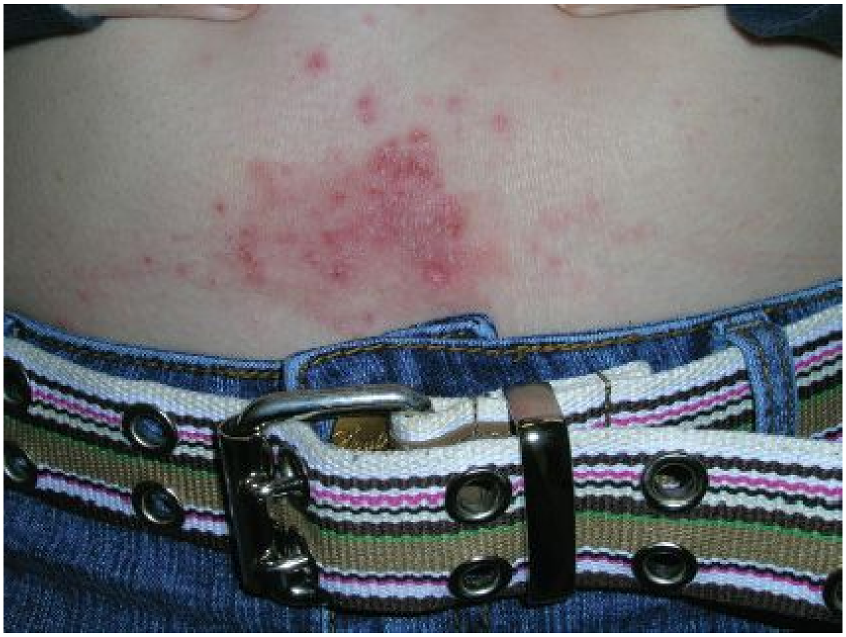

FIGURE 131-1 Allergic contact dermatitis to the nickel in the jeans' fastener and the belt buckle causing erythema, scaling, and hyperpigmentation. (*Used with permission from Richard P. Usatine, MD.*)

She denies other skin problems but her mother states that she had atopic dermatitis as a baby. The clinician readily identifies the problem as a nickel allergy to the nickel found in her belt buckle and jeans. He prescribes avoidance of nickel contact to the skin and prescribes 0.1 percent triamcinolone ointment to be applied twice daily until the contact dermatitis resolves. He describes various methods to cover medal snaps intense including sewing and fabric or painting clear nail polish over the metal. Neither method works 100 percent but it is hard to find jeans without metal snaps. The patient responded rapidly to treatment.[1,2]

INTRODUCTION

Contact dermatitis (CD) is a common inflammatory skin condition characterized by erythematous and pruritic skin lesions resulting from the contact of skin with a foreign substance. Irritant contact dermatitis (ICD) is caused by the non–immune-modulated irritation of the skin by a substance, resulting in a skin changes. Allergic contact dermatitis (ACD) is a delayed-type hypersensitivity reaction in which a foreign substance comes into contact with the skin, and upon reexposure, skin changes occur.[3]

EPIDEMIOLOGY

- Some of the most common types of CD are secondary to exposures to poison ivy, nickel, and fragrances.[4]
- Patch testing data indicate that the five most prevalent contact allergens out of more than 3700 known contact allergens are nickel (14.3% of patients tested), fragrance mix (14%), neomycin (11.6%), balsam of Peru (10.4%), and thimerosal (10.4%).[5]
- Occupational skin diseases (chiefly CD) rank second only to traumatic injuries as the most common type of occupational disease. Chemical irritants such as solvents and cutting fluids account for most ICD cases. Sixty percent were ACD and 32 percent were ICD. Hands were primarily affected in 64 percent of ACD and 80 percent of ICD[4] (**Figure 131-2**).

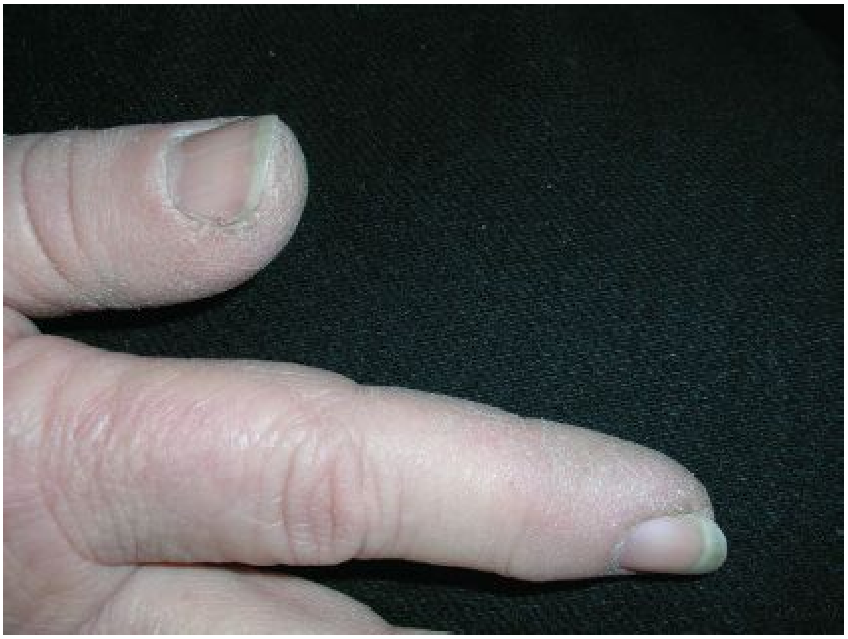

FIGURE 131-2 Occupational irritant contact dermatitis in a woman whose hands are exposed to chemicals while making cowboy hats in Texas. Occupational exposures might affect teens as they begin to enter the work force. (*Used with permission from Richard P. Usatine, MD*.)

ETIOLOGY AND PATHOPHYSIOLOGY

- CD is a common inflammatory skin condition characterized by erythematous and pruritic skin lesions resulting from the contact of skin with a foreign substance.
- ICD is caused by the non–immune-modulated irritation of the skin by a substance, resulting in a skin rash.
- ACD is a delayed-type hypersensitivity reaction in which a foreign substance comes into contact with the skin, and is linked to skin protein forming an antigen complex that leads to sensitization. Upon reexposure of the epidermis to the antigen, the sensitized T cells initiate an inflammatory cascade, leading to the skin changes seen in ACD.

DIAGNOSIS

HISTORY

Ask about contact with known allergens (i.e., nickel, fragrances, neomycin, and poison ivy/oak).

- Nickel exposure is often related to the wearing of rings, jewelry, and metal belt buckles (**Figures 131-3** to **131-5**).

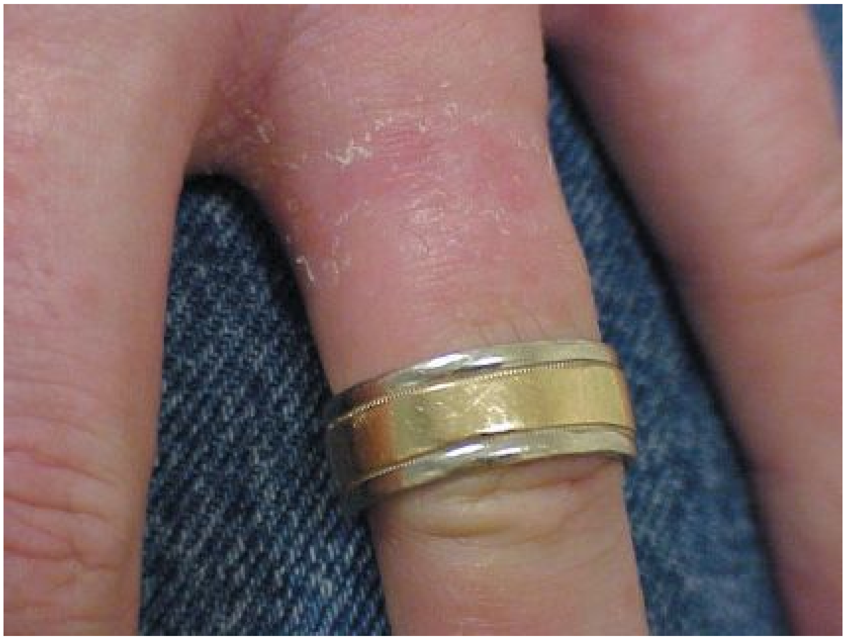

FIGURE 131-3 Patient moved up his ring to show the allergic contact dermatitis secondary to a nickel allergy to the ring. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier, Inc; 2004*.)

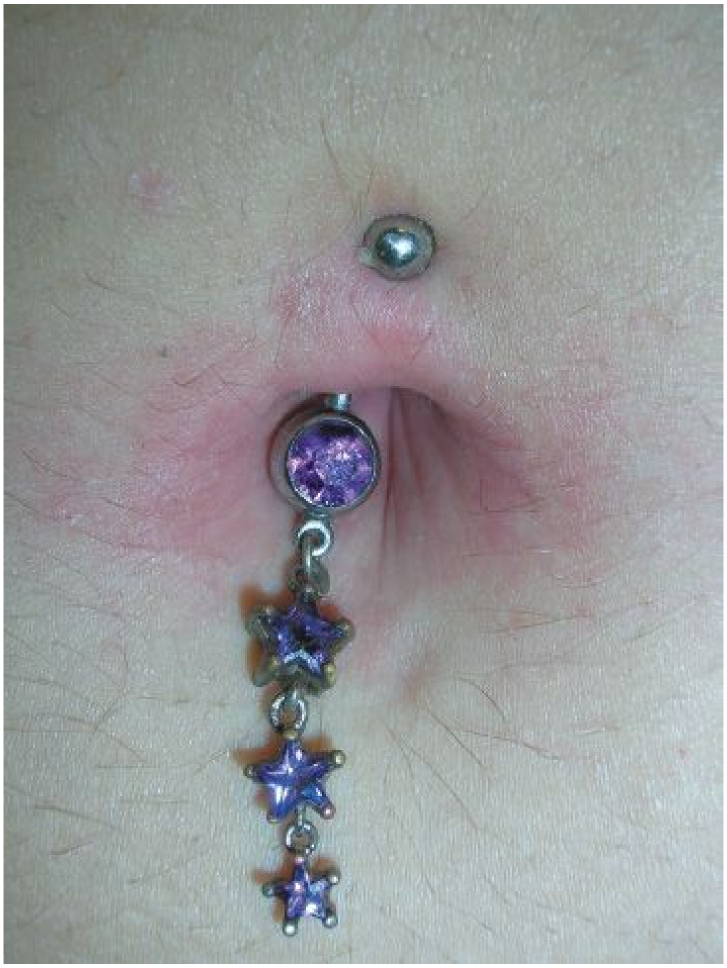

FIGURE 131-4 Allergic contact dermatitis to the metal in the bellybutton ring of a teenage girl. (*Used with permission from Richard P. Usatine, MD.*)

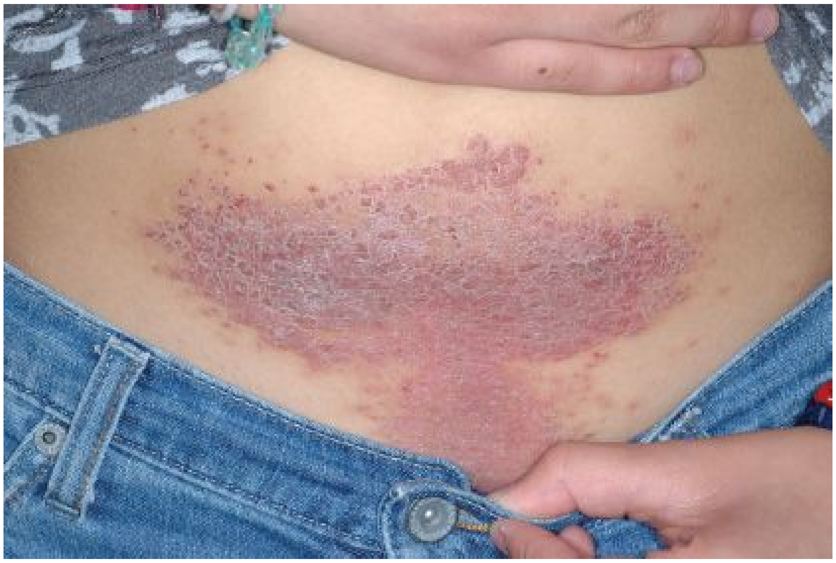

FIGURE 131-5 A 12-year-old girl with atopic dermatitis and allergy to the nickel in her pants' fastener and metal belts when she wears them. (*Used with permission from Richard P. Usatine, MD*.)

- Lip licking—Saliva can cause an irritant contact dermatitis (**Figure 131-6**).

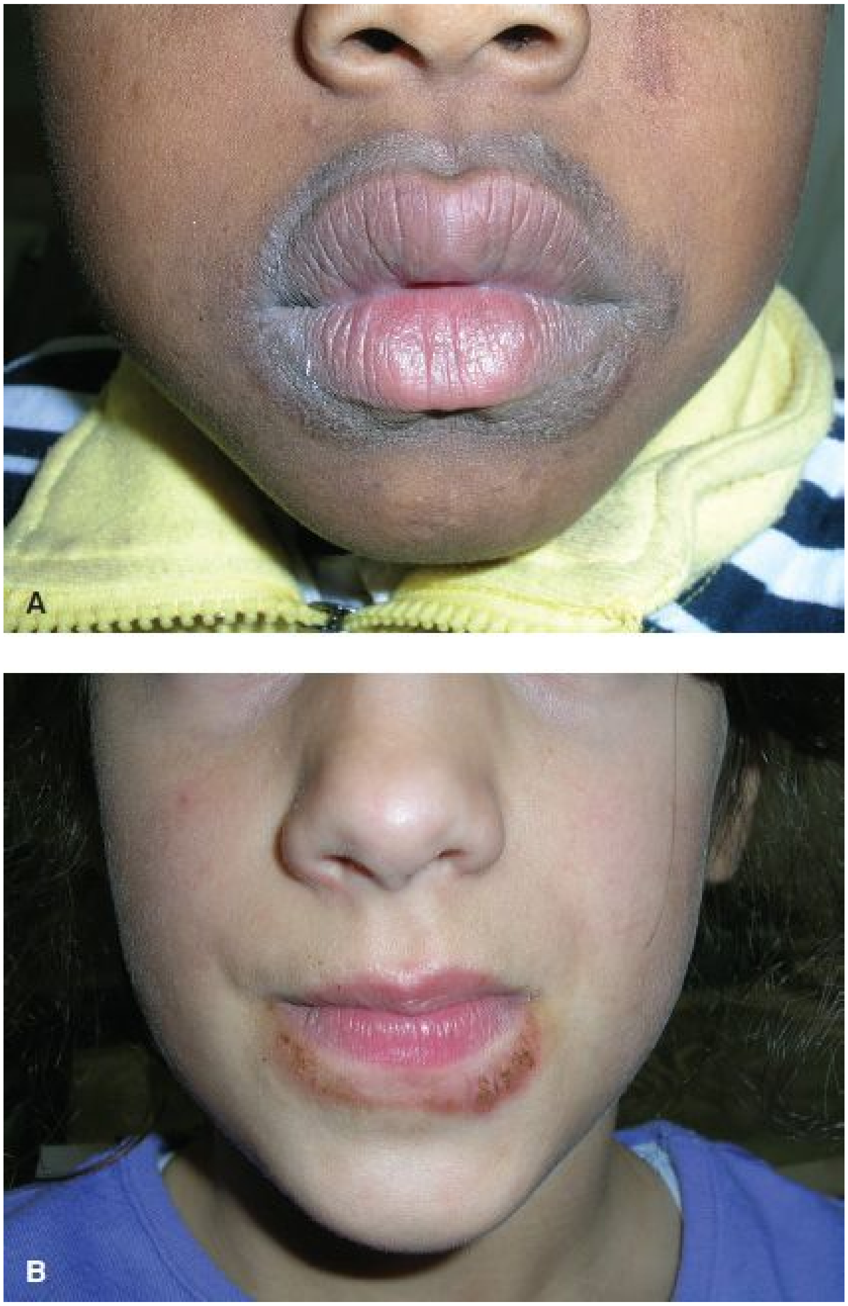

FIGURE 131-6 Two children with lip licking irritant contact dermatitis. **A.** Note the postinflammatory hyperpigmentation. **B.** Note the pink color and crusting. (*Used with permission from Richard P. Usatine, MD*.)

- Fragrances in the forms of deodorants and perfumes (**Figure 131-7**).

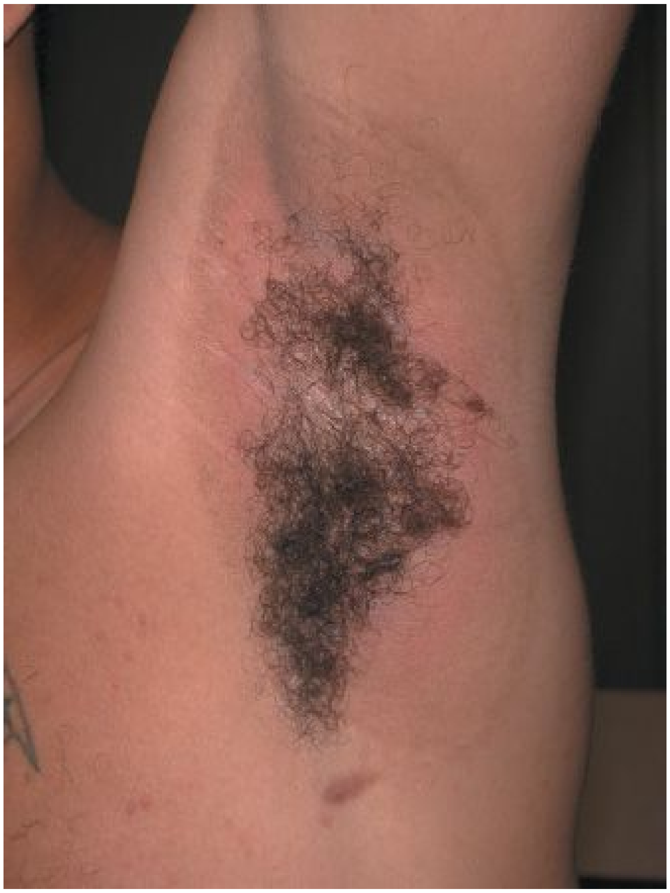

FIGURE 131-7 Allergic contact dermatitis to the fragrance in a new deodorant. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier, Inc; 2004*.)

- Neomycin applied as a triple antibiotic ointment by patients (**Figures 131-8** and **131-9**).

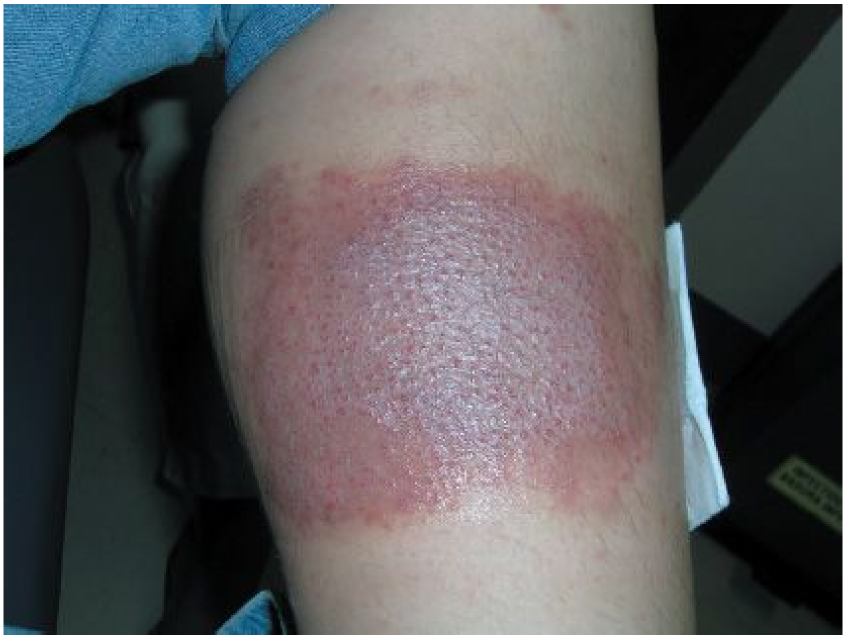

FIGURE 131-8 Allergic contact dermatitis to neomycin applied to the leg of a young woman. Her mom gave her triple antibiotic ointment to place over a bug bite with a large nonstick pad. The contact allergy follows the exact size of the pad and only occurs where the antibiotic was applied. (*Used with permission from Richard P. Usatine, MD.*)

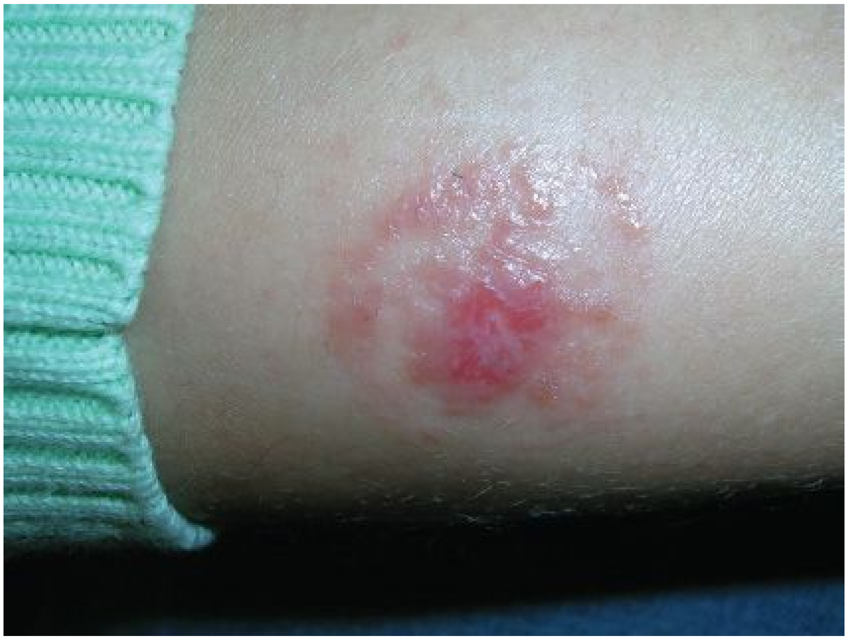

FIGURE 131-9 Allergic contact dermatitis to a neomycin containing topical antibiotic. (*Used with permission from Richard P. Usatine, MD.*)

- Poison ivy/oak in outdoor settings. Especially ask when the distribution of the reaction is linear (**Figures 131-10** and **131-11**).

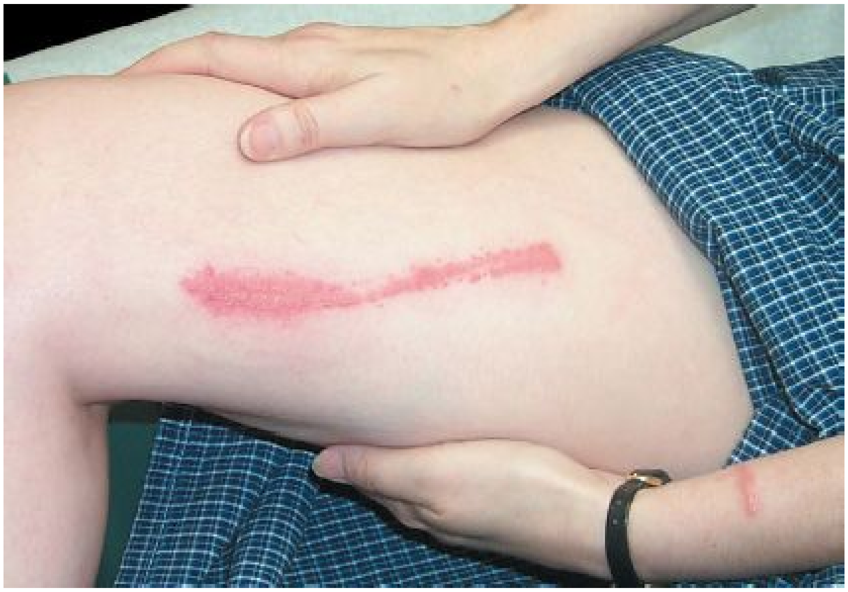

FIGURE 131-10 A linear pattern of allergic contact dermatitis from poison ivy. (*Used with permission from Jack Resneck, Sr., MD*.)

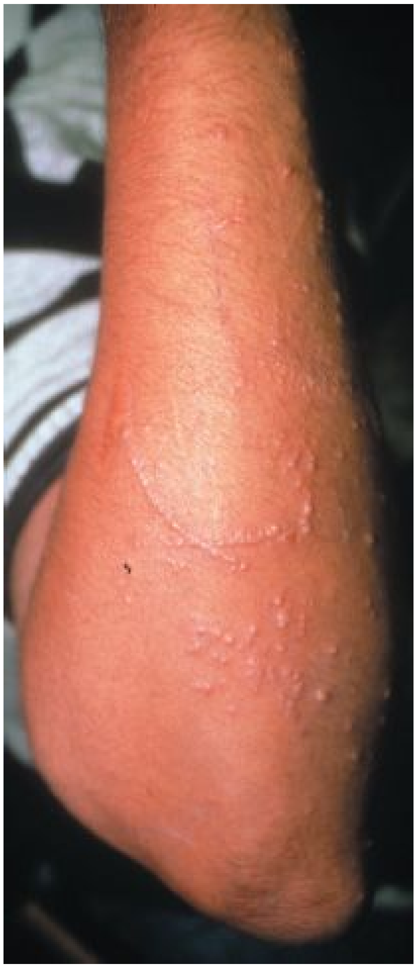

FIGURE 131-11 Multiple lines of vesicles from poison oak on the arm of this teen boy. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier, Inc; 2004.*)

- Ask about occupational exposures, especially solvents. For example, chemicals used in hat making can cause ICD on the hands (**Figure 131-2**).
- Tapes applied to skin after cuts or surgery are frequent causes of CD (**Figure 131-12**).

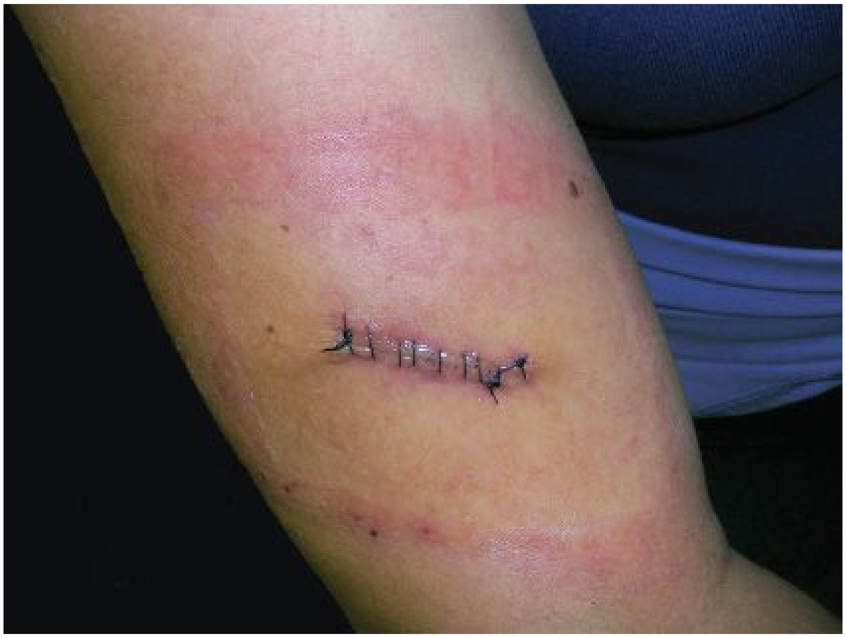

FIGURE 131-12 Contact dermatitis to tape. (*Used with permission from Richard P. Usatine, MD.*)

- If the CD is on the feet, ask about new shoes (**Figures 131-13** and **131-14**).

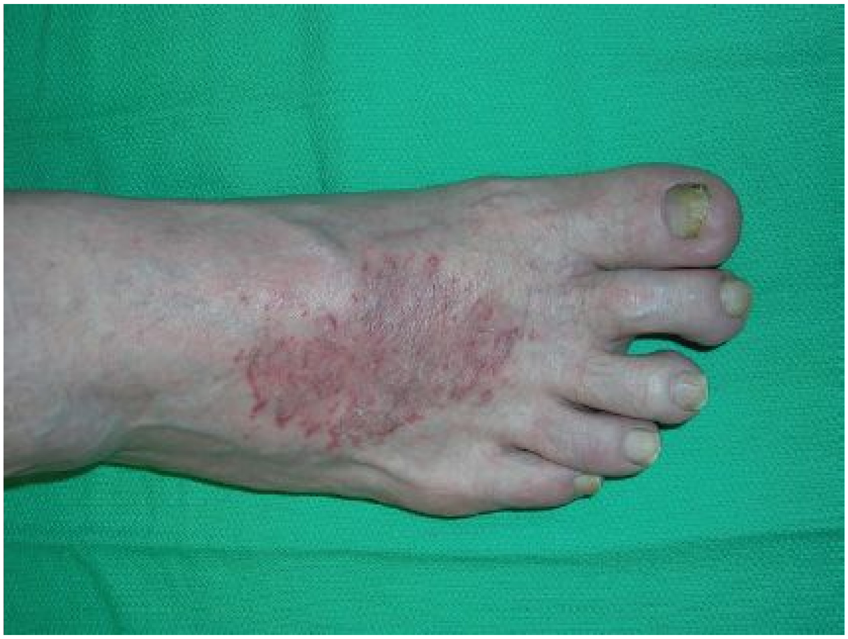

FIGURE 131-13 Allergic contact dermatitis from new shoes. This is the typical distribution found on the dorsum of the feet. Patch testing revealed

that the allergy was to thiurams found in rubber. (*Used with permission from Richard P. Usatine, MD*)

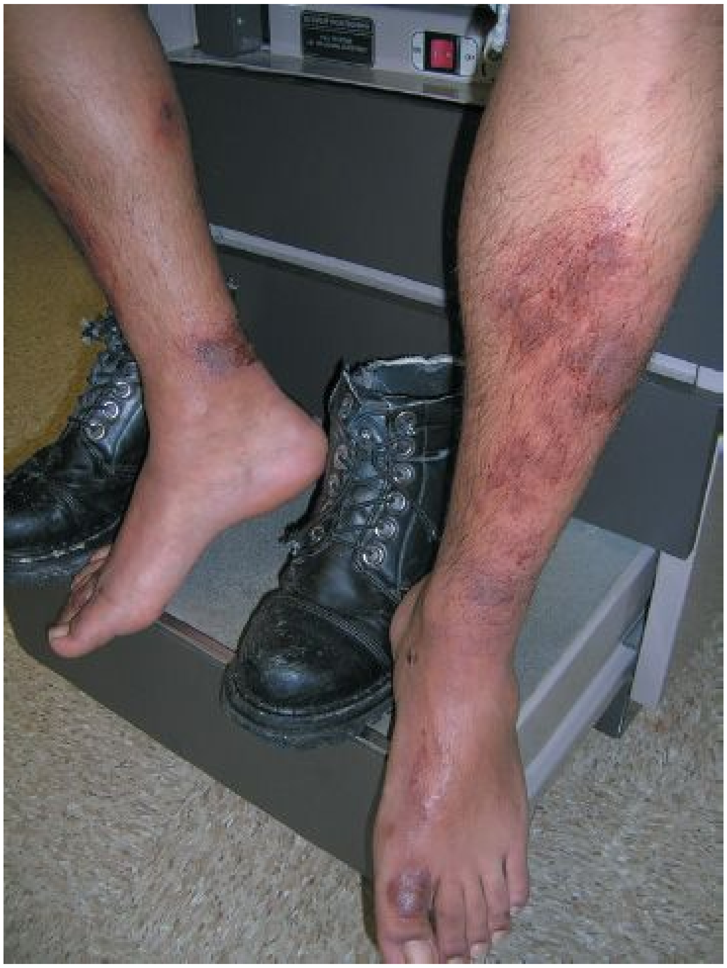

FIGURE 131-14 A young man with allergic contact dermatitis to a chemical in his boots. His boots were higher but he cut them down to try to alleviate the discomfort coming from the boots higher on his leg. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier, Inc; 2004*.)

A detailed history of products used on the skin may reveal a suspected allergen. Sometimes patch testing results will lead to the answer when the history is only suggestive. For example, an 8-year-old girl with mild atopic dermatitis was found to be allergic to a chemical in an over-the-counter product used to moisturize her skin. The history that her mother gave about the child developing a rash to a particular soap was a clue that the new hand dermatitis may have been secondary to contact dermatitis. Patch testing was used to identify the chemical (**Figures 131-15** to **131-17**).

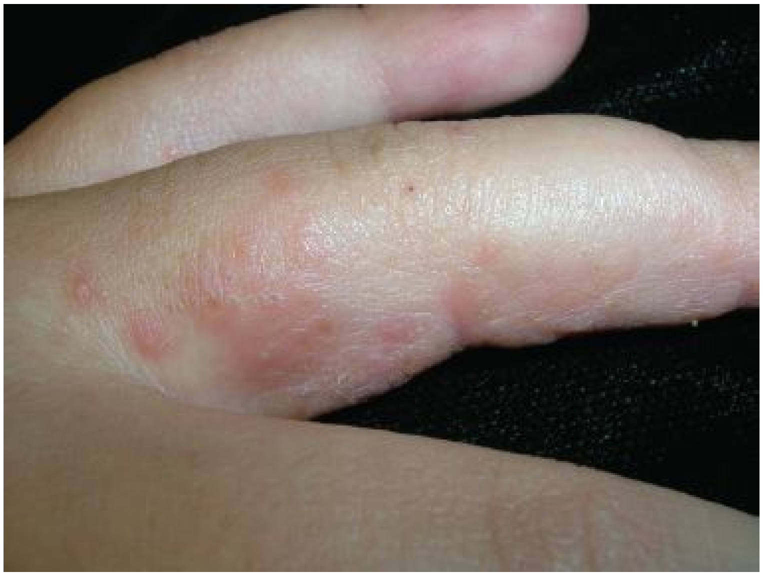

FIGURE 131-15 Allergic contact dermatitis on the hands of an 8-year-old girl with history of mild atopic dermatitis. Patch testing ultimately revealed that she was allergic to Cl+ Me isothiazolinone. Her mother discovered this was one of the ingredients in a moisturizer they were using on her skin. Her allergic contact dermatitis resolved once exposure to Cl+ Me isothiazolinone was eliminated. (*Used with permission from Richard P. Usatine, MD*.)

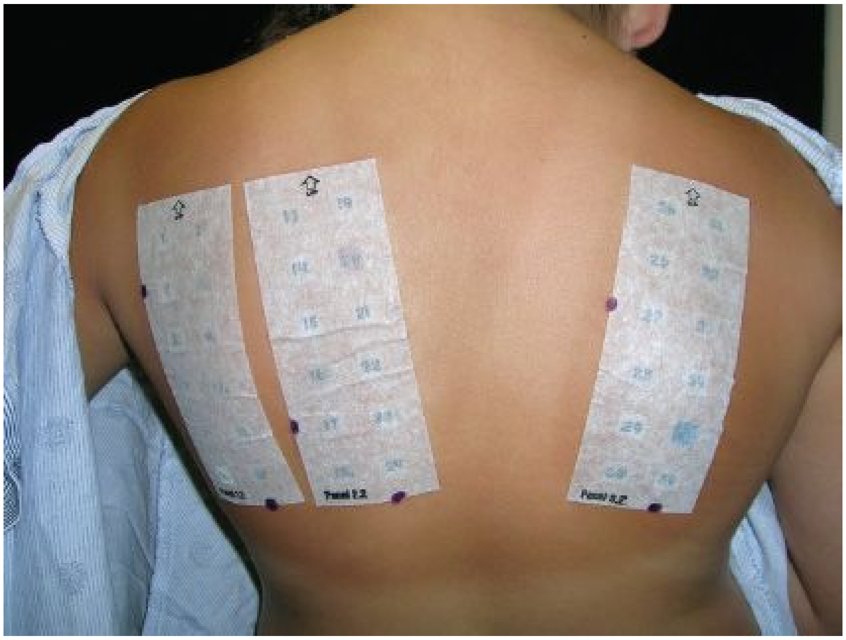

FIGURE 131-16 The T.R.U.E. Test is an easy-to-use standardized patch test that is applied to the back using 3 tape strips to test for 35 common allergens. This 8-year-old girl is starting the process of patch testing to determine the cause of her hand dermatitis. Hypoallergenic tape is about to be applied to keep the strips from peeling off for 2 days. (*Used with permission from Richard P. Usatine, MD.*)

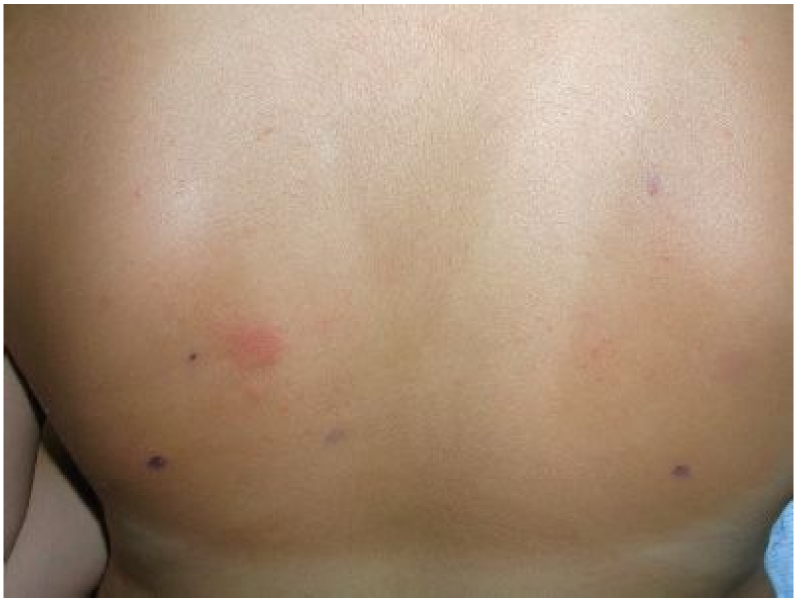

FIGURE 131-17 This positive patch test result for Cl+ Me isothiazolinone shows small vesicles on an erythematous base. The T.R.U.E. Test reading strip is held against the skin using the skin markings to identify the positive antigen. This is the same 8-year-old girl in **Figures 131-15** and **131-16**. (*Used with permission from Richard P. Usatine, MD.*)

CLINICAL FEATURES

All types of CD have erythema. Although it is not always possible to distinguish between ICD and ACD, here are some features that might help:

- ICD:
    - Location—Usually the hands.
    - Symptoms—Burning, pruritus, pain.
    - Dry and fissured skin (**Figure 131-2**).
    - Indistinct borders.

- ACD:
    - Location—Usually exposed area of skin, often the hands.
    - Pruritus is the dominant symptom.
    - Vesicles and bulla (**Figures 131-1** and **131-8**).
    - Distinct angles, lines, and borders (**Figures 131-8** to **131-12**).

Both ICD and ACD may be complicated by bacterial superinfection showing signs of exudate, weeping, and crusts.

Toxicodendron (Rhus) dermatitis (poison ivy, poison oak, and poison sumac) is caused by urushiol, which is found in the saps of this plant family. Clinically, a line of vesicles can occur from brushing against one of the plants. Also, the linear pattern occurs from scratching oneself and dragging the oleoresin across the skin with the fingernails (**Figures 131-10** and **131-11**).

Systemic CD is a rare form of CD seen after the systemic administration of a substance, usually a drug, to which topical sensitization has previously occurred.[6]

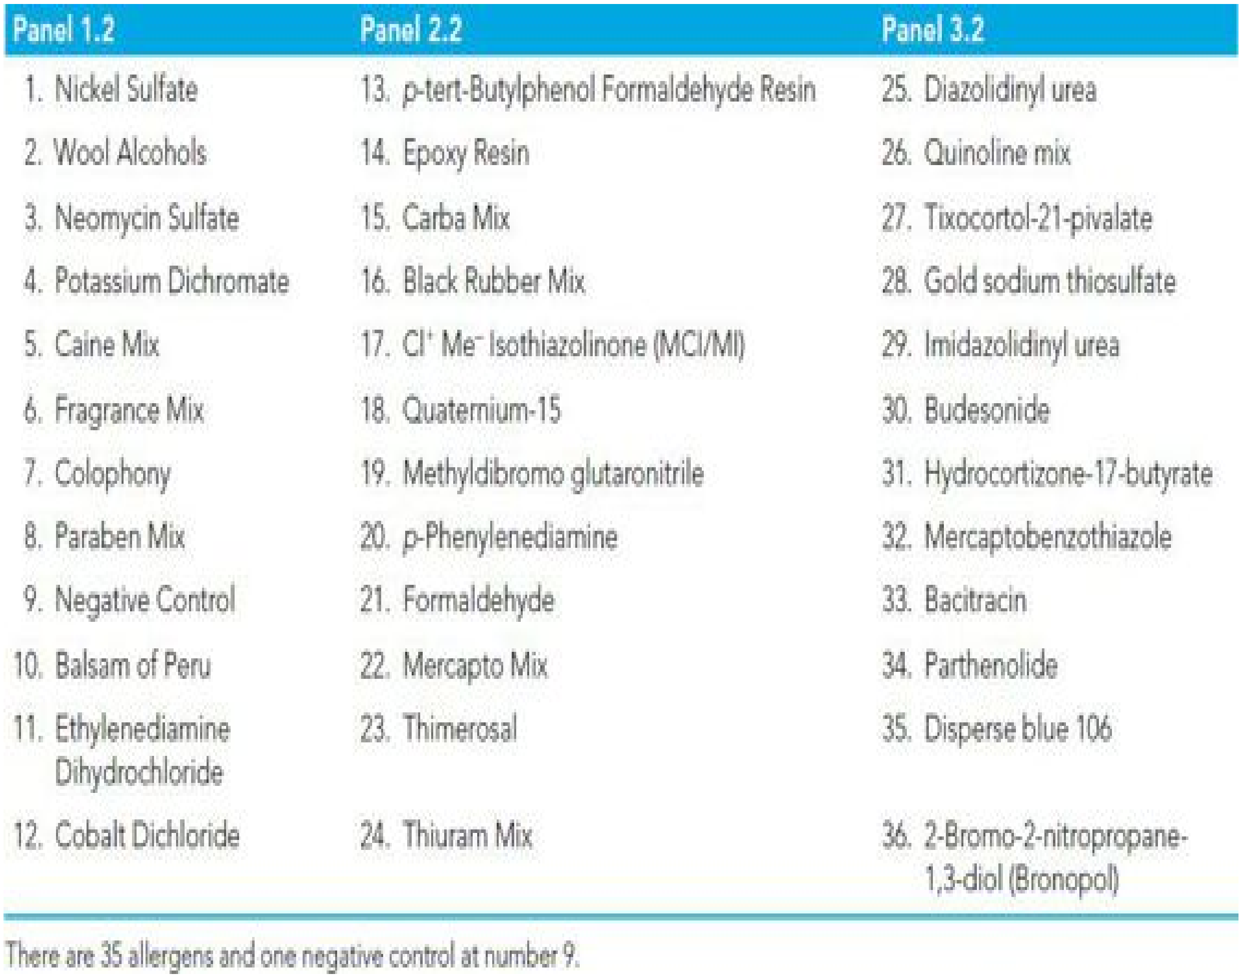
LABORATORY STUDIES

The diagnosis is most often made by history and physical examination. Consider culture if there are signs of superinfection and there is a concern for methicillin-resistant *Staphylococcus aureus* (MRSA). The following tests may be considered when the diagnosis is not clear.

- KOH preparation and/or fungal culture if tinea is suspected.
- Microscopy for scabies mites and eggs.
- Latex allergy testing—This type of reaction is neither ICD (nonimmunologic) nor ACD. The latex allergy type of reaction is a type I, or immunoglobulin (Ig)E-mediated response to the latex allergen.
- Patch testing—Common antigens are placed on the skin of a patient. The T.R.U.E. Test comes in three tape strips that are easy to apply to the back (**Figure 131-16**). There is no preparation needed to test for the 35 common allergens embedded into these strips (**Table 131-1** for a list of the 35 allergens). The strips are removed in 2 days and read at that time and again in two more days (**Figure 131-17**). The T.R.U.E. Test website

provides detailed information on how to perform the testing and how to counsel patients about the meaning of their results. Any clinician with an interest in patch testing can easily perform this service in the office.

TABLE 131-1 Allergens in T.R.U.E. Test (Patch Test for Contact Dermatitis)



Panel 1.2	Panel 2.2	Panel 3.2
1. Nickel Sulfate	13. *p*-tert-Butylphenol Formaldehyde Resin	25. Diazolidinyl urea
2. Wool Alcohols	14. Epoxy Resin	26. Quinoline mix
3. Neomycin Sulfate	15. Carba Mix	27. Tixocortol-21-pivalate
4. Potassium Dichromate	16. Black Rubber Mix	28. Gold sodium thiosulfate
5. Caine Mix	17. Cl^{+} Me^{-} Isothiazolinone (MCI/MI)	29. Imidazolidinyl urea
6. Fragrance Mix	18. Quaternium-15	30. Budesonide
7. Colophony	19. Methyldibromo glutaronitrile	31. Hydrocortizone-17-butyrate
8. Paraben Mix	20. *p*-Phenylenediamine	32. Mercaptobenzothiazole
9. Negative Control	21. Formaldehyde	33. Bacitracin
10. Balsam of Peru	22. Mercapto Mix	34. Parthenolide
11. Ethylenediamine Dihydrochloride	23. Thimerosal	35. Disperse blue 106
12. Cobalt Dichloride	24. Thiuram Mix	36. 2-Bromo-2-nitropropane-1,3-diol (Bronopol)

There are 35 allergens and one negative control at number 9.

- A meta-analysis of the T.R.U.E. Test shows that nickel (14.7% of tested patients), thimerosal (5.0%), cobalt (4.8%), fragrance mix (3.4%), and balsam of Peru (3.0%) are the most prevalent allergens detected using this system.[5]
- Critics of the T.R.U.E. Test state that it misses other important antigens. There are a number of dermatologists who create their own more extensive panels in their office. If the suspected allergen is not in the T.R.U.E. Test, refer to a specialist who will customize the patch testing.

    Also, personal products, such as cosmetics and lotions, can be diluted for special patch testing.
  - A meta-analysis of children patch tested for ACD showed the top five allergens to be nickel, ammonium persulfate, gold sodium thiosulfate, thimerosal, and toluene-2,5-diamine (*p*-toluenediamine).[7] Only two of these five allergens are in the T.R.U.E. Test, so it may be best to not use this standardized patch testing for children.
  - Once the patch test results are known, it is important to determine if the result is “relevant” to the patient’s dermatitis. One method for classifying clinical relevance of a positive patch test reaction is:
    - current relevance—the patient has been exposed to allergen during the current episode of dermatitis and improves when the exposure ceases;
    - past relevance—past episode of dermatitis from exposure to allergen;
    - relevance not known—not sure if exposure is current or old;
    - cross-reaction—the positive test is a result of cross-reaction with another allergen; and
    - exposed—a history of exposure but not resulting in dermatitis from that exposure, or no history of exposure but a definite positive allergic patch test.[6]

- Punch biopsy—When another underlying disorder is suspected that is best diagnosed with histology (e.g., psoriasis).

DIFFERENTIAL DIAGNOSIS

- Atopic dermatitis is usually more widespread than CD. There is often a history of other atopic conditions, such as allergic rhinitis and asthma. There may be family history of allergies. However, persons with atopic dermatitis are more prone to CD (**Figure 131-6**; Chapter 130, Atopic Dermatitis).
- Dyshidrotic eczema—Seen on the hands and feet with tapioca vesicles, erythema, and scale. Although this is not primarily caused by contact to allergens, various irritating substances can make it worse.

- Immediate IgE contact reaction (e.g., latex glove allergy)—Immediate erythema, itching, and possibly systemic reaction after contact with a known (or suspected) allergen.
- Fungal infections—A dermatophyte infection that can closely resemble CD when it occurs on the hands and feet. Tinea pedis is usually seen between the toes, on the soles or on the sides of the feet. CD of the feet is often on the dorsum of the foot and related to rubber or other chemicals in the shoes (**Figures 131-13** and **131-14**; Chapter 125, Tinea Pedis).
- Scabies on the hands can be mistaken for CD. Look for burrows and for the typical distribution of the scabies infestation to distinguish this from CD (see Chapter 128, Scabies).
- Allergies to the dyes used in tattoos can occur. Although this is not strictly a CD because the dye is injected below the skin, the allergic process is similar (**Figure 131-18**).

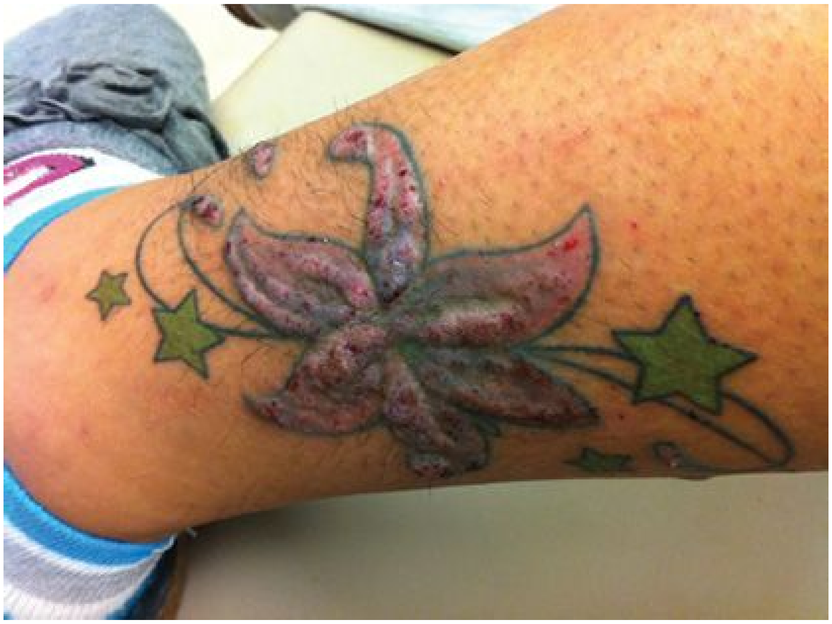


FIGURE 131-18 Allergic dermatitis to the red dye in a new tattoo. (*Used with permission from Jonathan Karnes, MD.*)

MANAGEMENT

- Identify and avoid the offending agent(s).[4] SOR Ⓐ
    - Be aware that some patients are actually allergic to topical steroids. This unfortunate situation can be diagnosed with patch testing.
    - In cases of nickel ACD, we recommend the patient cover the metal tab of their jeans with an iron-on patch or a few coats of clear nail polish.
- Cool compresses can soothe the symptoms of acute cases of CD.[4] SOR Ⓒ
- Calamine and colloidal oatmeal baths may help to dry and soothe acute, oozing lesions.[3,4] SOR Ⓒ
- Localized acute ACD lesions respond best with mid-potency to high-potency topical steroids such as 0.1 percent triamcinolone to 0.05 percent clobetasol, respectively.[4] SOR Ⓐ
- On areas of thinner skin (e.g., flexural surfaces, eyelids, face, or anogenital region) lower-potency steroids such as desonide ointment can minimize the risk of skin atrophy.[3,4] SOR Ⓑ
- There is insufficient data to support the use of topical steroids for ICD, but because it is difficult to distinguish clinically between ACD and ICD, these agents are frequently tried. SOR Ⓒ
- If ACD involves extensive skin areas (>20%), systemic steroid therapy is often required and offers relief within 12 to 24 hours. The recommended dose is 0.5 to 1 mg/kg daily for 5 to 7 days, and if the patient is comfortable at that time, the dose may be reduced by 50 percent for the next 5 to 7 days. The rate of reduction of steroid dosage depends on factors such as severity, duration of ACD, and how effectively the allergen can be avoided.[4] SOR Ⓑ
- Oral steroids should be tapered over 2 weeks because rapid discontinuance of steroids can result in rebound dermatitis. Severe poison ivy/oak is often treated with oral prednisone for 2 to 3 weeks. Avoid using a Medrol dose-pack, which has insufficient dosing and duration.[4] SOR Ⓑ
- The efficacy of topical immunomodulators (tacrolimus and pimecrolimus) in ACD or ICD has not been well established.[4] However, one randomized controlled trial (RCT) did demonstrate that tacrolimus ointment is more

effective than vehicle in treating chronically exposed, nickel-induced ACD.[8] SOR Ⓑ

- Although antihistamines are generally not effective for pruritus associated with ACD, they are commonly used. Sedation from more soporific antihistamines may offer some degree of palliation (diphenhydramine, hydroxyzine).[4] SOR Ⓒ
- Bacterial superinfection should be treated with an appropriate antibiotic that will cover *Streptococcus pyogenes* and *S. aureus*. Treat for MRSA if suspected.
- Once the diagnosis of any CD is established, emollients and moisturizers may help soothe irritated skin.[4] SOR Ⓒ

For ICD and occupational CD of the hands:

- Wear protective gloves when working with known allergens or potentially irritating substances such as solvents, soaps, and detergents.[6,9] SOR Ⓐ
- Use cotton liners under the gloves for both comfort and the absorption of sweat. Wearing cotton glove liners can prevent the development of an impaired skin barrier function caused by prolonged wearing of occlusive gloves.[9] SOR Ⓑ
    - There is insufficient evidence to promote the use of barrier creams to protect against contact with irritants.[6,9] SOR Ⓐ
    - After work, conditioning creams can improve skin condition in workers with damaged skin.[9] SOR Ⓐ
- Keep hands clean, dry, and well-moisturized whenever possible.
- Petrolatum applied twice a day is a great way to moisturize dry and cracked skin without exposing the patient to new irritants.

If the CD is severe enough, the patient may need to change activities to completely avoid the offending irritant or antigen.

FOLLOW-UP

May need frequent follow-up if the offending substance is not found, the rash does not resolve and if patch testing will be needed.

PATIENT EDUCATION

Avoid the offending agent and take the medications as prescribed to relieve symptoms.

132 ECZEMA HERPETICUM

Carla Torres-Zegarra, MD
Camille Sabella, MD

PATIENT STORY

A 16-year-old-boy with a past medical history significant for atopic dermatitis presented to the Emergency Department with a 1-day history of sudden onset of tender blistering lesions on the face and neck associated with a burning sensation. Associated symptoms included lethargy, headache, and four episodes of vomiting since onset of symptoms. On exam, the boy was noted to be ill-appearing, moderately dehydrated, and febrile to 39°C. He was tachycardic but normotensive, warm, and well perfused. The skin exam revealed pustules, vesicles and crusts over his face, neck, elbows, both hands and both knees (**Figure 132-1**). He was admitted and treated with intravenous (IV) fluids, IV antibiotics, and IV acyclovir. Viral culture taken from an unroofed vesicular lesion revealed herpes simplex virus type 1. Bacterial cultures taken from the impetiginized lesions grew *Staphylococcus aureus*.

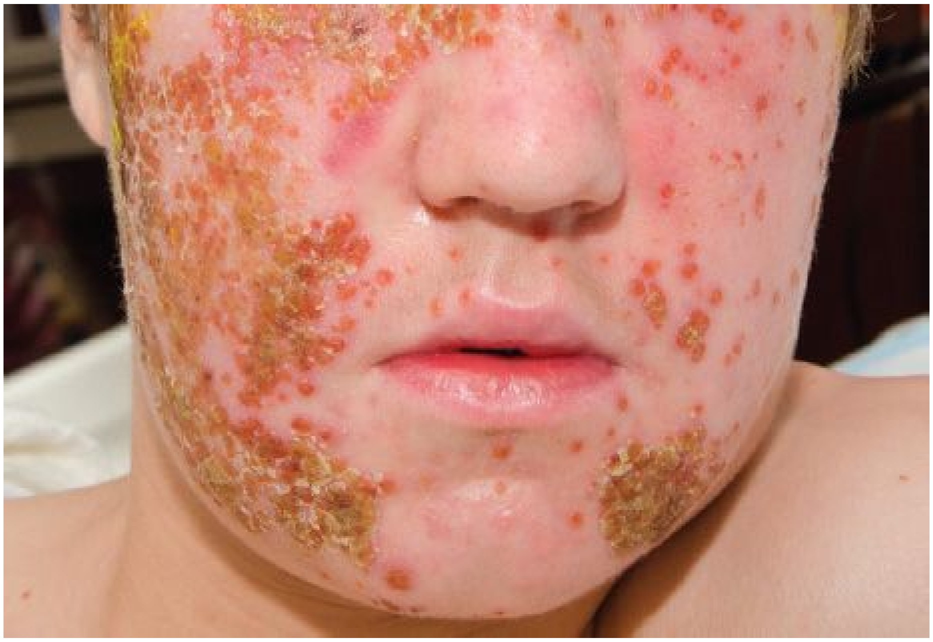

FIGURE 132-1 Eczema herpeticum in a 16-year-old-boy with a history of severe atopic dermatitis. Eczema herpeticum is a severe HSV infection in a patient with atopic dermatitis. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

Eczema herpeticum is an acutely disseminated herpes simplex virus (HSV) infection associated with systemic symptoms that develops in the setting of underlying skin conditions or epidermal barrier disruption, such as atopic dermatitis. HSV type 1 is most commonly involved, but cases of HSV type 2 infection and other viruses have rarely been implicated.

SYNONYMS

Kaposi varicelliform eruption.

EPIDEMIOLOGY

- Infants and children with atopic dermatitis are at highest risk.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Diverse immune mechanisms have been proposed to explain the development of eczema herpeticum in patients with atopic dermatitis:
  - A disruption of the immune response against herpes simplex mediated by T cells.
  - A defect in antibody production against the virus.
  - A decrease in natural killer cells and IL-2 receptors.
  - Inhibition of TH-1 response due to increase in IL-4.
  - Decrease in dendritic cells that produce IL-1.[2]
- Another possibility is that viral dissemination is directly favored by the disruption of the skin barrier that exists in atopic dermatitis.[3]

RISK FACTORS

- Early onset of atopic dermatitis and high levels of IgE in atopic patients, based on a retrospective study involving 100 patients with eczema herpeticum.[4]
- The use of topical corticosteroids is not a predisposing factor.
- Patients with chronic skin pathology like Darier disease, cutaneous T cell lymphoma, pityriasis rubra pilaris, benign familial pemphigus, seborrheic dermatitis, Wiskott-Aldrich syndrome, psoriasis, and systemic lupus erythematosis are susceptible to eczema herpeticum. Severe infections may develop even when the dermatitis is inactive.[2]

- Other risk factors include conditions where the epidermal barrier has been disrupted, like burns, contact dermatitis, skin grafts, and dermabrasion.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis is primarily clinical, supported by isolation of HSV in culture.
- Eczema herpeticum is characterized by cutaneous pain and multiple clusters of monomorphic papules, vesicles, pustules and crusts in areas of preexisting atopic dermatitis (**Figure 132-2**).

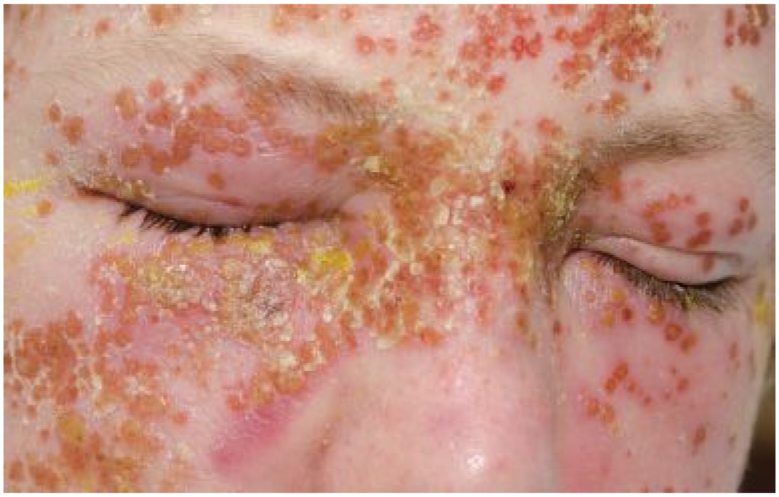

FIGURE 132-2 Close up of the eczema herpeticum lesions in the atopic patient in **Figure 132-1** showing clusters of papules, vesicles and crusted lesions secondary to HSV. Some of the crusting is secondary to impetiginized lesions from a S. aureus bacterial superinfection. (*Used with permission from Camille Sabella, MD*.)

- These lesions can spread rapidly leading to severe morbidity and mortality.[5]

- The eruption of eczema herpeticum may sometimes be difficult to distinguish from the patient’s baseline eczema if the latter is poorly controlled.
- Impetigo secondary to bacterial infection can be difficult to differentiate from eczema herpeticum, and can complicate the diagnosis.
- The lesions can appear pustular or hemorrhagic (**Figure 132-3**) and can be associated with systemic symptoms like fever and general malaise. Such a presentation is also consistent with bacterial superinfection, which is one of the key considerations in the differential diagnosis.

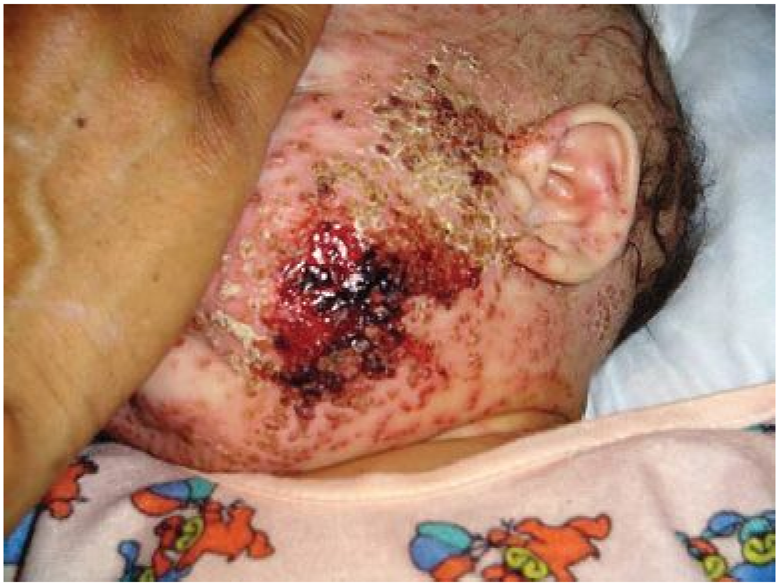

FIGURE 132-3 Eczema herpeticum in a 5-month-old infant with severe atopic dermatitis presenting with ulcerated and hemorrhagic lesions along with vesicles, papules and crusts. Viral culture from an unroofed vesicle yielded HSV. (*Used with permission from Camille Sabella, MD*.)

- Erythema and swelling of the periorbital area may be marked and may represent the primary process or a secondary bacterial cellulitis (**Figure 132-4**).

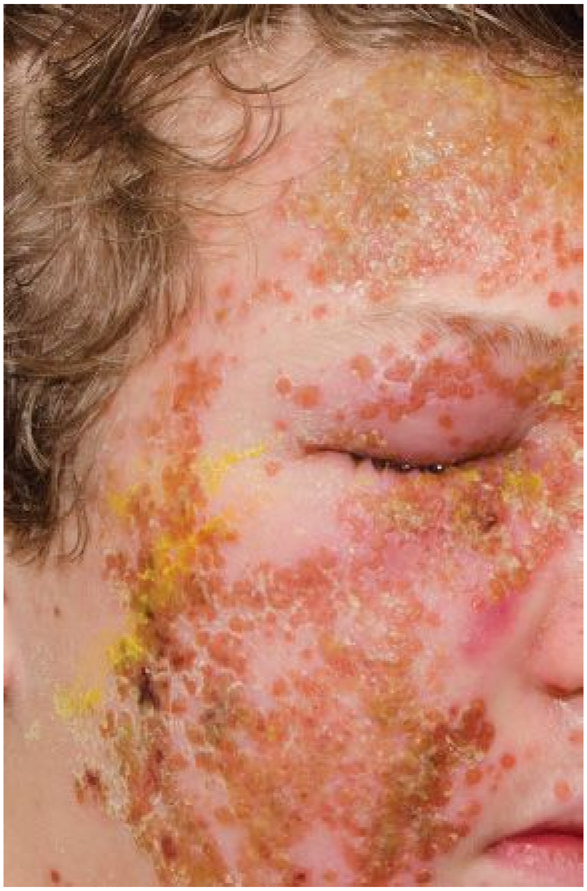

FIGURE 132-4 Periorbital erythema and induration associated with eczema herpeticum in the same patient as **Figure 132-1**. (*Used with permission from Camille Sabella, MD*.)

- Duration of illness is 16 days on average, but ranges from 2 to 6 weeks. About 13 to 16 percent of patients can develop recurrent episodes, which tend to be milder, with limited skin involvement and are less commonly associated with systemic symptoms.[2]
- The most common complication is secondary bacterial infection of the skin; *S aureus* is the most common pathogen isolated.
- Rarely, eczema herpeticum may present as a fulminating disease with widespread lesions, multiorgan involvement, bone marrow suppression, and disseminated intravascular coagulation.

LABORATORY TESTING

- Culture of HSV from skin lesions is the most sensitive and specific method of diagnosing an active HSV infection.[6]
- Direct fluorescent antibody (DFA) staining of infected cells is 80 to 90 percent sensitive and very specific. DFA can provide a rapid diagnosis within 24 hours.[7,8] Many labs will do the DFA staining and then set up a culture if this is negative.
- Cells for culture and DFA are best obtained by unroofing an intact vesicle and removing cells from the base of the lesion. When an intact vesicle is not available, new lesions are better than old lesions and ulcers are better than crusts.
- Tzank smear of material from the floor of an intact vesicle may reveal multinucleated giant cells, which supports the diagnosis. Although this provides a rapid and inexpensive method of diagnosis, it is no longer recommended, given the availability of culture and DFA, which are more sensitive and specific.
- Bacterial cultures from the skin lesions and blood cultures should be obtained if secondary bacterial infection is suspected.

DIFFERENTIAL DIAGNOSIS

- Coxsackie virus A16, which causes hand-foot-and-mouth disease. The lesions are usually flat-topped vesicles on the palms, soles and oral mucosa. These lesions do not have the same degree of crusting seen in eczema herpeticum (see Chapter 113, Hand, Foot, and Mouth Disease).
- Impetigo that presents with honey-crusted lesions usually has slower evolution and fewer systemic symptoms. Discrete vesicular lesions are not usually present (see Chapter 99, Impetigo).
- Varicella (Chickenpox) is characterized by crops of polymorphic lesions in various stages of development. It often has a more widespread distribution (see Chapter 108, Varicella).

- Other uncommon causes of vesicobullous virus infections include Coxsackie virus A5, 9, and 10; Echovirus 4, 9, 11, 17, and 25; and variola and vaccinia (cowpox).

MANAGEMENT

MEDICATIONS

- Prompt intravenous antiviral therapy with acyclovir is indicated while awaiting diagnostic testing for HSV. Patients should be hospitalized and the route should be intravenous if systemic symptoms are present.[9,10] SOR B
- Delay of acyclovir initiation is associated with increased length of stay (LOS) in hospitalized children with eczema herpeticum.[11] SOR B
- Use of topical corticosteroids on admission is not associated with increased LOS.[11] SOR B
- Emollients may be used to treat the underlying eczema.
- If bacterial superinfection is suspected, intravenous or oral systemic antibiotics active against *S aureus* and *Streptococcus pyogenes* should be given. SOR C
- There is no evidence to support the use of topical antibiotics.[2] SOR B
- Topical ophthalmic acyclovir may be added if there is evidence of periocular involvement, to prevent herpetic keratitis.

REFERRAL

- Dermatology consultation should be obtained on admission.
- Ophthalmology consultation should be obtained if periocular involvement is present.

PREVENTION AND SCREENING

- Good control of atopic dermatitis may be important in helping to control the severity of involvement and decrease risk of bacterial superinfection.

PROGNOSIS

- Prompt use of acyclovir has decreased mortality from 50 to 10 percent.[10,11]
- If left untreated, skin loss may lead to all complications usually associated with severe burns: hypovolemia, hypothermia, hypoalbuminemia, hypokalemia, disseminated intravascular coagulation, and superadded bacterial infections.
- With periocular involvement, herpetic keratitis and conjunctivitis can occur.

FOLLOW-UP

- Dermatology and ophthalmology follow-up may be indicated depending on the initial presentation and course.
- If the original atopic dermatitis was not controlled, then dermatology follow-up is needed for that reason alone.

PATIENT EDUCATION

- With early recognition, eczema herpeticum can be effectively treated. Any patient with history of atopic dermatitis, who develops acute blistering should be evaluated and treated empirically for eczema herpeticum.

- Consider advising patients to discard previously used emollients or creams (especially if it is stored in tubs) if contamination is suspected.
- It is important to keep atopic dermatitis well treated and under control to preserve the important barrier function of the skin.

133 NUMMULAR ECZEMA

Yu Wah, MD
Richard P. Usatine, MD

PATIENT STORY

A 2-year-old Hispanic male presents to the clinic with erythematous, round, moist, crusted lesions on the left thigh (**Figure 133-1**) and right arm. His mother noted several small bumps initially, which developed into coin-shaped lesions over the next few weeks. The child is scratching them but is otherwise healthy. A KOH preparation of the scraping from the lesions did not show fungal structures. The child responds well to treatment with topical mid-potency corticosteroids, emollients, and dressing in long-sleeve clothes to prevent scratching the lesions. His nummular eczema resolved in 6 weeks.

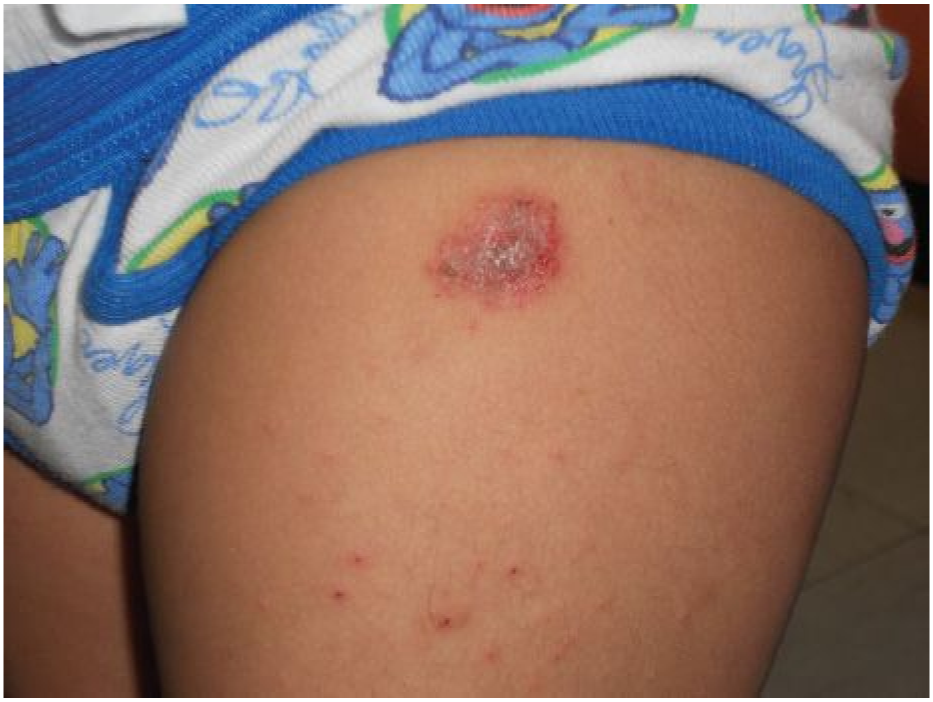

FIGURE 133-1 A 2-year-old child with nummular eczema on the left thigh. The lesion shows abrasions and excoriations from scratching. He has another similar lesion on the right arm. (*Used with permission from Yu Wah, MD*.)

INTRODUCTION

Nummular eczema (NE) is a type of eczema characterized by circular or oval-shaped scaling plaques with well-defined borders. The term *nummular* refers to the shape of a coin (Latin for coin is *nummus*). The lesions are typically multiple and most commonly found on the dorsa of the hands, arms, and legs. It often overlaps with other clinical types of eczema: atopic dermatitis, stasis dermatitis, and asteatotic eczema.[1,2]

SYNONYMS

Nummular dermatitis, discoid eczema, microbial eczema, and orbicular eczema.

EPIDEMIOLOGY

- Prevalence is reported to range widely from 0.1 to 9.1 percent.[1]
- It is slightly more common in males than in females.[1]
- Males are also affected at a later age (peak older than age 50 years) than females (peak younger than age 30 years).[1]
- It is less common in children.

ETIOLOGY AND PATHOPHYSIOLOGY

Many factors have been reported in association with NE but their role in the etiology and pathogenesis is not well established:

- NE has been viewed as microbial in origin, either secondary to bacterial colonization or hematogenous spread of bacterial toxins,[1,3] but an infectious source is not identified in most cases of NE.
- NE is reported to be associated with xerosis of the skin that subsequently weakens the skin barrier function and sensitizes it to environmental allergens.[4]
- NE is frequently reported in association with contact sensitization to various agents, including nickel, chromate, balsam of Peru, and fragrances. Allergic or chronic contact dermatitis has been frequently reported to manifest as NE on the dorsa of the hands.[1,5]
- Onset of NE has been reported in association with various medications, including interferon and ribavirin therapy for hepatitis C[6,7] and isotretinoin.[8] Most of these reports are based on single or limited number of cases.
- Mercury in the dental amalgam was reported to induce NE in two cases with relapsing NE.[9]

DIAGNOSIS

HISTORY

- Onset is reported to be within days to week. Simultaneous or subsequent development of multiple lesions is often reported.
- Intense pruritus or burning is common.

- Lesions may last months to years without treatment and may be recurrent.
- History of medications, atopy, and exposure to allergens may be helpful to tailor the management of NE.

PHYSICAL EXAMINATION

- Primary morphology includes small papules and vesicles that coalesce to form circular to oval shape patches and plaques (**Figures 133-2** and **133-3**).

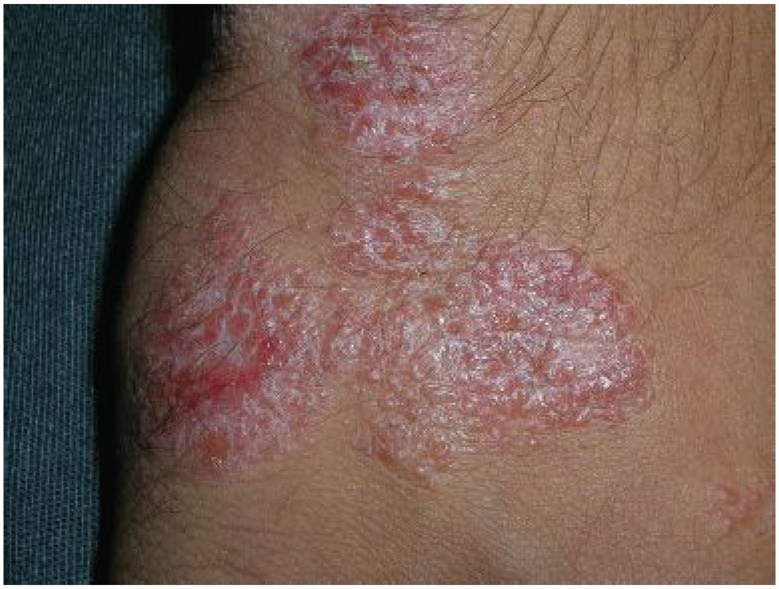

FIGURE 133-2 Multiple nummular lesions on the dorsum of the hand, a common site of nummular eczema. The lesions show multiple papules and vesicles that coalesce to form coin-shaped plaques; oozing and crusting can be seen from ruptured vesicles. (*Used with permission from Richard P. Usatine, MD*.)

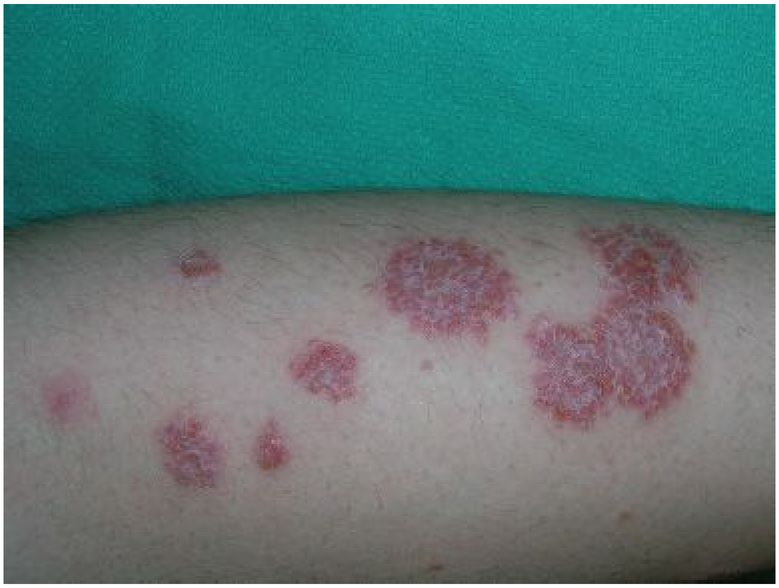

FIGURE 133-3 Nummular eczema on the forearm of a young man. The lesions show multiple papules and vesicles that coalesce to form coin-shaped plaques; oozing and crusting can be seen from ruptured vesicles. (*Used with permission from Richard P. Usatine, MD*.)

- Secondary morphology includes abrasion and excoriations from scratching (**Figure 133-1**), weeping and crusting after the vesicles leak (**Figures 133-2** to **133-4**), and scaling and lichenification in more chronic lesions (**Figures 133-5** and **133-6**). Excessive weeping and crusting may indicate secondary bacterial infection.

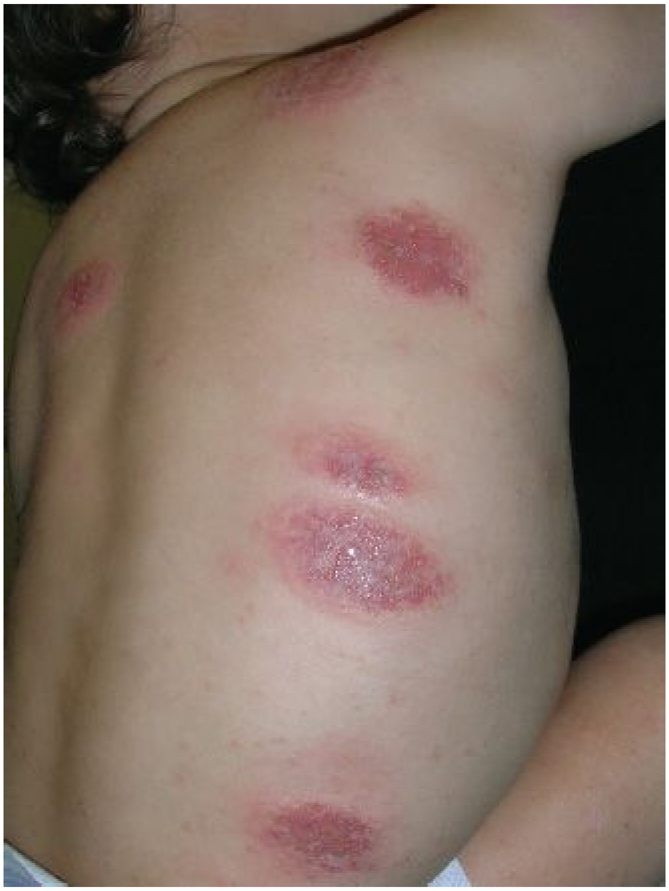

FIGURE 133-4 Superinfected nummular eczema healing on the trunk of a 2-year-old girl receiving topical triamcinolone ointment and oral cephalexin. (*Used with permission from Richard P. Usatine, MD.*)

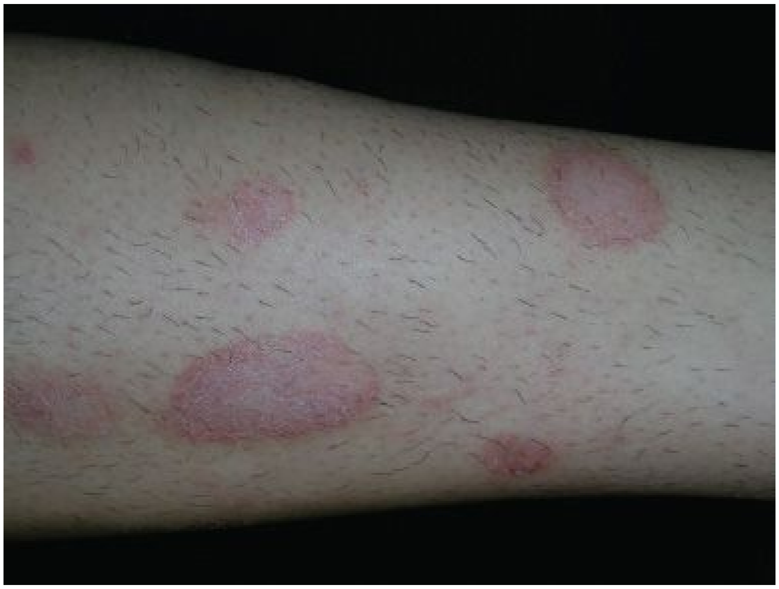

FIGURE 133-5 Multiple nummular lesions on the lower leg of a 15-year-old girl. Lesions of nummular eczema can be dry and scaly. The lesions prevented the patient from shaving her legs. (*Used with permission from Richard P. Usatine, MD*.)

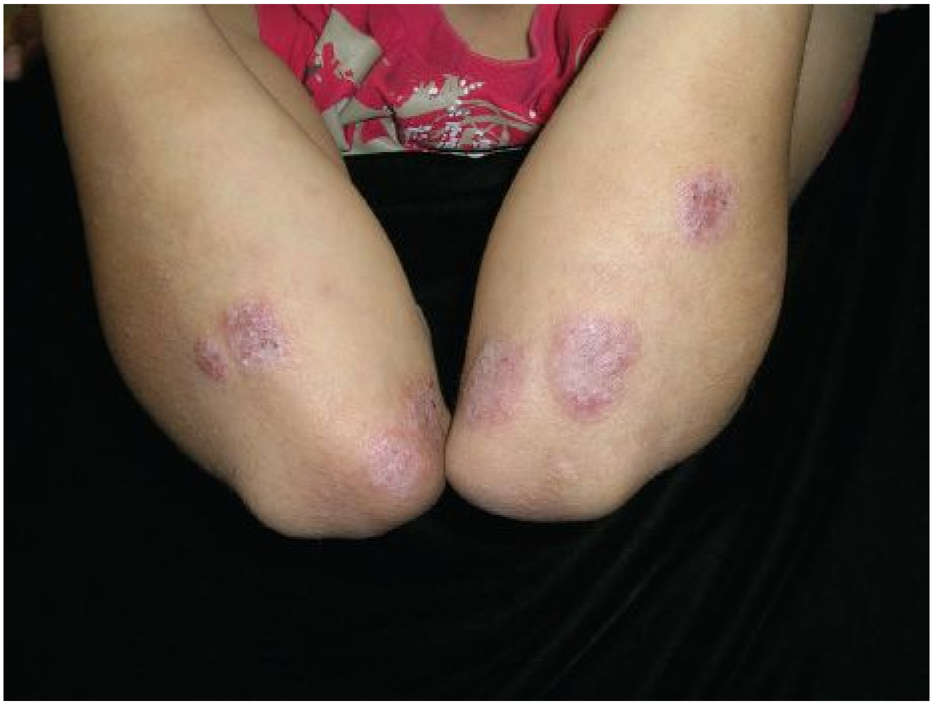

FIGURE 133-6 Nummular eczema on the extensor surface of the forearms and elbows. Thickened, scaly lesions resemble psoriatic plaques. A biopsy was performed to confirm the diagnosis of nummular eczema. (*Used with permission from Richard P. Usatine, MD*.)

TYPICAL DISTRIBUTION

- Dorsal hand is most commonly affected (**Figures 133-2** and **133-7**). The extensor aspects of the forearm (**Figures 133-3** and **133-6**) and the lower leg (**Figure 133-5**), the thighs (**Figure 133-1**), and the flanks are frequently involved, but NE may be seen in any part of the body (**Figures 133-4**, **133-8**, and **133-9**).

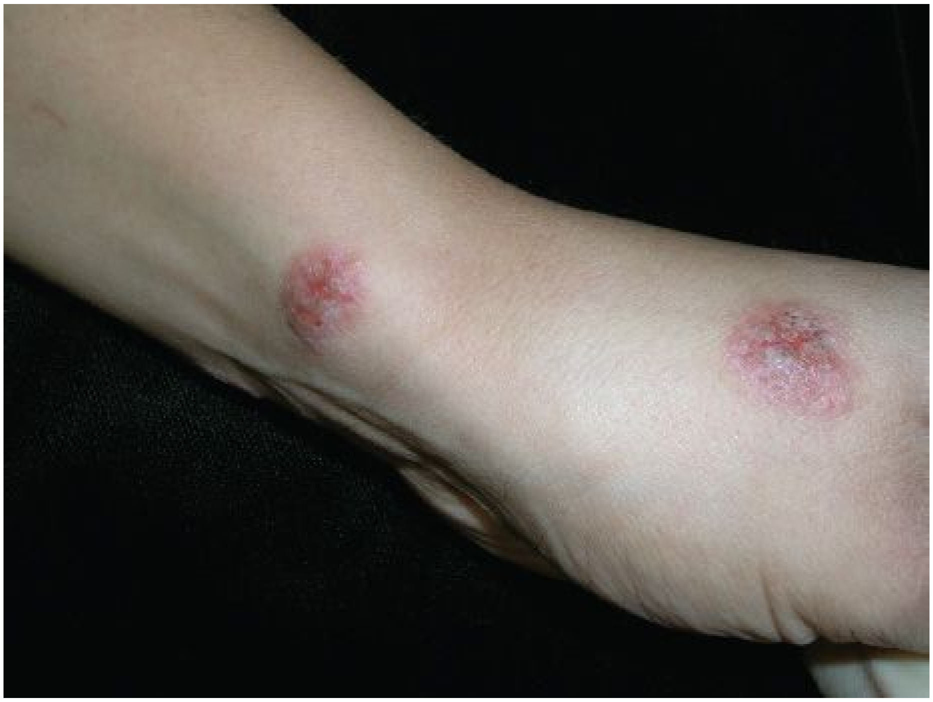

FIGURE 133-7 Nummular eczema on the dorsum of the hand and wrist. (*Used with permission from Richard P. Usatine, MD*.)

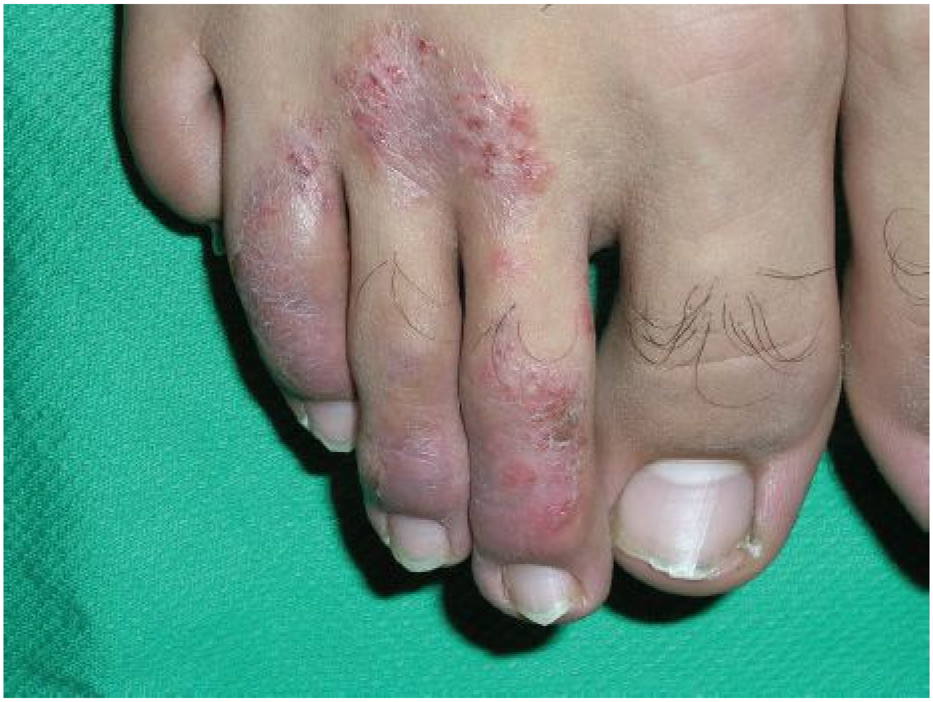

FIGURE 133-8 Nummular eczema on the dorsum of the foot. Contact dermatitis and tinea pedis are also in the differential diagnosis. KOH

preparation was negative and the lesions did resolve with a topical steroid. (*Used with permission from Richard P. Usatine, MD.*)

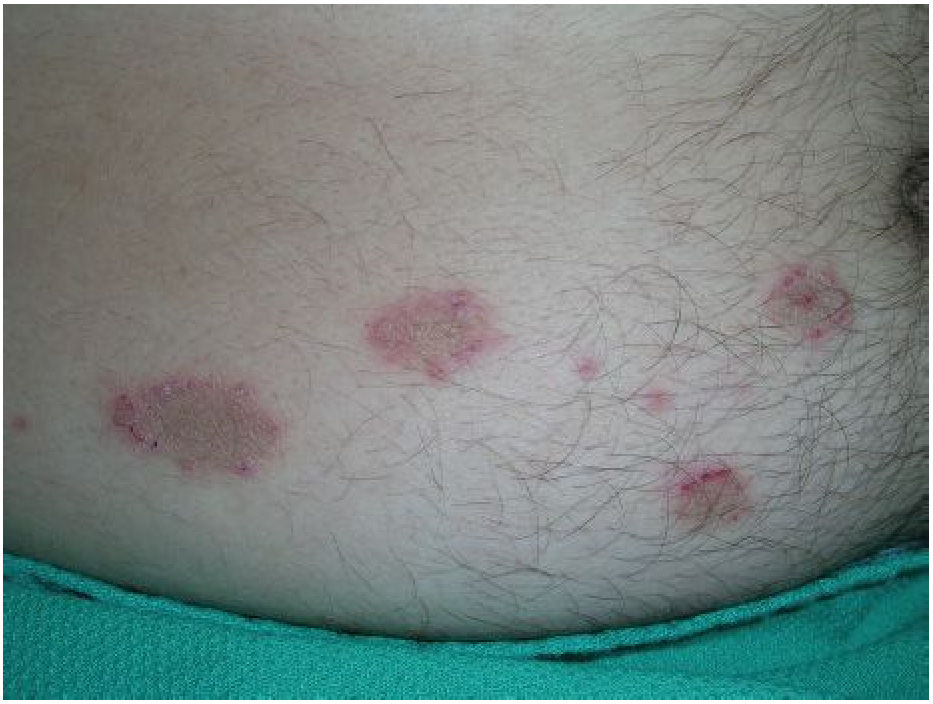

FIGURE 133-9 Nummular eczema on the abdomen of a young man. (*Used with permission from Richard P. Usatine, MD.*)

LABORATORY TESTING

- Diagnosis in most cases is made from clinical features.
- KOH preparation is helpful to investigate for tinea corporis.
- Patch testing may be considered if contact allergy is suspected.

BIOPSY

- Biopsy is rarely needed, but should be performed if there is suspicion of other serious clinical entities (e.g., mycosis fungoides, psoriasis) or if the diagnosis is uncertain.

DIFFERENTIAL DIAGNOSIS

- Tinea corporis may present as pruritic annular lesions with scales and vesicles. Vesicles are typically at the periphery of the lesion compared to NE, where they are also seen in the center. A positive KOH preparation for hyphae can help with the diagnosis (see Chapter 123, Tinea Corporis).
- Psoriasis typically presents with thickened plaques on the extensor surfaces of arms and legs, scalp and sacral areas. Nail changes may be present (see Chapter 136, Psoriasis).
- Lichen simplex chronicus usually presents as a single plaque in an area easily accessible to scratching such as the ankle, wrist, and neck (**Figures 133-10** to **133-12**).

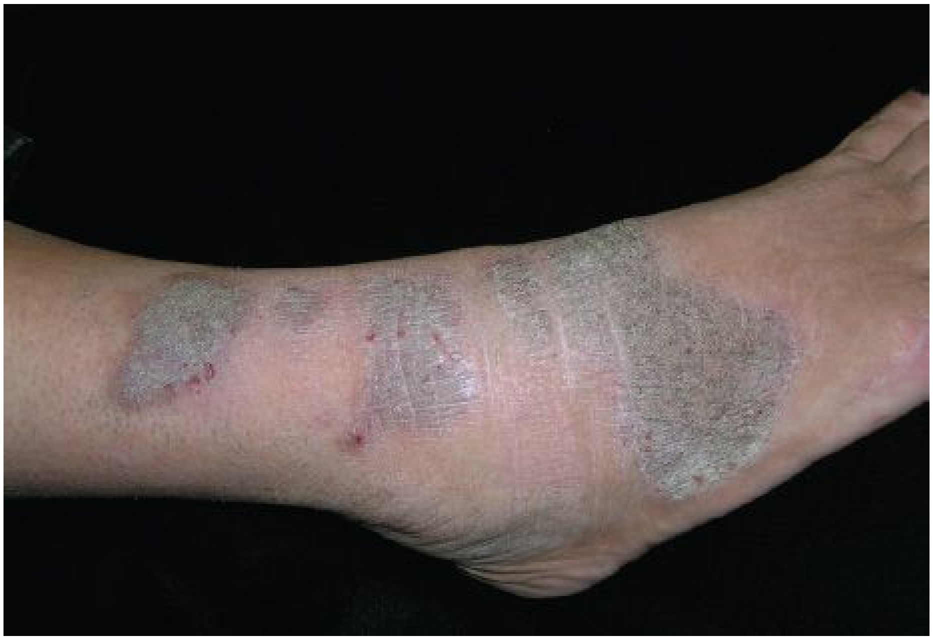

FIGURE 133-10 Lichen simplex chronicus on the ankle. Note the lichenification of the involved skin which has become thickened with accentuated skin lines. There is also postinflammatory hyperpigmentation. (*Used with permission from Richard P. Usatine, MD.*)

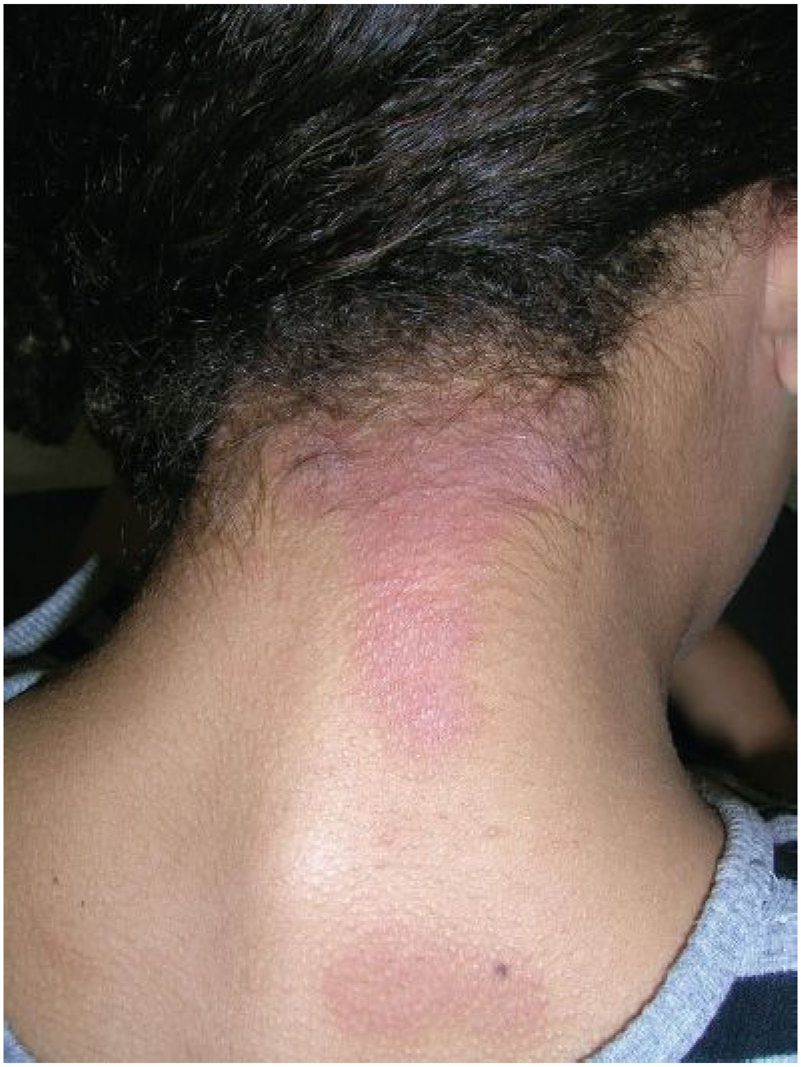

FIGURE 133-11 Lichen simplex chronicus on the neck of a 13-year-old girl. Lichen simplex chronicus is frequently found on the neck. (*Used with permission from Richard P. Usatine, MD.*)

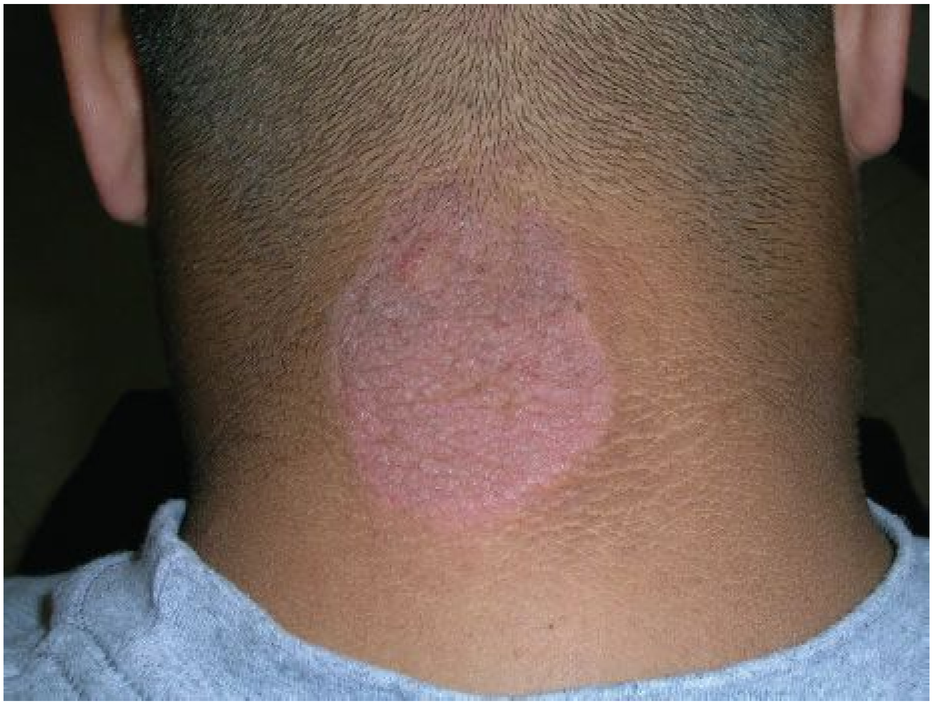

FIGURE 133-12 Lichen simplex chronicus on the neck of a 15-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

- Nummular lesions of atopic dermatitis may have features similar to NE. Presence of other lesions typically on flexural surfaces, and a history of atopy, asthma, or seasonal allergies may help make the diagnosis (see Chapter 130, Atopic Dermatitis).
- Contact dermatitis (CD) may present with nummular lesions. History of exposure to contact allergens at the affected areas can raise the suspicion for CD. Patch testing may be used to confirm the clinical suspicion (see Chapter 131, Contact Dermatitis).

MANAGEMENT

- Emollients are beneficial to help restore and maintain normal skin barrier function. SOR Ⓒ
- Hydration by bathing before bedtime followed by ointment application to wet skin is reported as an effective method of skin care in patients with

eczema.[10] SOR Ⓑ

- A medium- to high-potency topical corticosteroid ointment is the first line of treatment. A cream preparation may be used if patient compliance is a concern with ointments. SOR Ⓒ
- Topical calcineurin inhibitors such as topical tacrolimus and pamicrolimus have the benefit of not causing skin atrophy and have been shown to be effective in many types of eczema.[1] SOR Ⓑ They have a higher cost compared to topical corticosteroids and have a black box warning because of a reported risk of malignancies.
- Short courses of systemic corticosteroids may be necessary in severe or acute cases. SOR Ⓒ
- Methotrexate is reported to be safe, effective, and well-tolerated in treatment of moderate to severe childhood NE.[11] This was reported in a case series of 25 pediatric patients with refractory NE treated with 5 or 10 mg of methotrexate per week. Sixty-four percent had total clearance after an average of 10.5 months. No serious adverse events were observed in this study.[11] SOR Ⓑ
- Phototherapy may be used in generalized, severe, or refractory cases.[1,2] Narrow-band UVB is commonly used and psoralen UVA has been used in more severe cases.[2] SOR Ⓒ
- Topical and oral antihistamines are often needed to treat pruritus. Topical doxepin is reported to be effective in treatment of pruritus associated with eczematous conditions and has a favorable safety profile.[12] SOR Ⓑ
- Topical and systemic antibiotics may be needed to treat secondary or associated bacterial infection. SOR Ⓒ
- Complementary therapy with probiotics is not effective in treatment of eczema and carries a small risk of adverse events.[13] SOR Ⓐ

FOLLOW-UP

Regular follow-up is needed for the patient with chronic, refractory, or relapsing nummular dermatitis until remission or resolution is achieved.

PATIENT EDUCATION

Hydration and protection of skin form irritants is important. Apply moisturizer or topical medications immediately after bathing while the skin is still moist. Avoid strong soaps and use mild fragrance-free soap, or soap alternatives. Avoid tight clothing and fabrics that irritate the skin.

134 URTICARIA AND ANGIOEDEMA

Richard P. Usatine, MD

PATIENT STORY

A penicillin allergic young boy was given trimethoprim-sulfamethoxazole for otitis media and broke out in hives one week later. The hives were on his trunk and arms (**Figure 134-1**). He had no airway symptoms and had only urticaria without angioedema. His fever was gone, his ear pain was resolved, and his tympanic membranes were not bulging, so his parents were told to stop the antibiotic. The pediatrician prescribed an H_1-blocker that gave him relief of symptoms and the wheals disappeared over the next 2 days.

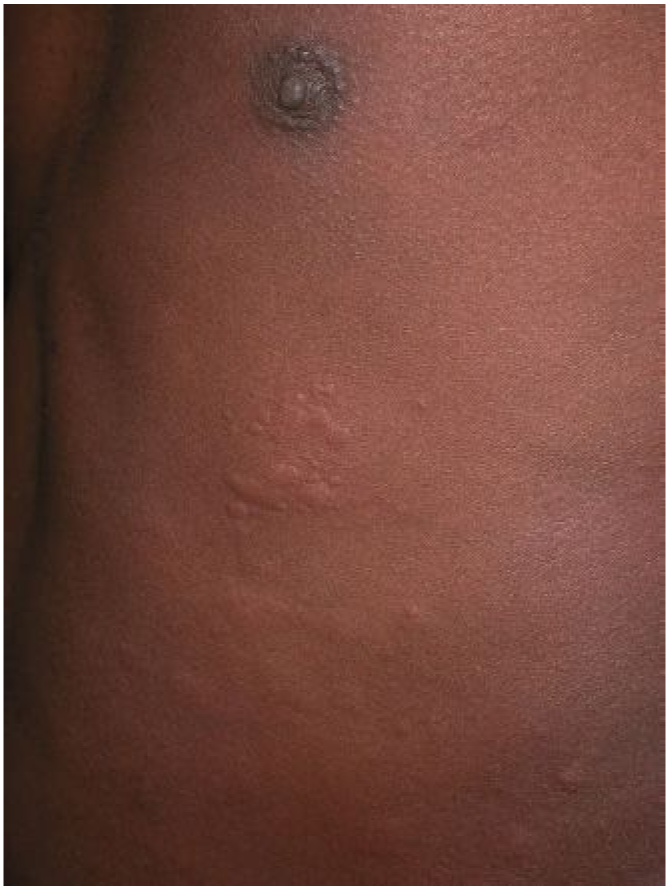

FIGURE 134-1 A young boy with acute urticaria due to trimethoprimsulfamethoxazole. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Urticaria and angioedema are a heterogeneous group of diseases that cause swelling of the skin and other soft tissues. They both result from a large variety of underlying causes, are elicited by a great diversity of factors, and present clinically in a highly variable way.[1] Standard hives with transient wheals is the most common manifestation of urticaria.

SYNONYMS

Hives.

EPIDEMIOLOGY

- It is estimated that 15 to 25 percent of the population may have urticaria sometime during their lifetime.[2]
- Urticaria affects 6 to 7 percent of preschool children and 17 percent of children with atopic dermatitis.[2]
- Among all age groups, approximately 50 percent have both urticaria and angioedema, 40 percent have isolated urticaria, and 10 percent have angioedema alone.[2]
- Acute urticaria is defined as less than 6 weeks' duration. A specific cause is more likely to be identified in acute urticaria.[2]
- The cause of chronic urticaria (>6 weeks' duration) is determined in less than 20 percent of cases.[2]
- Chronic urticaria predominantly affects adults.[3]
- Up to 40 percent of patients with chronic urticaria of more than 6 months' duration still have urticaria 10 years later.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathophysiology of angioedema and urticaria can be immunoglobulin (Ig) E mediated, complement mediated, related to physical stimuli, autoantibody mediated, or idiopathic.
- These mechanisms lead to mast cell degranulation resulting in the release of histamine. The histamine and other inflammatory mediators produce the wheals, edema, and pruritus.

- Urticaria is a dynamic process in which new wheals evolve as old ones resolve. These wheals result from localized capillary vasodilation, followed by transudation of protein-rich fluid into the surrounding skin. The wheals resolve when the fluid is slowly reabsorbed.
- Angioedema is an edematous area that involves transudation of fluid into the dermis and subcutaneous tissue (**Figures 134-2** and **134-3**).

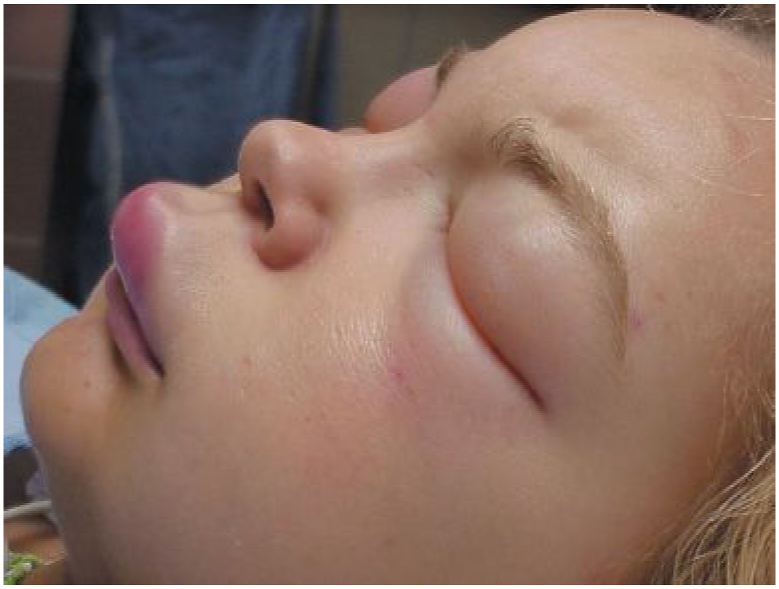

FIGURE 134-2 Severe angioedema around the eyes and mouth in a high school girl. (*Used with permission from Daniel Stulberg, MD.*)

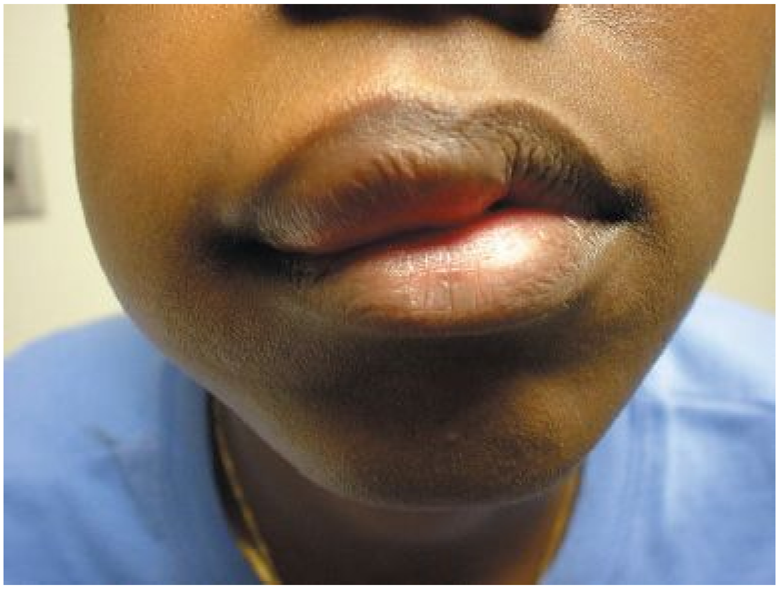

FIGURE 134-3 Young black woman with angioedema after being started on an angiotensin-converting enzyme (ACE) inhibitor for essential hypertension. (*Used with permission from Adrian Casillas, MD.*

The following etiologic types exist:

- Immunologic—IgE mediated, complement mediated. Occurs more often in patients with an atopic background. Antigens are most commonly foods or medications. The most common foods are milk, nuts, wheat, and shellfish.
- Physical urticaria—Dermatographism, cold, cholinergic, solar, pressure, and vibratory urticaria (**Figures 134-4** to **134-6**).

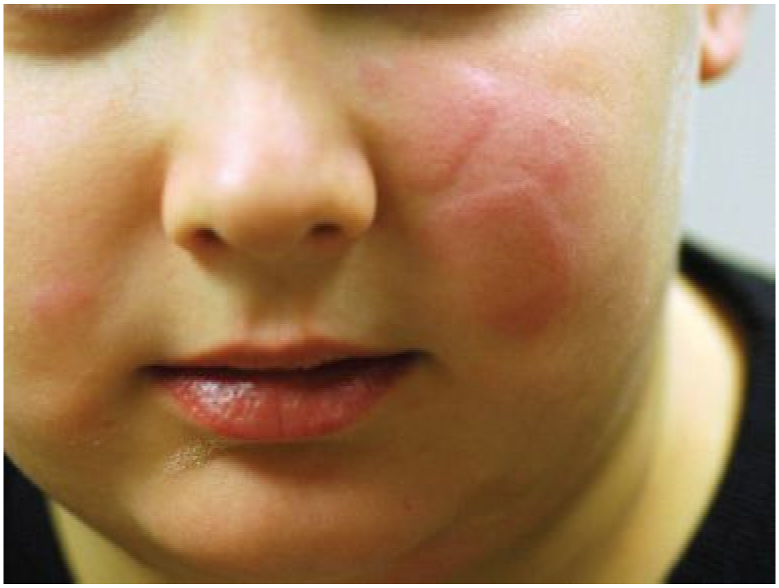

FIGURE 134-4 Cold urticaria demonstrated on the face of a young boy using a 2-minute application of an ice cube to the face. This “ice cube test” is diagnostic as the reaction mirrored the shape of the cube held against the skin. Avoiding cold and the use of antihistamines are the mainstay of treatment. Jumping into a pool can lead to hypotension and drowning in these children. Prescribe an Epi Pen for safety. (*Image used with permission from Robert Brodell, MD.*)

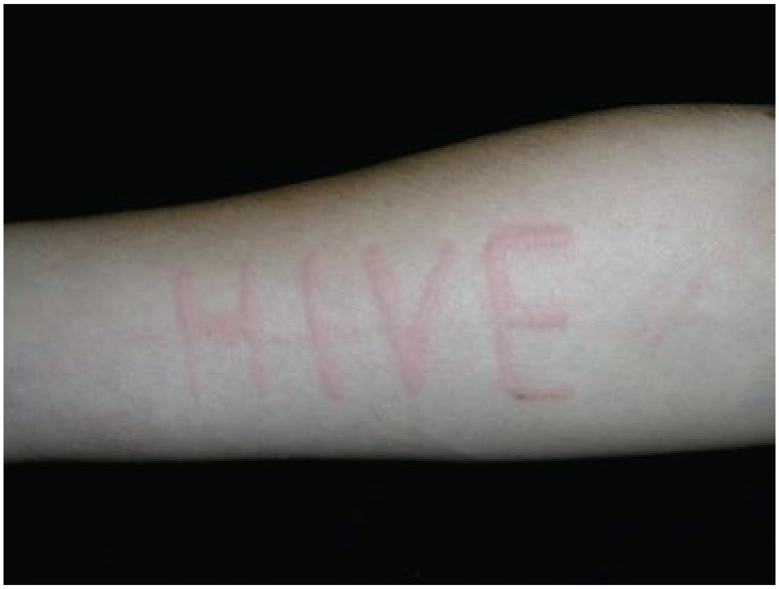

FIGURE 134-5 Dermatographism in a 15-year-old girl with chronic urticaria. Note the exaggerated triple reaction. (*Used with permission from Richard P. Usatine, MD.*)

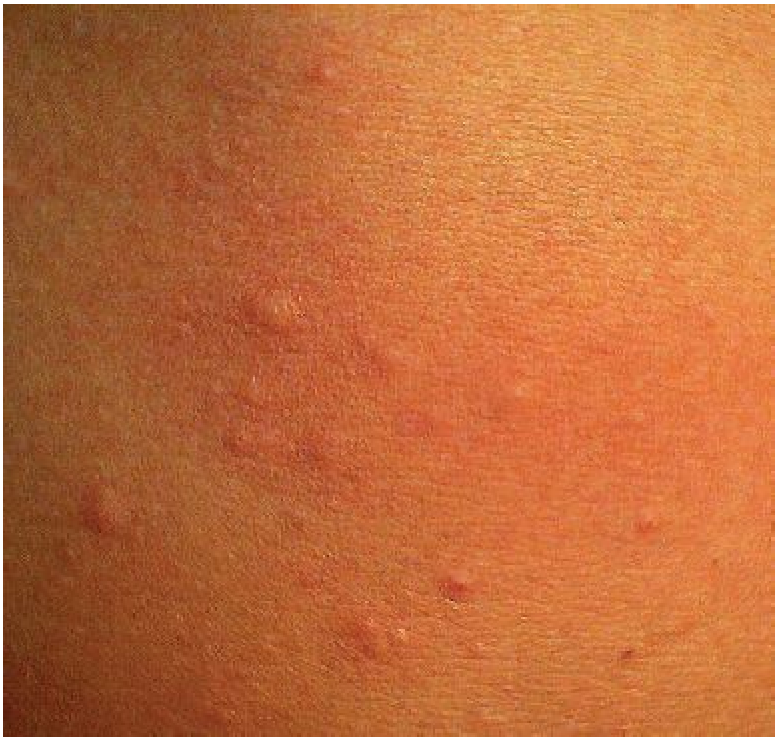

FIGURE 134-6 Cholinergic urticaria showing small wheals. The patient would get this urticaria after exercising. (*Used with permission from Philip C. Anderson, MD.*)

- Urticaria caused by mast cell-releasing agents—Mastocytosis and urticaria pigmentosa (**Figures 134-7** and **134-8**).

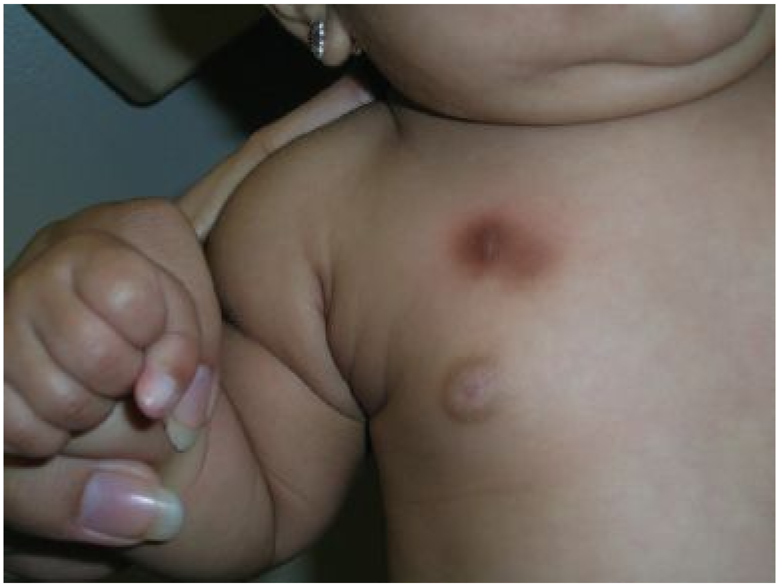

FIGURE 134-7 Urticaria pigmentosa on the chest of this 9-month-old girl. She has a positive Darier sign in which stroking the lesion results in edema. (*Used with permission from Richard P. Usatine, MD*.)

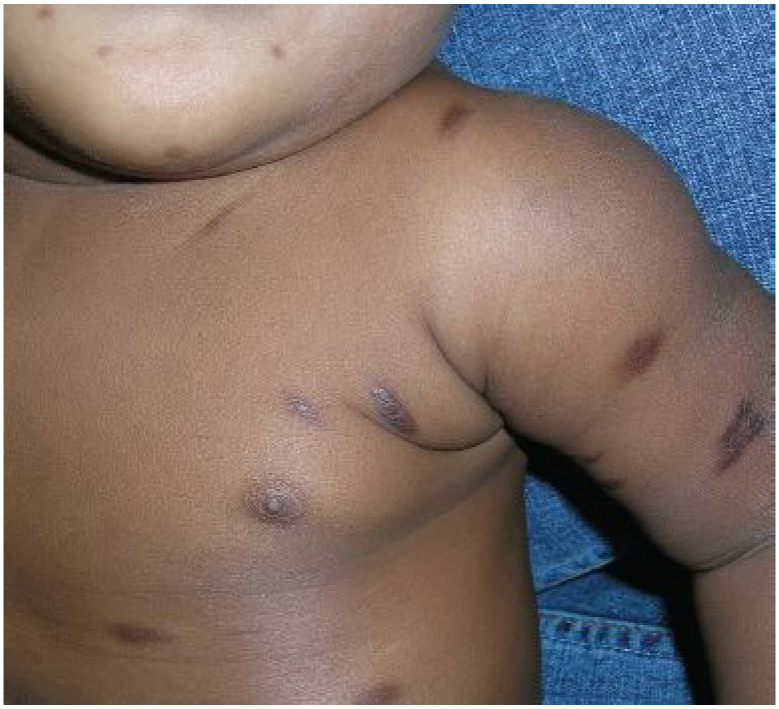

FIGURE 134-8 Urticaria pigmentosa in a 4-month-old black boy. His lesions started on day 2 of life and have proliferated. (*Used with permission from Richard P. Usatine, MD*.)

- Urticaria associated with vascular/connective tissue autoimmune disease.
- Hereditary angioedema is a potentially life-threatening disorder that is inherited in an autosomal dominant manner. In this disease, angioedema occurs without urticaria.

DIAGNOSIS

CLINICAL FEATURES

- Symptoms include itching, burning, and stinging.
- Wheals vary in size from small, 2-mm papules of cholinergic urticaria (**Figure 134-6**) to giant hives where a single wheal may cover a large portion of the trunk.
- The wheal may be all red or white, or the border may be red with the remainder of the surface white.
- Wheals may be annular (**Figures 134-9** to **134-11**).

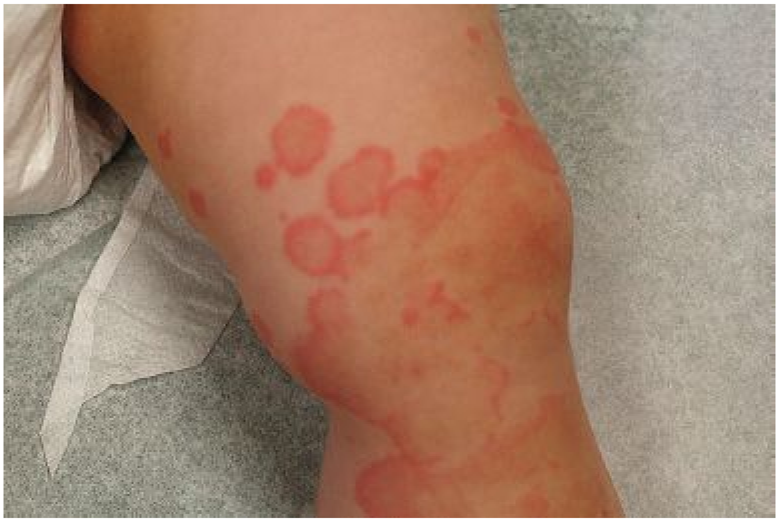

FIGURE 134-9 Giant urticaria on the left thigh of a 1-year-old boy with some areas that are annular (urticaria multiforme). No underlying cause identified. (*Image used with permission from Robert Brodell, MD*.)

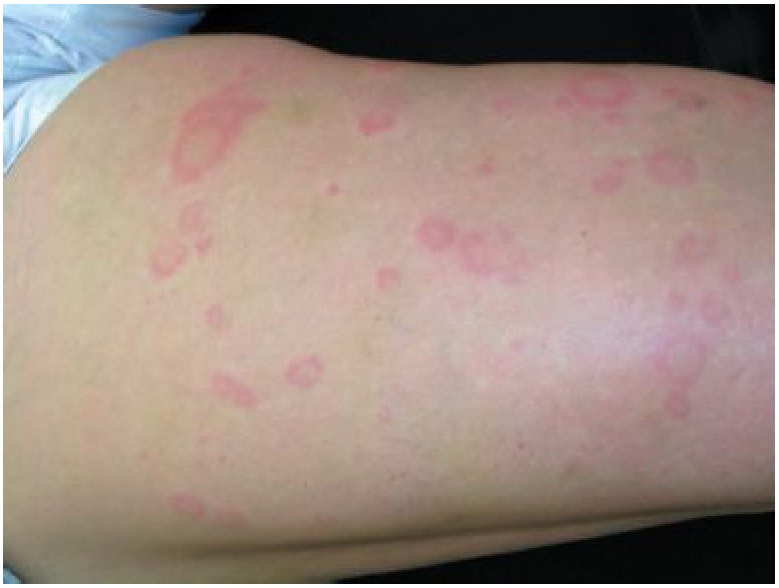

FIGURE 134-10 Chronic urticaria with annular urticarial wheals. (*Used with permission from Richard P. Usatine, MD*.)

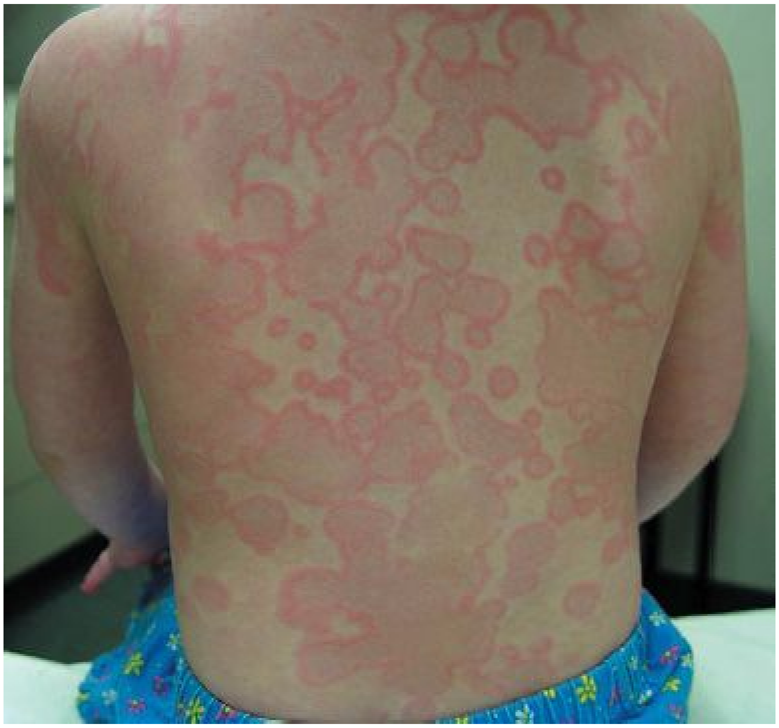

FIGURE 134-11 Giant urticaria (urticaria multiforme). Although this appears to have targets the real target lesions of erythema multiforme have a central lesion with a scaling or bullous component affecting the epidermis. The history suggests that this may have been a serum sickness type reaction. (*Used with permission from Milgrom EC, Usatine RP, Tan RA, Spector SL. Practical Allergy. Philadelphia, PA: Elsevier; 2003; and Daniel Stulberg, MD.*)

- If dermatographism is present, one can write on the skin and be able to see the resulting words or shapes (**Figure 134-5**).
- If you suspect urticaria pigmentosa, stroke a lesion with the wooden end of a cotton-tipped applicator. This induces erythema of the plaque and the wheal is confined to the stroke site. This is called Darier sign (**Figures 134-12** and **134-13**).

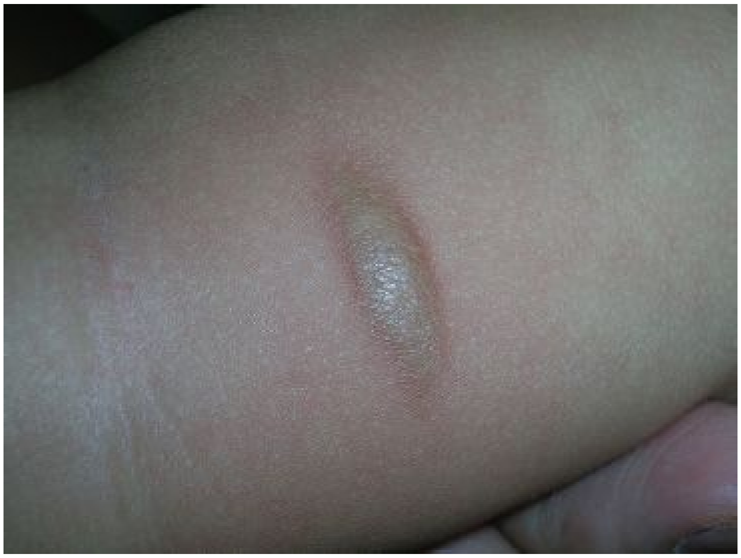

FIGURE 134-12 Positive Darier sign in which stroking the lesion of urticaria pigmentosum results in edema. (*Used with permission from Richard P. Usatine, MD.*)

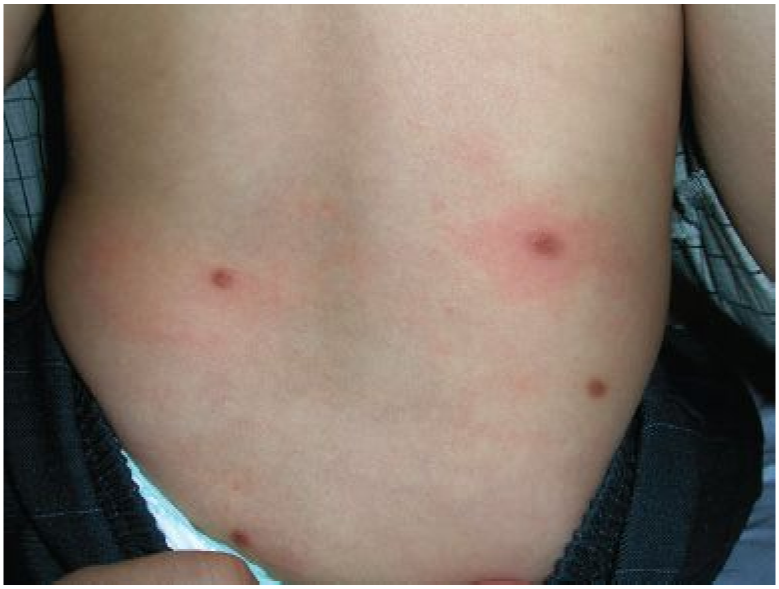

FIGURE 134-13 Positive Darier sign in which stroking the lesions of urticaria pigmentosum on the back resulted in erythema and edema at the site of the stroke. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

- Angioedema is seen more often on the face and is especially found around the mouth and eyes (**Figures 134-2** and **134-3**). Sometimes angioedema can occur on the genitals or the trunk.
- Urticaria can be found anywhere on the body and is often on the trunk and extremities (**Figures 134-14** and **134-15**).

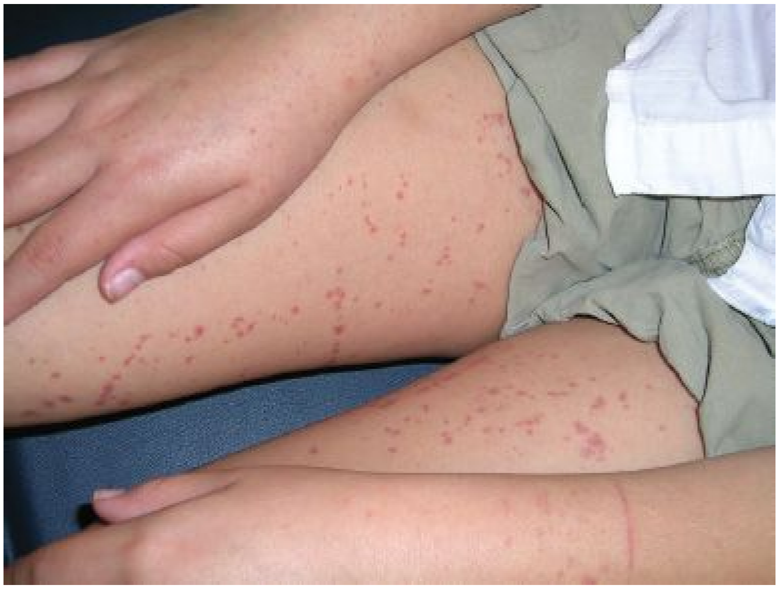

FIGURE 134-14 Henoch-Schonlein purpura on the leg of an 11-year-old girl. This is a type of urticarial vasculitis. (*Used with permission from Richard P. Usatine, MD.*)

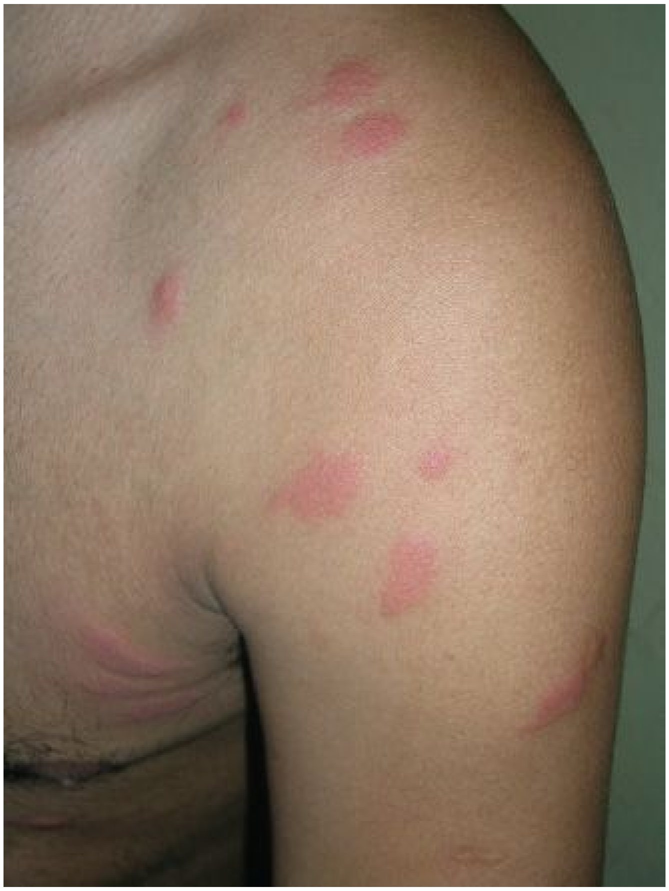

FIGURE 134-15 Urticaria in a young man that was acute and idiopathic. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY STUDIES

Consider tests that might help reveal the cause of the urticaria and/or angioedema.

- Order complement studies to investigate for hereditary or acquired C1 esterase inhibitor deficiency when angioedema occurs repeatedly without urticaria.
- Consider allergen skin testing and/or in vitro tests for when the history reveals that urticaria/angioedema occurs after direct contact with a suspected allergen.
- Punch biopsy of the involved area may be used to diagnose urticarial vasculitis or mastocytosis.

DIFFERENTIAL DIAGNOSIS

- Insect bites—A good history and physical examination should help to distinguish between insect bites and urticaria.
- Erythema multiforme like urticaria can occur in response to an allergic/immunologic reaction to medications, infections, and neoplasms. The classic lesion of erythema multiforme is the target lesion in which there is disruption of the epithelium in the center. This disruption may be a vesicle, bulla, or erosion. Do not confuse annular lesions or concentric rings with erythema multiforme if the epidermis is intact (**Figure 134-11** is *not* erythema multiforme) (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Urticarial vasculitis typically has lesions that last longer than 24 hours. The lesions are found more commonly on the lower extremities, and when they heal, they often leave hyperpigmented areas. Causes range

from a hypersensitivity vasculitis, such as Henoch-Schönlein purpura, to underlying connective tissue disease (**Figure 134-14**).[2]

- Mast cell releasability syndromes are syndromes in which there are too many mast cells in the skin or other organs of the body. These include cutaneous mastocytosis and urticaria pigmentosa (**Figures 134-5**, **134-6**, **134-11**, and **134-12**).

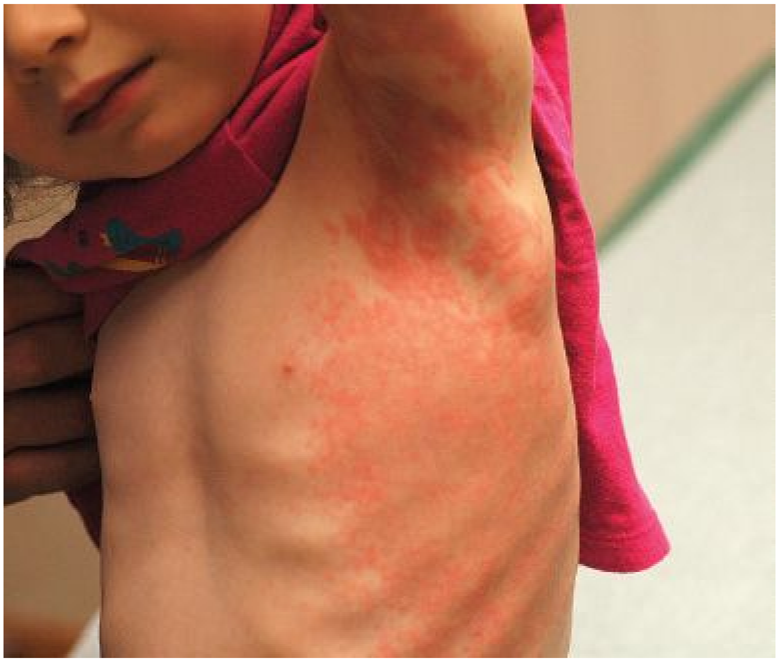

FIGURE 134-16 Asymmetric periflexural exanthem of childhood on the left flank of a 9-year-old girl. This resolves on its own over weeks or months and is often misdiagnosed as a contact dermatitis or eczema. These kids are healthy and asymptomatic unless they have mild pruritus. The cause is unknown. (*Image used with permission from Robert Brodell, MD*.)

- Asymmetric periflexural exanthem of childhood. This condition resolves on its own over weeks or months. It is often misdiagnosed as a contact dermatitis, eczema, or urticaria. These children are healthy and asymptomatic unless they have mild pruritus. The cause is unknown and serologic studies are generally negative (**Figure 134-16**).

MANAGEMENT

NONPHARMACOLOGIC

- Avoid any causative agent, medication, stimulus, or antigen if found. SOR Ⓑ
- Angiotensin-converting enzyme inhibitors (ACEIs) are especially prone to causing angioedema so should be stopped as soon as possible when suspected to be causative of angioedema or urticaria (**Figure 134-3**).[1] SOR Ⓐ Even an angiotensin receptor blocker (ARB) can cause angioedema and should be suspected in a patient on this class of medication (**Figure 134-16**).
- In chronic urticaria, patients may benefit from avoidance of potential urticarial precipitants such as aspirin, NSAIDs (**Figure 134-17**), opiates, and alcohol.[1] SOR Ⓑ

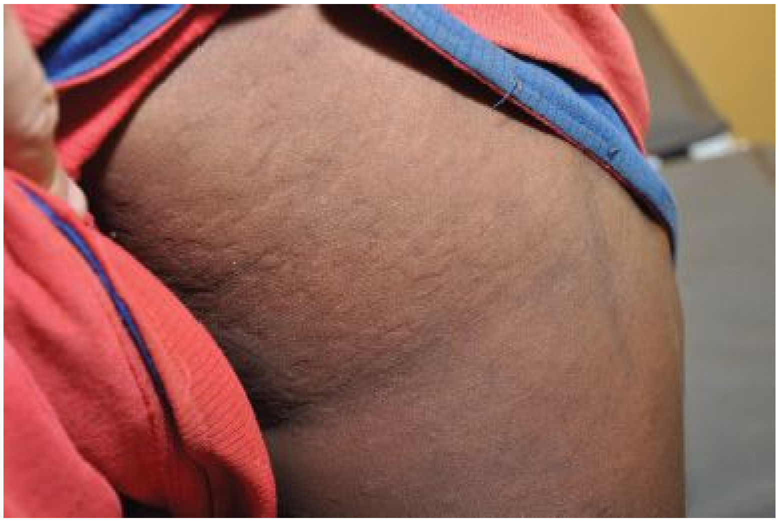

FIGURE 134-17 Urticaria that occurred within an hour after a boy was given ibuprofen to treat a high fever. (*Used with permission from Richard P. Usatine, MD*.)

- Infections may be a cause, an aggravating factor, or an unassociated bystander.[1] Look for sources of chronic infections such as parasitic infections, dental infections, GI infections, respiratory infections, and tinea pedis. Treat these, as it is possible, but unproven, that they can contribute to the chronic urticaria. SOR Ⓒ

- Stop all unnecessary nonprescription medications, supplements, and vitamins in chronic urticaria. SOR Ⓒ
- Avoidance of physical stimuli for the treatment of physical urticaria is desirable, but not always possible (observational studies only).[1] SOR Ⓑ
- Stress reduction techniques may help in chronic urticaria but this is unproven. SOR Ⓒ

ANTIHISTAMINES

- Low-sedating, second-generation antihistamines should be prescribed as a first-line treatment for chronic urticaria.[4–6] SOR Ⓐ
- Increasing the dose of cetirizine from 10 mg to 20 mg daily produced a significant improvement in the severity of wheal and itching in urticaria refractory to the standard doses of antihistamines.[7] SOR Ⓑ
- The British guidelines even suggest using antihistamines at up to quadruple the manufacturers' recommended dosages before changing to an alternative therapy. They also recommend waiting up to 4 weeks to allow full effectiveness of the antihistamines before considering referral to a specialist.[1] SOR Ⓒ
- All patients should be offered the choice of at least two low-sedating H_1 antagonists because responses and tolerance vary between individuals.[8] SOR Ⓐ
- Addition of a sedating antihistamine at night may help patients sleep better, although they probably add little to existing H_1 receptor blockade.[8]
- The addition of an H_2 antagonist may give better control of urticaria than H_1 antagonists alone, although a benefit is not always seen.[8] SOR Ⓑ In one study, adding H_2 blockers to H_1 antagonists resulted in improvement of certain cutaneous outcomes for patients presenting with acute allergic syndromes to an emergency department.[9] SOR Ⓑ

- Low-sedating antihistamines seem to be effective in the treatment of acquired cold urticaria by significantly reducing the presence of wheals and pruritus after cold exposure.[10] SOR Ⓐ

CORTICOSTEROIDS

- Oral corticosteroids should be restricted to short courses for severe acute urticaria or angioedema affecting the mouth (e.g., prednisone 1–2 mg/kg/day for 3 to 4 days).[8,11] SOR Ⓑ
- Short tapering courses of oral steroids over 3 to 4 weeks may be necessary for urticarial vasculitis and severe delayed pressure urticaria.
- Long-term oral corticosteroids should not be used in chronic urticaria. It is better to use oral cyclosporine if needed as it has a far better risk-to-benefit ratio compared with steroids.[1,8]
- A randomized controlled trial showed that clobetasol 0.05 percent in a foam formulation was safe and effective in the short-term treatment of patients with delayed pressure urticaria.[12] SOR Ⓑ

OTHERS

- Epinephrine is valuable in severe acute urticaria or angioedema, especially if there is a suspicion of airway compromise or anaphylaxis.
- The evidence for leukotriene modifiers in the treatment of urticaria is poor. SOR Ⓒ
- Ecallantide is a new plasma kallikrein inhibitor for the subcutaneous treatment of acute attacks of hereditary angioedema.[13] SOR Ⓑ
- Anti-inflammatory drugs, such as colchicine, dapsone and sulfasalazine, have been reported as helpful in uncontrolled trials or case series.[1]

FOLLOW-UP

Follow-up is especially needed when the urticaria/angioedema persist or recur.

PATIENT EDUCATION

In most cases, it is not possible to find the cause of urticaria. This is especially true for chronic urticaria. Fortunately, most chronic urticaria will subside over time and there are medicines to treat the condition until it runs its course. If one medication doesn't work keep your follow-up visits to try other medications. Carefully observe for causative agents.

SECTION 8 PAPULOSQUAMOUS CONDITIONS

135 SEBORRHEIC DERMATITIS

Meredith Hancock, MD
Yoon-Soo Cindy Bae-Harboe, MD
Richard P. Usatine, MD

PATIENT STORY

A 3-month-old African American boy is brought to the clinic with white spots on his face for one month (**Figure 135-1**). The child is otherwise in great health, eating well and gaining weight. The mother was negative for HIV during pregnancy. On physical exam, there are hypopigmented patches on the face especially at the hair line and under the eyebrows. There is visible scale in each of these patches. The hypopigmentation occurs secondary to the toxic effect of the Malassezia (Pityrosporum) on the melanocytes (as seen in tinea versicolor). The diagnosis of seborrheic dermatitis is made and treatment is begun with appropriate topical agents to treat the inflammation and the Malassezia. The mother is told to shampoo the infant's hair with a selenium-based shampoo every 1 to 2 days and to apply 1 percent hydrocortisone cream to the hypopigmented areas twice daily for the next 2 weeks. At a 2-week follow-up, the scale is gone and the hypopigmentation is resolving.

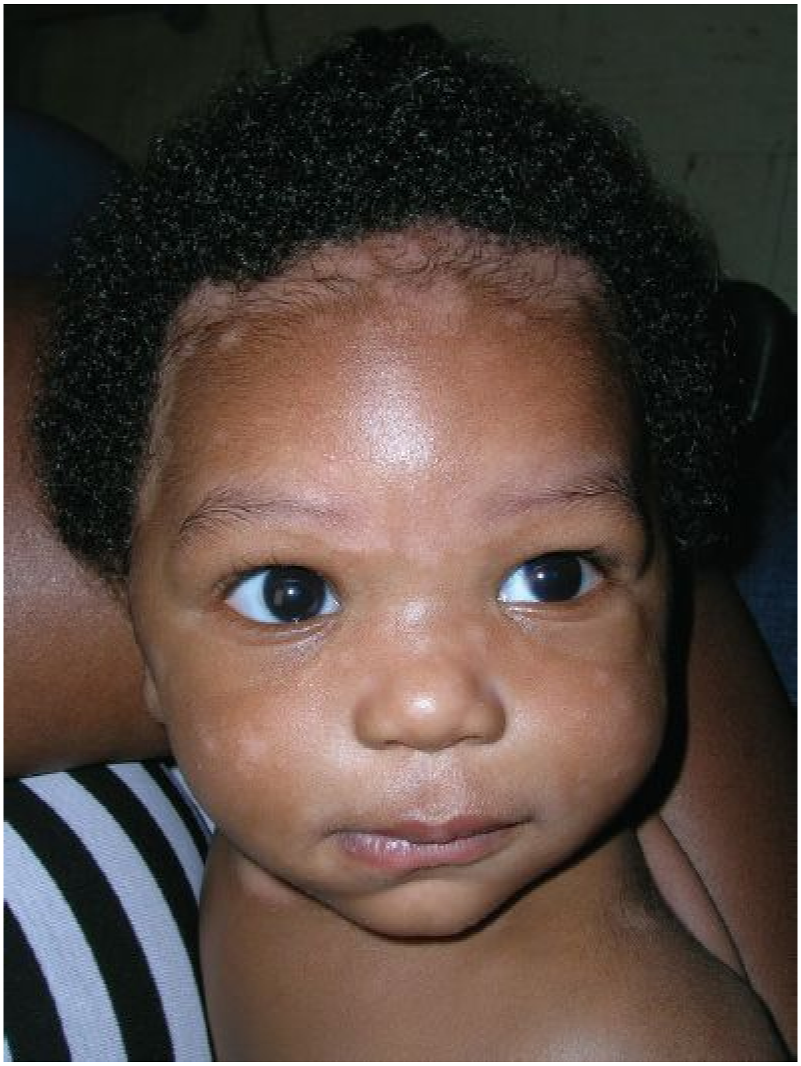

FIGURE 135-1 Seborrheic dermatitis on the scalp and face with visible hypopigmentation. Note how the hypopigmentation is particularly visible around the hairline and under the eyebrows. (*Used with permission from Richard P. Usatine, MD*.)

PATIENT STORY

A 13-year-old African American boy presented to clinic with a mildly pruritic central facial rash and scalp dandruff that had persisted for two years (**Figure 135-2**). There was no history to suggest an allergic contact dermatitis or drug allergy. On physical exam, confluent scaling and erythema with areas of hypopigmentation were noted in the naso-mesial folds and over the eyebrows. Additionally, diffuse scaling and erythema were noted throughout the scalp. The patient was diagnosed with seborrheic dermatitis. Patients with more pigmentation often show a raised lateral margin reminiscent of the advancing border of dermatophyte infections and subsequent postinflammatory hypopigmentation that can be temporarily disfiguring. This patient responded to ketoconazole 2 percent cream applied twice daily to the face and other non-hair-bearing areas and ketoconazole 2 percent shampoo twice weekly for his scalp. His hypopigmentation improved over time.

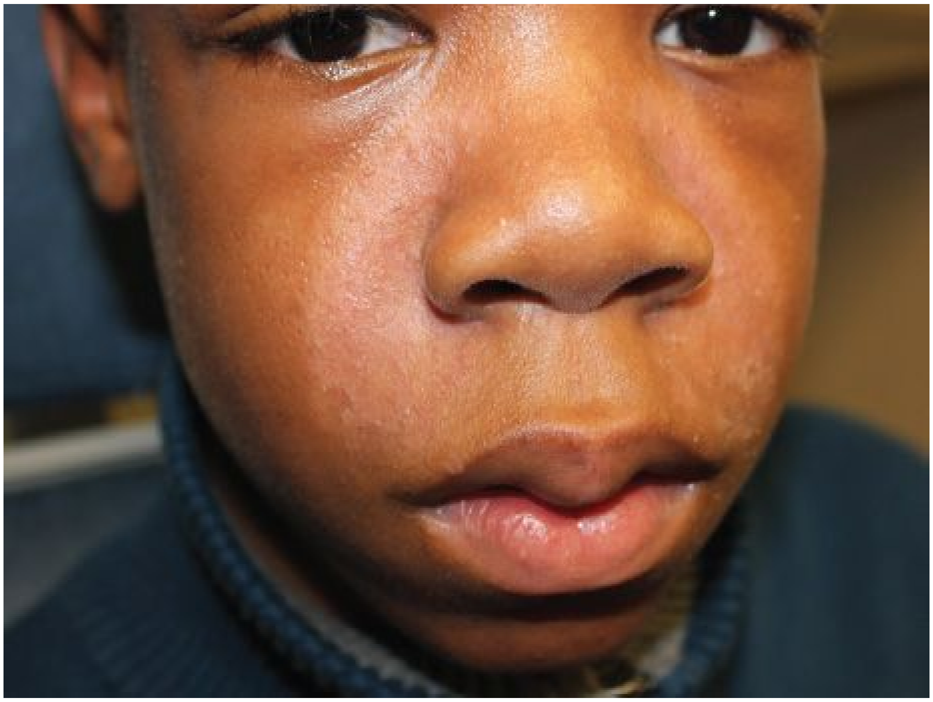

FIGURE 135-2 Seborrheic dermatitis in a 13-year-old boy demonstrating confluent scaling and erythema along with areas of hypopigmentation. Patients with more pigmentation often show a raised lateral margin reminiscent of the advancing border of dermatophyte infections and subsequent post-inflammatory hypopigmentation that can be temporarily disfiguring. (*Image used with permission from Robert Brodell, MD.*)

INTRODUCTION

Seborrheic dermatitis is a common, chronic, relapsing dermatitis affecting sebum-rich areas of the body. Children and adults, males and females may be affected. Presentation may vary from mild erythema to greasy scales, and rarelyas erythroderma. Treatment is targeted to reduce inflammation and irritation, as well as to eliminate Malassezia fungus, whose exact role is not completely understood.

SYNONYMS

Seborrhea, seborrheic eczema, dandruff, and cradle cap (pityriasis capitis).

EPIDEMIOLOGY

- The prevalence of seborrheic dermatitis was 10 percent in children from infancy to 5 years of age in a skin survey of over 1,000 children in Australia. The highest rate was in the first 3 months of life, decreasing rapidly by the age of 1 year, after which it slowly decreased over the next 4 years. Most (72%) had disease classified as minimal to mild. Cradle cap occurred in 42 percent of the children examined, with 86 percent categorized as minimal to mild only.[1]
- Prevalence of scalp seborrheic dermatitis in a survey of male adolescents in Brazil was 11 percent. The prevalence was higher in persons with white skin and a higher body fat content.[2]
- Seborrheic dermatitis affects 1 to 3 percent of the general population, 3 to 5 percent of young adults, and 20 to 83 percent of patients with AIDS.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Seborrheic dermatitis is a chronic, superficial, localized inflammatory dermatitis that is found in sebum-producing areas of the body.
- The actual cause of seborrheic dermatitis is not well understood. It appears to be related to the interplay between host susceptibility, environmental factors, and local immune response to antigens.[4–6]
- Patients with seborrheic dermatitis may be colonized with certain species of lipophilic yeast of the genus *Malassezia*; however, *Malassezia* is considered normal skin flora and unaffected persons also may be colonized.
- Recent evidence suggests that *Malassezia* may produce different irritants or metabolites on affected skin.[6]

RISK FACTORS

- Infancy.
- Male gender.
- Immunocompromise (HIV/AIDS, Parkinson disease, or malignancy).
- Stress.
- Environmental factors (cold, dry weather).

DIAGNOSIS

The clinical diagnosis is made by history and physical examination. **Figures 135-3** and **135-4** reveal erythema and scale across the eyebrows, forehead, central face, and scalp. Biopsy is not generally indicated unless ruling out other possibilities (see the following section “Differential Diagnosis”).

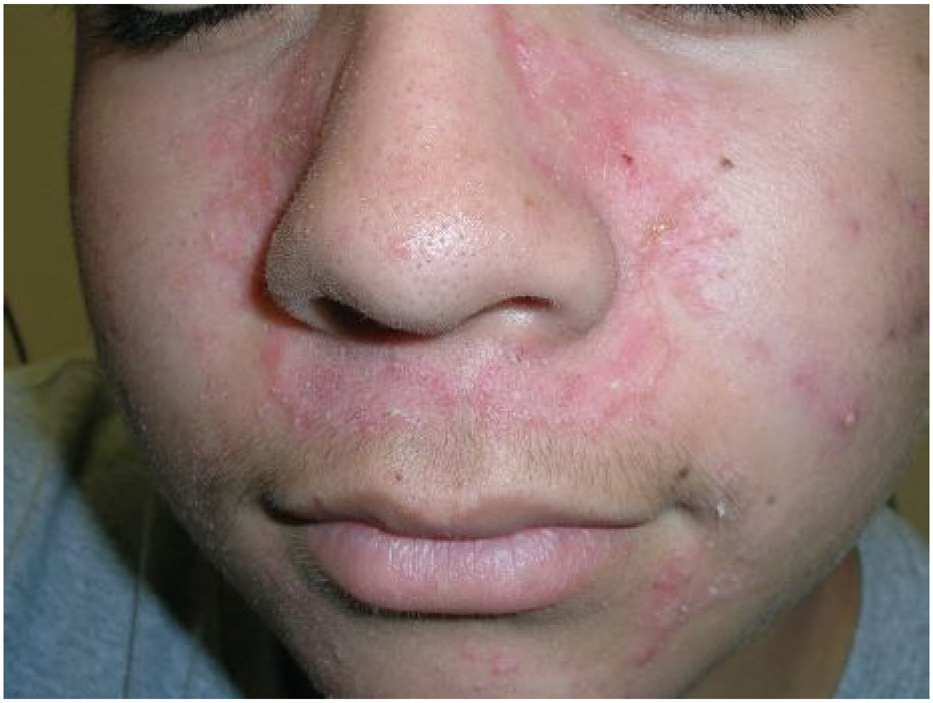

FIGURE 135-3 Seborrheic dermatitis on the face of a 14-year-old boy. Note the erythema and scale especially concentrated around the central face. He also had seborrhea of the scalp and acne. (*Used with permission from Richard P. Usatine, MD*.)

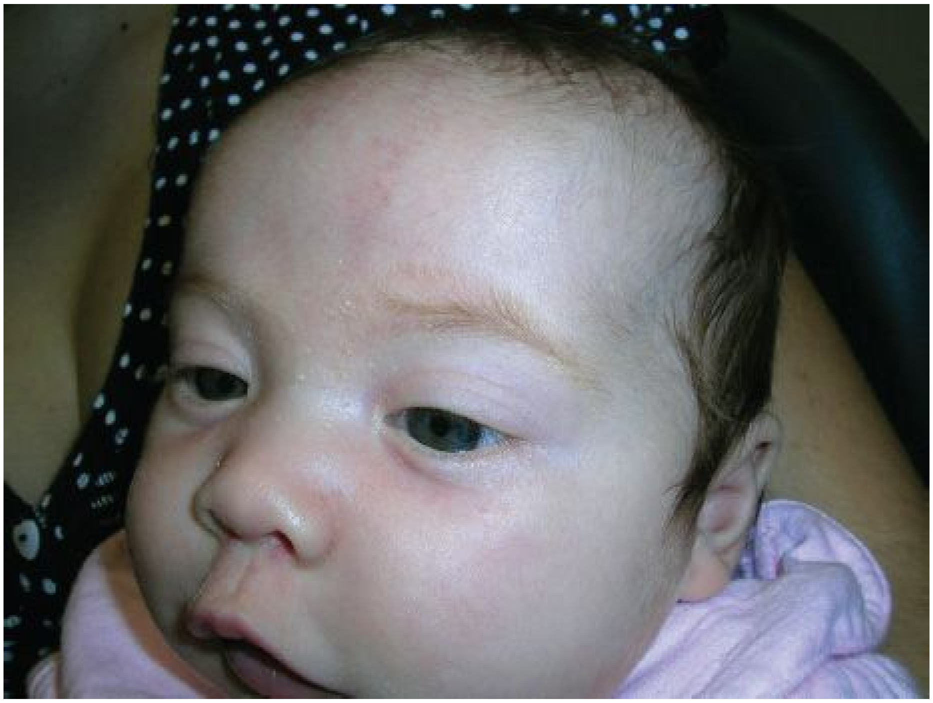

FIGURE 135-4 Mild seborrheic dermatitis with subtle flaking around the eyebrows of a 2-month-old girl who also has cradle cap. (*Used with permission from Richard P. Usatine, MD*.)

CLINICAL FEATURES

- Chronic skin condition characterized by remissions and exacerbations.
- Poorly demarcated, erythematous plaques of greasy, yellow scale (**Figure 135-3**), in the characteristic seborrheic distribution (see the following description).
- Common precipitating factors are stress, immunosuppression, and cold weather.
- Face, scalp, and ears may be very pruritic.
- May be the presenting sign of HIV seropositivity.
- In dark-skinned individuals, the involved skin and scale may become hyperpigmented or hypopigmented (**Figures 135-2**, **135-3**, and **135-5**).

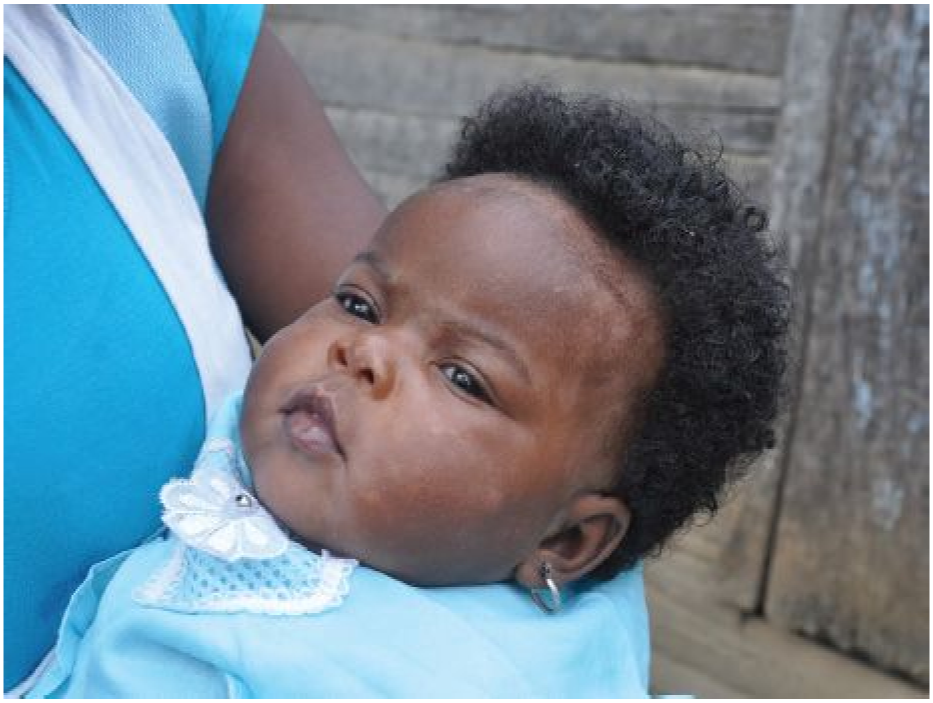

FIGURE 135-5 Seborrheic dermatitis on the face of an infant with hypopigmentation around the scalp and over the eyebrows. Hypopigmentation is secondary to postinflammatory changes. (*Used with permission from Richard P. Usatine, MD*.

TYPICAL DISTRIBUTION

Scalp (i.e., dandruff), eyebrows (**Figures 135-4** and **135-5**), nasolabial creases, forehead, cheeks, around the nose, behind the ears (**Figure 135-6**), external auditory meatus, and under facial hair. Seborrhea can also occur over the sternum and in the axillae, submammary folds, umbilicus, groin, and gluteal creases.

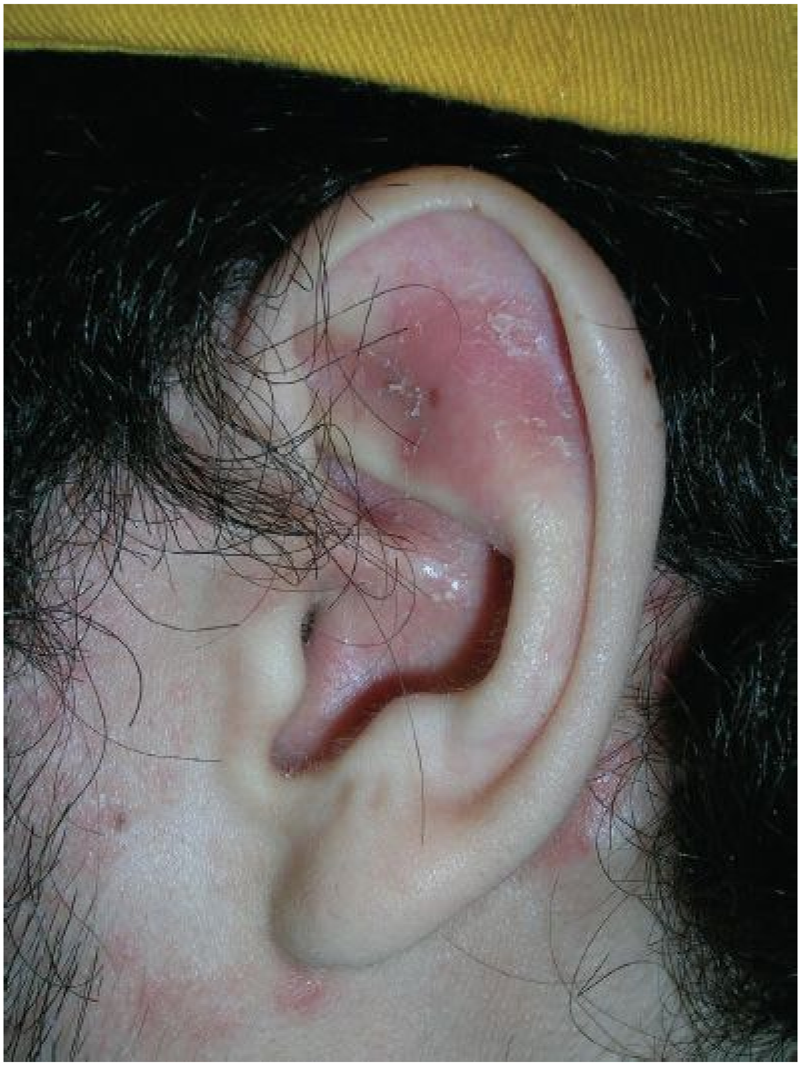

FIGURE 135-6 Seborrheic dermatitis in and around the ear of a teenager. (*Used with permission from Richard P. Usatine, MD.*)

Infants may develop scales on the scalp, known as cradle cap (**Figures 135-7** and **135-8**). The eyebrows may also be affected (**Figure 135-5**). Some infants have a wider distribution involving the neck creases, armpits, leg creases, and groin (**Figure 135-9**).

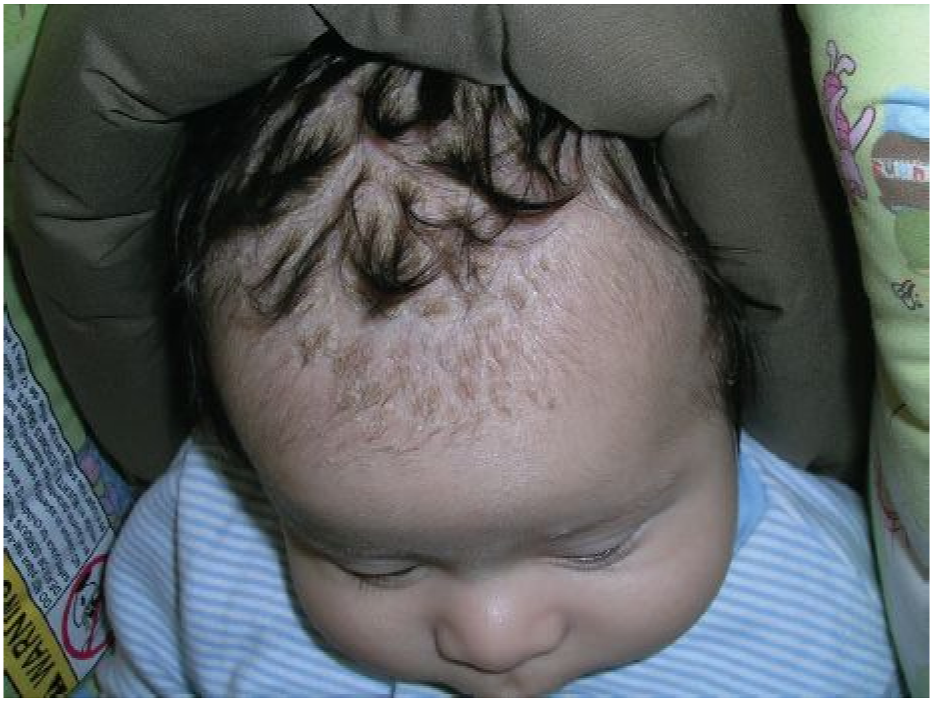

FIGURE 135-7 Cradle cap in a healthy infant showing brown adherent scale over the central scalp. (*Used with permission from Richard P. Usatine, MD.*)

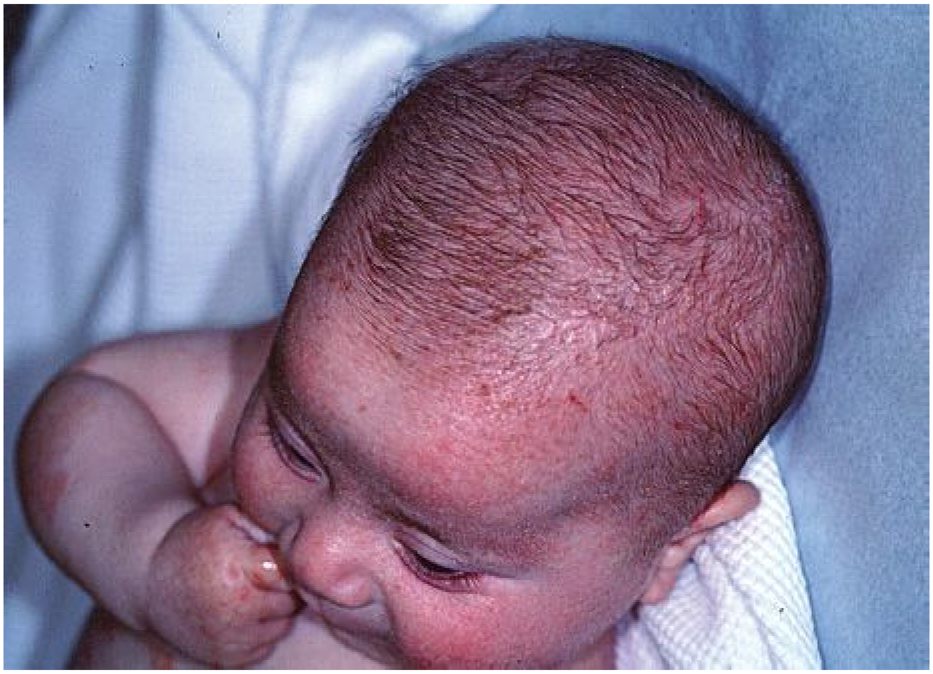

FIGURE 135-8 Widespread severe seborrheic dermatitis with cradle cap in an infant that also has atopic dermatitis. (*Used with permission from Richard P. Usatine, MD.*)

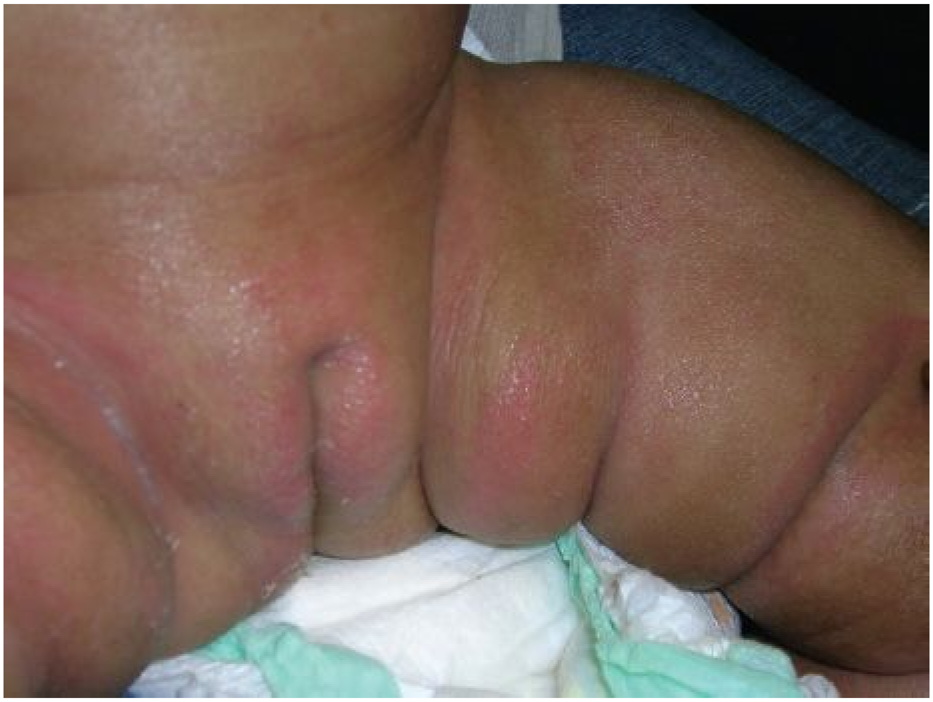

FIGURE 135-9 Seborrheic dermatitis in the diaper area and skin folds of the thighs in an otherwise healthy infant. (*Used with permission from*

Richard P. Usatine, MD.)

LABORATORY STUDIES

- Test for HIV if patient has risk factors.
- Consider KOH preparation to look for the spaghetti and meatballs pattern of Malassezia furfur (Pityrosporum yeast).
- Consider zinc level or alkaline phosphatase to rule out nutritional/zinc deficiency.

DIFFERENTIAL DIAGNOSIS

- Langerhans cell histiocytosis is a group of disorders characterized by proliferation of Langerhans cells. The proliferation leads to lesions in the skin, bone marrow, endocrine system, or lungs. It may present with a severe refractory diaper rash that has scattered erythematous papules and a petechial component (**Figure 135-10**). A skin biopsy is needed to make the diagnosis (see Chapter 214, Langerhans cell Histiocytosis).

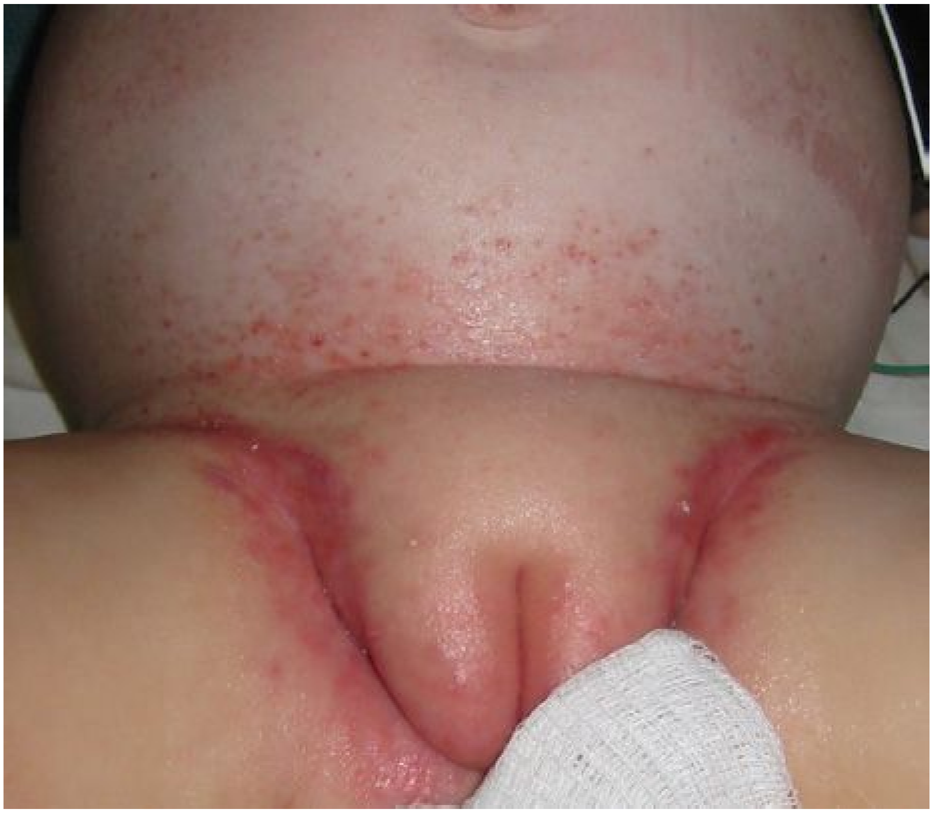

FIGURE 135-10 Langerhans cell histiocytosis in the diaper area presented as a diaper rash, which did not respond to treatment. This refractory diaper rash has scattered erythematous papules and a petechial component. A skin biopsy revealed Langerhans' cells. (*Used with permission from Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 3-6, New York, NY: McGraw-Hill, 2009*.)

- Psoriasis—The scale of psoriasis tends to be thicker, on well-demarcated plaques distributed over extensor surfaces along with the scalp. Look for signs of nail involvement that may support the diagnosis of psoriasis (see Chapter 136, Psoriasis).
- Rosacea—The erythema on the face is often associated with papules, pustules, telangiectasia, and an absence of scales. May also present with chalazia or hordeola (see Chapter 97, Rosacea).
- Tinea capitis—Scale and erythema commonly with associated hair loss. KOH and/or culture can help make the distinction (see Chapter 122, Tinea Capitis).

- Perioral dermatitis—Usually restricted around the mouth with minimal scale.
- Tinea versicolor (trunk and neck)—The scale of tinea versicolor is fine and white and scales with scraping. The *Malassezia* infection affects the melanocytes leading to changes in color of the affected areas (white, pink and brown). As this condition is caused by the same organism as seborrhea there are many similarities in clinical appearance and treatment (see Chapter 126, Tinea Versicolor).
- Allergic or irritant contact dermatitis—May present with a well demarcated lesion with fine white scale, secondarily impetiginized lesions may have associated yellow colored crust, not scale.
- Candidiasis—May be found in intertriginous areas, but presents with significant erythema and satellite lesions.
- Nutritional deficiency (i.e., zinc)—May present with facial lesions and acral rash as seen in acrodermatitis enteropathica (see Chapter 7, Global Health).

MANAGEMENT

As seborrheic dermatitis is a recurrent, chronic condition, repeated and/or maintenance therapy is often required.

- Mainstay of treatment is topical antifungals.
- For seborrheic dermatitis of the scalp, patients should wash their hair with antifungal shampoos (containing selenium sulfide, ketoconazole, or ciclopirox) several times per week, each time leaving the lather on the affected areas for several minutes until remission is attained. Patients may continue to use antifungal shampoo as maintenance therapy.[5]
- Shampoos containing ketoconazole, selenium sulfide or zinc pyrithione (ZPT) are active against the *Malassezia* and are effective in the treatment of moderate to severe dandruff.[7,8] SOR Ⓐ

- Ketoconazole 2 percent shampoo was found to be superior to ZPT 1 percent shampoo when used twice weekly. Ketoconazole led to a 73 percent improvement in the total dandruff severity score compared with 67 percent for ZPT 1 percent at 4 weeks.[8] SOR Ⓑ
- Ciclopirox shampoo 1 percent is effective and safe in the treatment of seborrheic dermatitis of the scalp.[9,10] SOR Ⓐ It is by prescription only and is expensive.
- Ketoconazole 2 percent cream, gel, or emulsion is safe and effective for facial seborrheic dermatitis[11–13] SOR Ⓑ
- Ciclopirox 1 percent cream is also safe and effective for facial seborrheic dermatitis and is equivalent to ketoconazole 2 percent cream.[11,14] SOR Ⓑ
- Oral terbinafine 250 mg daily for 4 weeks was found to be effective for moderate to severe seborrhea in adults.[15,16] SOR Ⓑ However, because of the potential for harmful side effects of oral antifungals and the limited study of their efficacy, they are not first-line treatments.[5] Oral terbinafine may be considered to treat erythroderma caused by seborrhea in an adolescent.

Topical corticosteroids are useful in treating associated erythema and pruritis.[5] Long-term use may lead to skin atrophy[5] and should be used with caution.

- Lotion or solution is preferable on hair-covered area for patient comfort and usability.
- Hydrocortisone 1 to 2.5 percent cream or lotion can be used bid on the face, scalp, and other affected areas.[13,17] SOR Ⓑ
- Desonide 0.05 percent lotion is safe and effective for short-term treatment of seborrheic dermatitis of the face.[15] SOR Ⓑ It is a nonfluorinated low to midpotency steroid that is higher in potency than hydrocortisone 1 percent.
- For moderate to severe seborrheic dermatitis on the scalp of a teenager:
    - Fluocinonide 0.05 percent solution once daily is affordable and beneficial. SOR Ⓒ

OTHER TREATMENTS

- Pimecrolimus cream 1 percent is an effective and well-tolerated treatment for facial seborrheic dermatitis.[17,19,20] SOR Ⓑ In one study, there was more burning noted with the pimecrolimus than with the betamethasone 17-valerate 0.1 percent cream.[19]
- Metronidazole gel—Two small studies have found different results in the treatment of seborrheic dermatitis on the face. One suggests it works better than the vehicle alone and the other found no statistically significant difference from placebo.[21,22] SOR Ⓑ

COMPLEMENTARY/ALTERNATIVE THERAPY

- Tea tree oil 5 percent shampoo showed a 41 percent improvement in the quadrant-area-severity score compared with 11 percent in the placebo. Statistically significant improvements were also observed in the total area of involvement score, the total severity score, and the itchiness and greasiness components of the patients' self-assessments.[23] SOR Ⓑ
- One small randomized controlled trial using homeopathic medication consisting of potassium bromide, sodium bromide, nickel sulfate, and sodium chloride for 10 weeks showed significant improvement over placebo.[24] SOR Ⓑ

FOLLOW-UP

Patients with longstanding and severe seborrhea will appreciate a follow-up visit in most cases. Milder cases can be followed as needed.

PATIENT EDUCATION

For improved treatment results, encourage patients (or the parents of younger children) to wash the hair and scalp daily with an antifungal shampoo. Some patients (or their parents) fear that washing their hair too often will cause a "dry" scalp and need to understand that the scaling and flaking will improve rather than worsen with more frequent hair washing. It is helpful to explain that the flaking is not because the scalp is dry but secondary to the overgrowth of the fungus that needs to be washed off the scalp.

136 PSORIASIS

Richard P. Usatine, MD

PATIENT STORY

A 5-year-old boy presents to his pediatrician with a new onset rash 2 weeks after being treated for strep pharyngitis. He had been treated with a10-day course of amoxicillin after a positive rapid strep test in the office. The mother states that her son is otherwise feeling well with a good appetite and no change in his activities. The pediatrician notes small plaques on the child's face, arms and trunk and sees the resemblance to drops of water (**Figure 136-1**). The vital signs are normal as is the rest of the physical examination. A diagnosis of guttate psoriasis is made without any laboratory tests or biopsies. The child is started on 0.1 percent triamcinolone ointment to be applied twice daily. A referral to dermatology is also made.

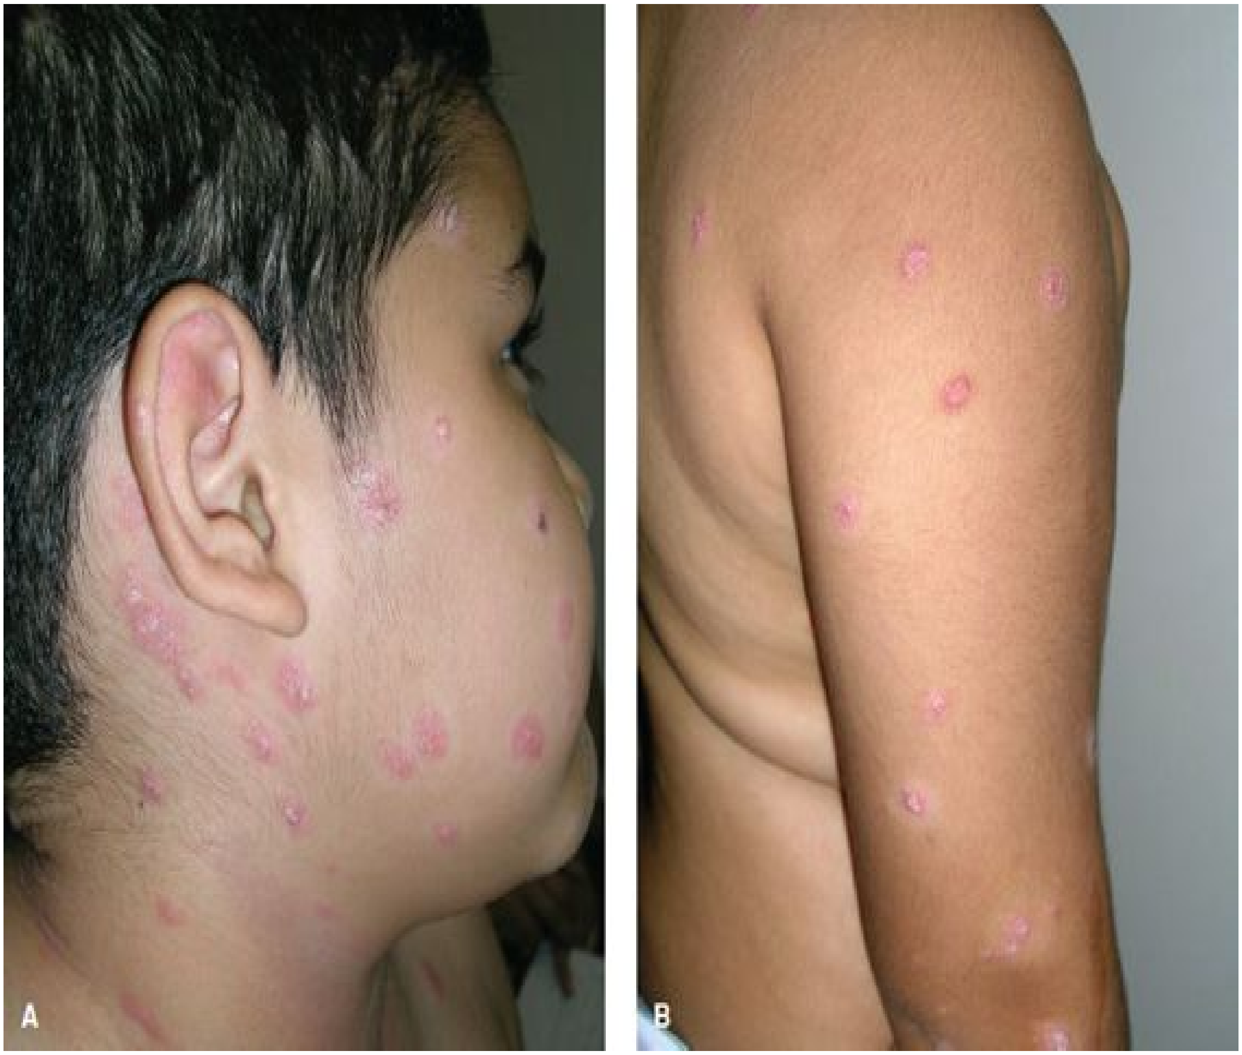

FIGURE 136-1 This 5-year-old boy developed guttate psoriasis 2 weeks after a strep throat. **A.** Note the drop-like pink plaques on the face and neck. **B.** Drop-like plaques on the arms and trunk. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Psoriasis is a chronic inflammatory papulosquamous and immune-mediated skin disorder. It is also associated with joint and cardiovascular comorbidities. Psoriasis can present in many different patterns, from the scalp to the feet, and cause psychiatric distress and physical disabilities. It is crucial to be able to identify psoriasis in all its myriad presentations so that patients receive the best possible treatments to improve their quality of life and avoid comorbidities.

EPIDEMIOLOGY

- Psoriasis affects approximately 2 percent of the world population.[1]
- The prevalence of psoriasis was 2.5 percent in white patients and was 1.3 percent in African American patients in one population study in the US.[2]
- Sex—No gender preference.
- Age—Psoriasis can begin at any age. In one population study of the age of onset of psoriasis two peaks was revealed, one occurring at the age of 16 years (female) or 22 years (males) and a second peak at the age of 60 years (female) or 57 years (males).[3]
- The prevalence rates for pediatric psoriasis increased in a linear way from 0.2 percent at the age of one year to 1.2 percent at the age of 18 years in a German study.[4]
- Psoriasis begins before the age of 20 in about 1/3 of patients.[5]
- Psoriatic arthritis affects about 20 percent of all psoriasis patients.[5]

ETIOLOGY AND PATHOPHYSIOLOGY

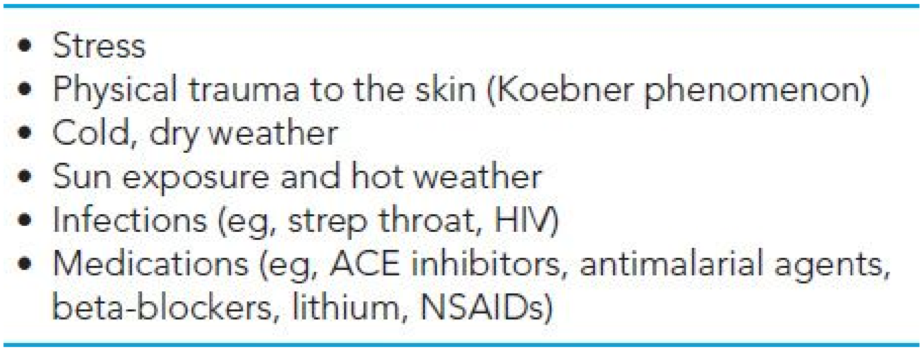
- Immune-mediated skin disease, where the T cell plays a pivotal role in the pathogenesis of the disease.
- Langerhans cell (antigen-presenting cells in the skin) migrate from the skin to regional lymph nodes, where they activate T cells that migrate to the skin and release cytokines.
- Cytokines are responsible for epidermal and vascular hyperproliferation and proinflammatory effects.

RISK FACTORS

- Family history.
- Obesity.
- Smoking and environmental smoke.
- Heavy alcohol use.

Table 136-1 lists the factors that trigger and exacerbate psoriasis.[6]

TABLE 136-1 Allergens in T.R.U.E. Test (Patch Test for Contact Dermatitis)



- Stress
- Physical trauma to the skin (Koebner phenomenon)
- Cold, dry weather
- Sun exposure and hot weather
- Infections (eg, strep throat, HIV)
- Medications (eg, ACE inhibitors, antimalarial agents, beta-blockers, lithium, NSAIDs)

The risk of psoriasis is higher with:[7]

- Family history of psoriasis (odds ratio [OR] = 33.96; 95 percent confidence interval [CI] 14.14 to 81.57).
- Urban dwellers (OR = 3.61; 95% CI = 0.99 to 13.18).
- Alcohol consumption (OR = 2.55; 95% CI = 1.26 to 5.17).
- Environmental tobacco smoke at home (OR = 2.29; 95% CI = 1.12 to 4.67).

In a multicenter case-control study of environmental risk factors in pediatric psoriasis the most important risk factors were:

- Environmental tobacco smoke at home or smoking—Odds ratio 2.90 (95% confidence interval [CI] = 2.27–3.78).
- Stressful life events—Odds ratio 2.94 (95% CI = 2.28–3.79).

- Higher BMI (>26)—odds ratio 2.52 (95% CI = 1.42–4.49).[8]

DIAGNOSIS

Psoriasis has many forms and locations. These nine categories were used to describe psoriasis in a consensus statement of the American Academy of Dermatology (AAD):[9]

1. Plaque psoriasis (**Figure 136-2**).

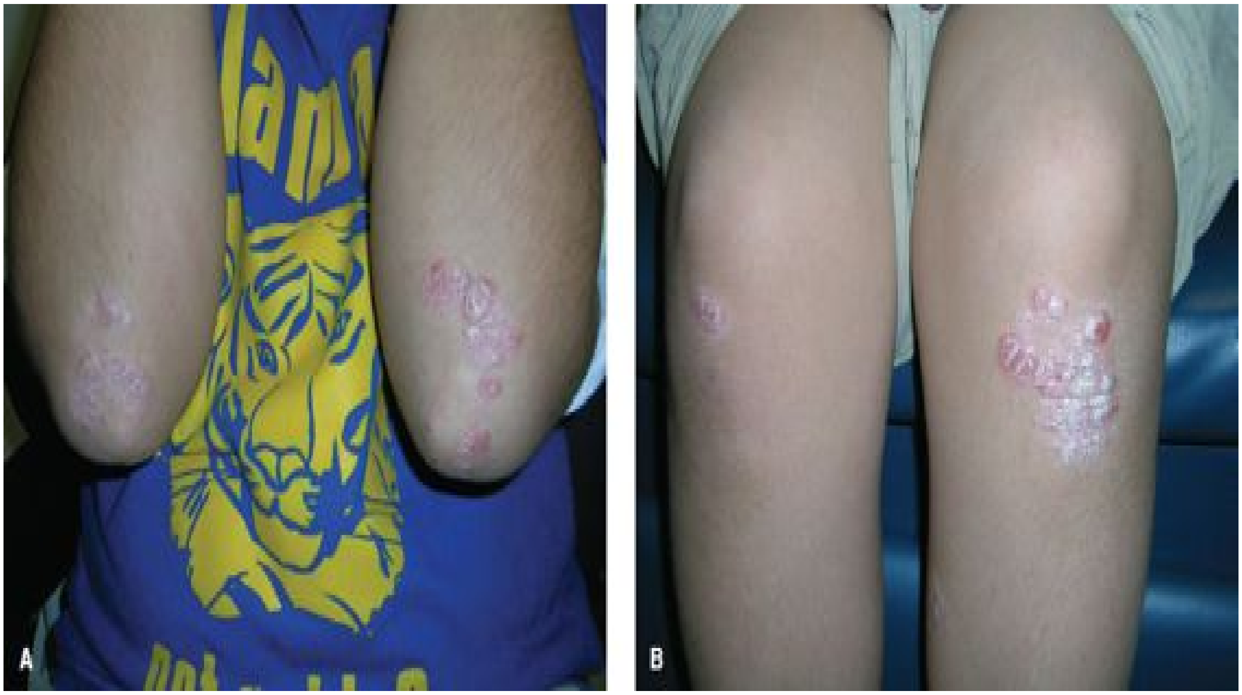


FIGURE 136-2 Typical plaque psoriasis in a 9-year-old child on the **A.** elbows and **B.** knees. (*Used with permission from Richard P. Usatine, MD*.)

2. Scalp psoriasis (**Figure 136-3**).

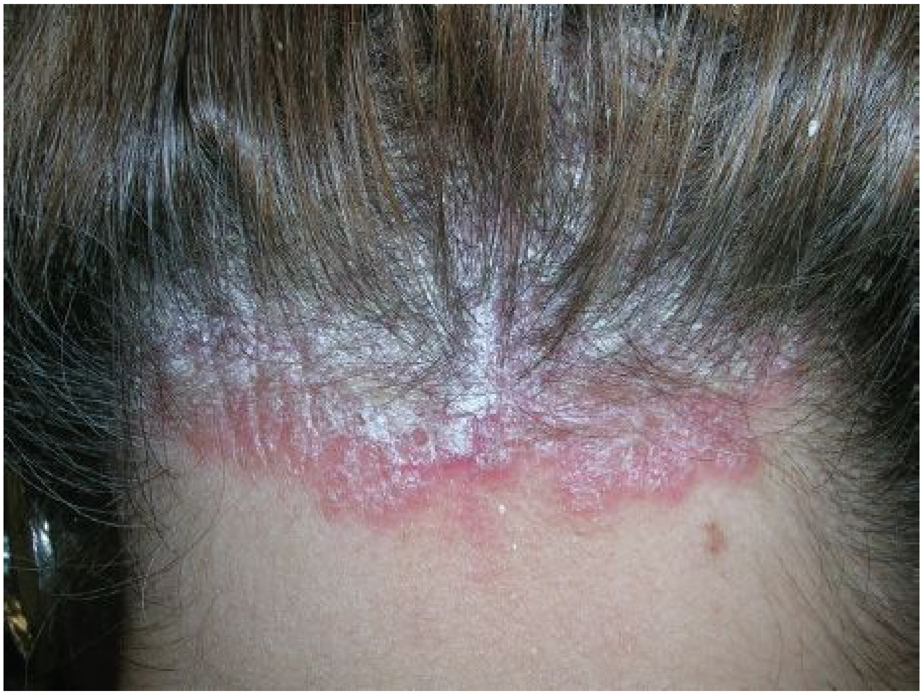

FIGURE 136-3 Scalp psoriasis visible at the posterior hairline in a teenage girl. (*Used with permission from Richard P. Usatine*, *MD*.)

3. Guttate psoriasis (**Figures 136-4** and **136-5**).

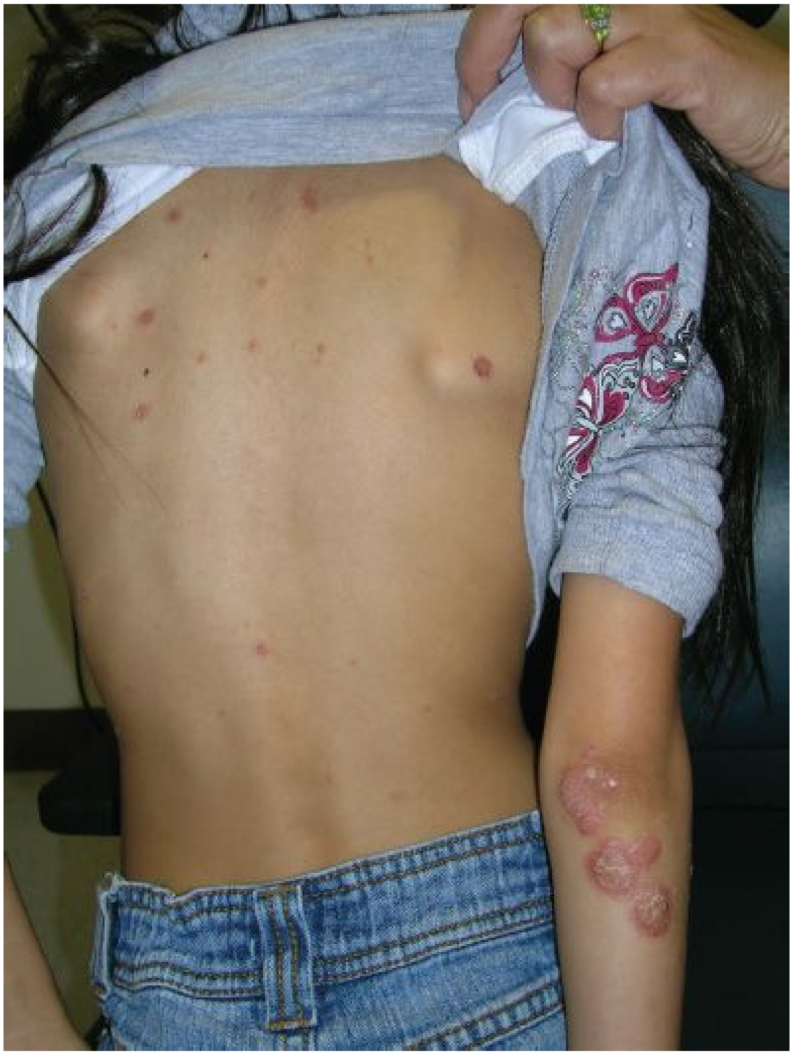

FIGURE 136-4 Guttate psoriasis in a 6-year-old girl seen 2 weeks after strep pharyngitis. Note the small drop-like plaques on her back along with larger plaques over her elbow. (*Used with permission from Richard P. Usatine, MD*.)

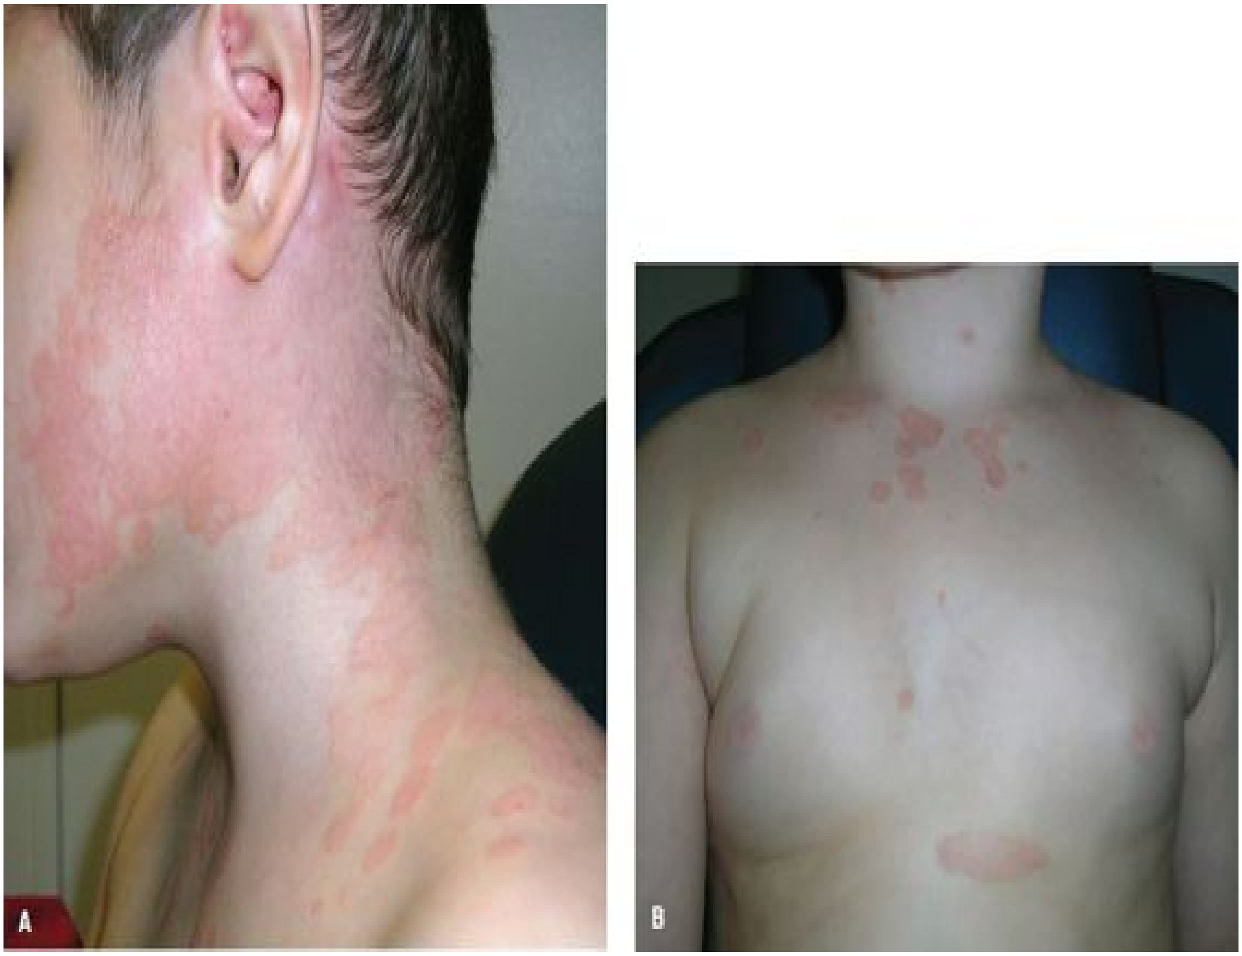

FIGURE 136-5 **A.** Guttate psoriasis that started 2 weeks after strep pharyngitis in this 7-year-old boy. The salmon patches of guttate psoriasis are prominent over the neck, ear, face and scalp. **B.** Other guttate plaques are visible on the chest. (*Used with permission from Richard P. Usatine, MD*.)

4. Inverse psoriasis (**Figure 136-6**).

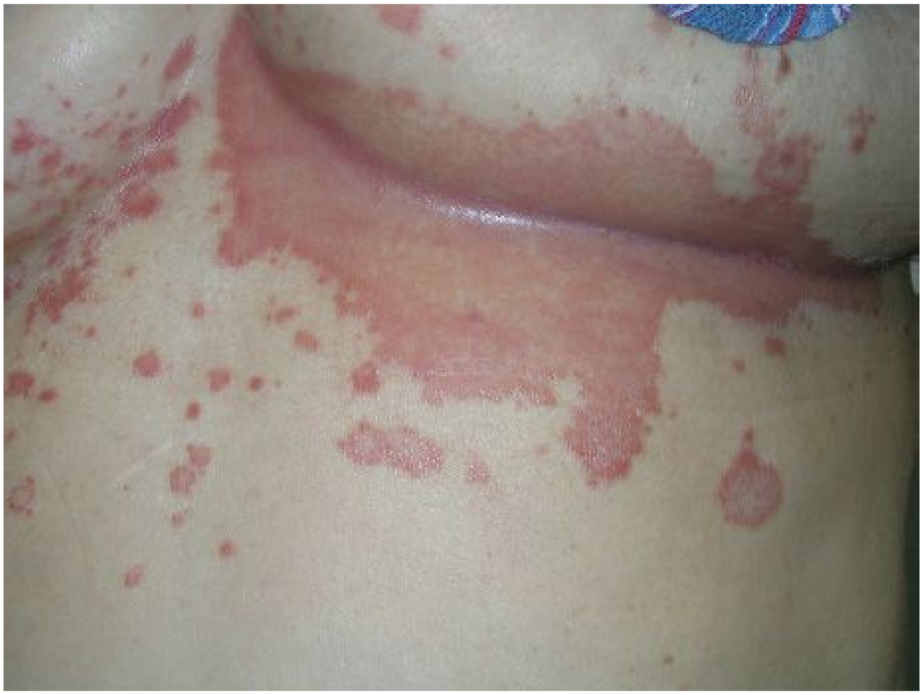

FIGURE 136-6 Inverse psoriasis in the inframammary folds of this obese teenage patient. This is not a *Candida* infection. (*Used with permission from Richard P. Usatine, MD.*)

5. Palmar-plantar psoriasis (**Figure 136-7**); also known as palmoplantar psoriasis.

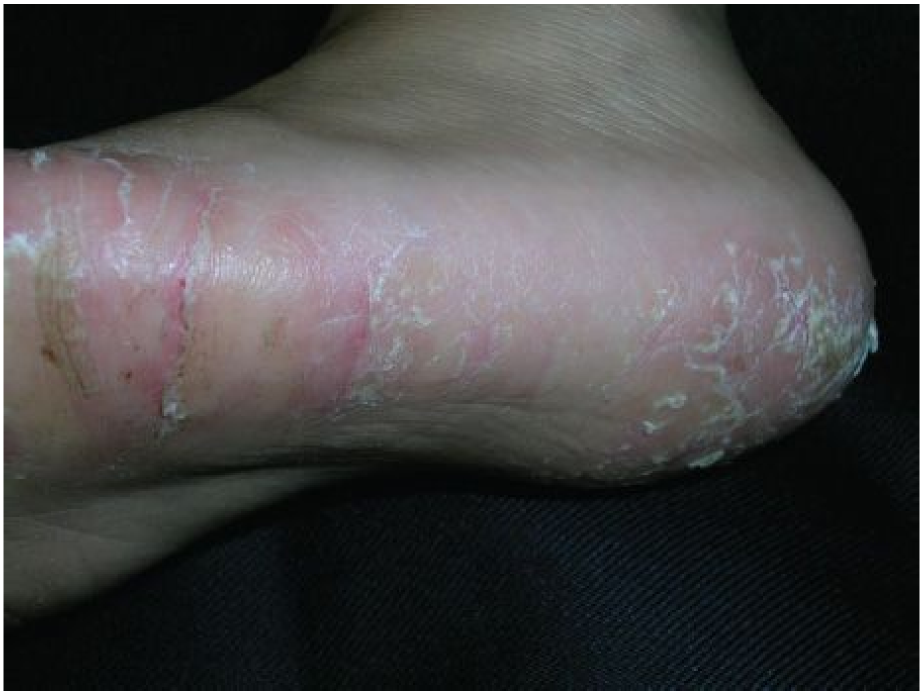

FIGURE 136-7 Plantar psoriasis in a 3-year-old girl who also has psoriasis on her hands and in her nails. Note that the widespread erythema and scale could be mistaken for tinea pedis. (*Used with permission from Richard P. Usatine, MD.*)

6. Erythrodermic psoriasis (**Figure 136-8**).

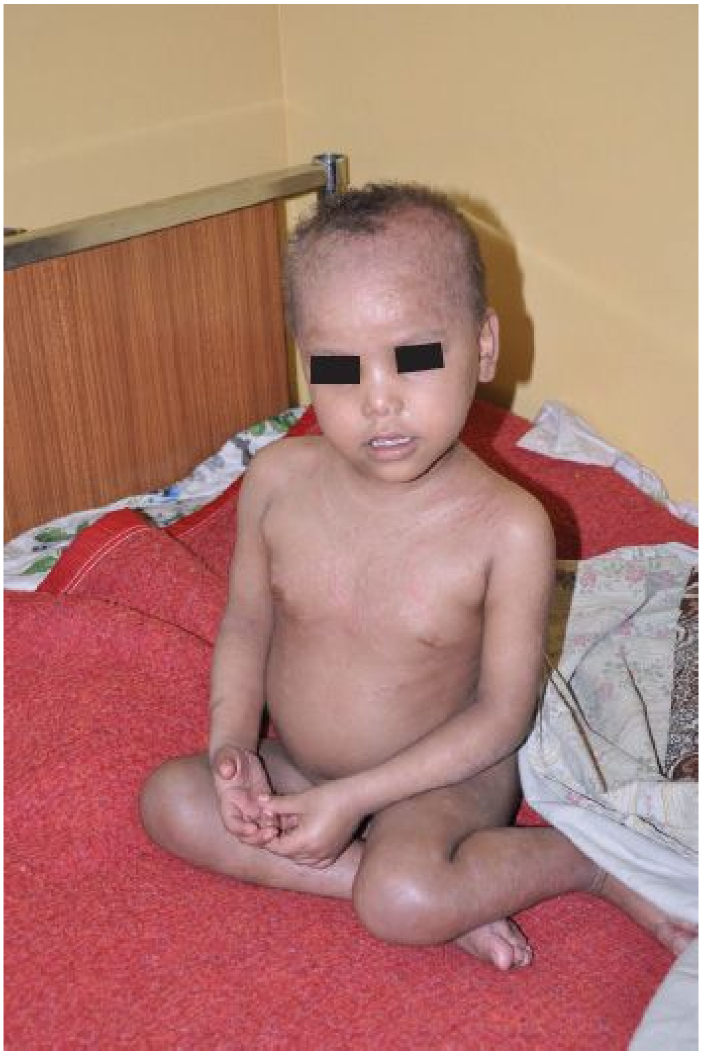

FIGURE 136-8 Erythrodermic psoriasis being treated in a young girl. This young girl was covered with erythematous psoriasis from head to toe prior to being started on systemic treatment in the hospital. (*Used with permission from Richard P. Usatine, MD*).

7. Pustular psoriasis—Localized and generalized (**Figure 136-9**).

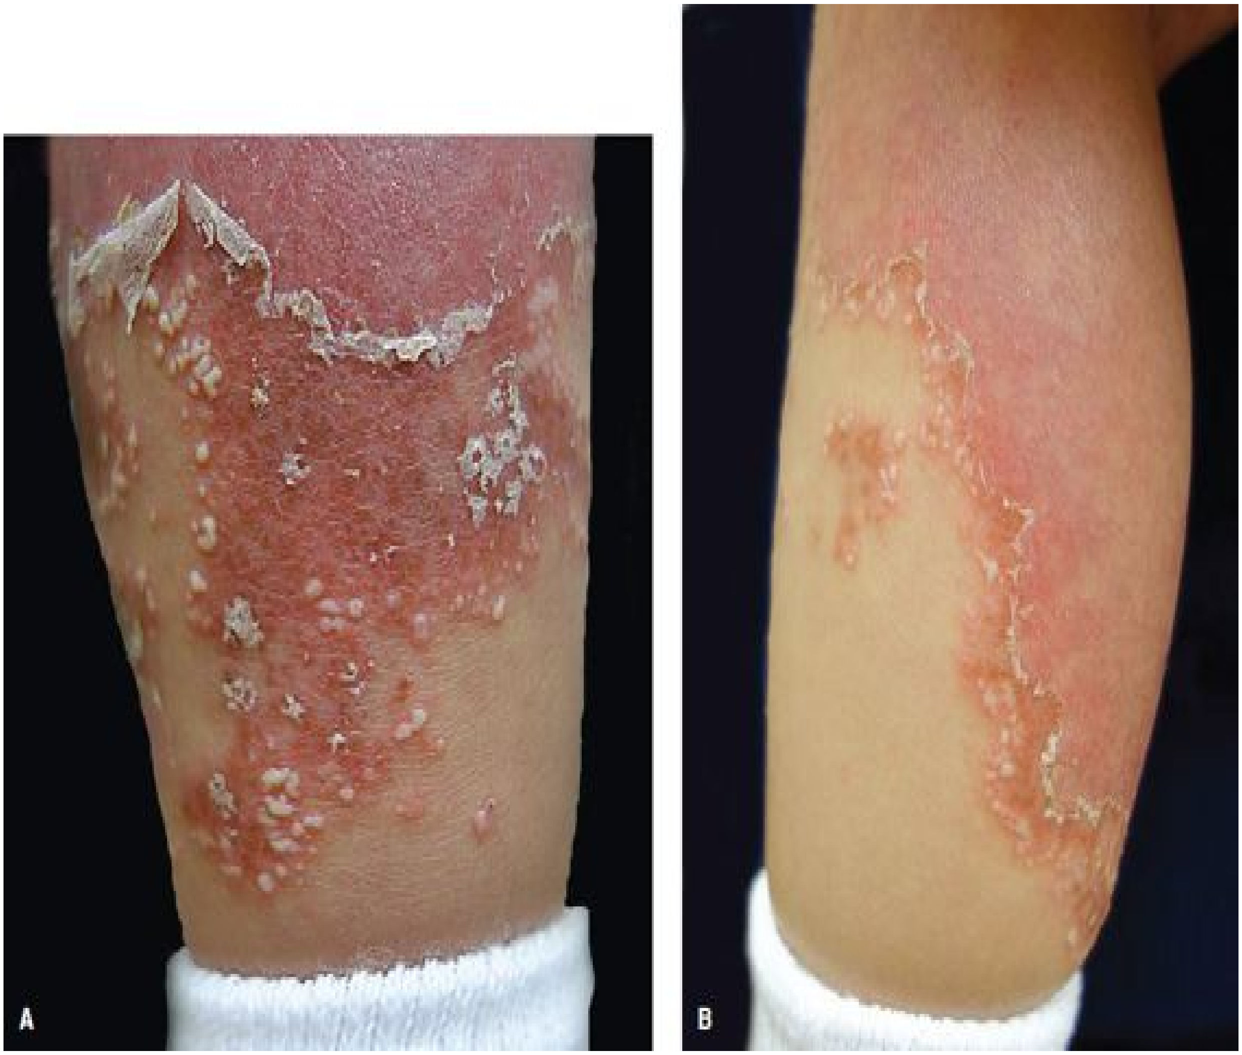

FIGURE 136-9 Pustular psoriasis in a 3-year-old boy. He presented with fever, erythroderma and no history of psoriasis. He was admitted for a presumed infection and then developed pustules. He was started on cyclosporine as an inpatient and then transitioned to acitretin as an outpatient. Note the clusters of pustules and the exfoliation of skin at the borders of the involved areas. **A.** Many pustules are visible on the lower leg. **B.** Pustules on the other leg are on the edge of an area of erythema. (*Used with permission from Emily Becker, MD.*)

8. Nail psoriasis (**Figure 136-10**; see Chapter 165, Psoriatic Nails).

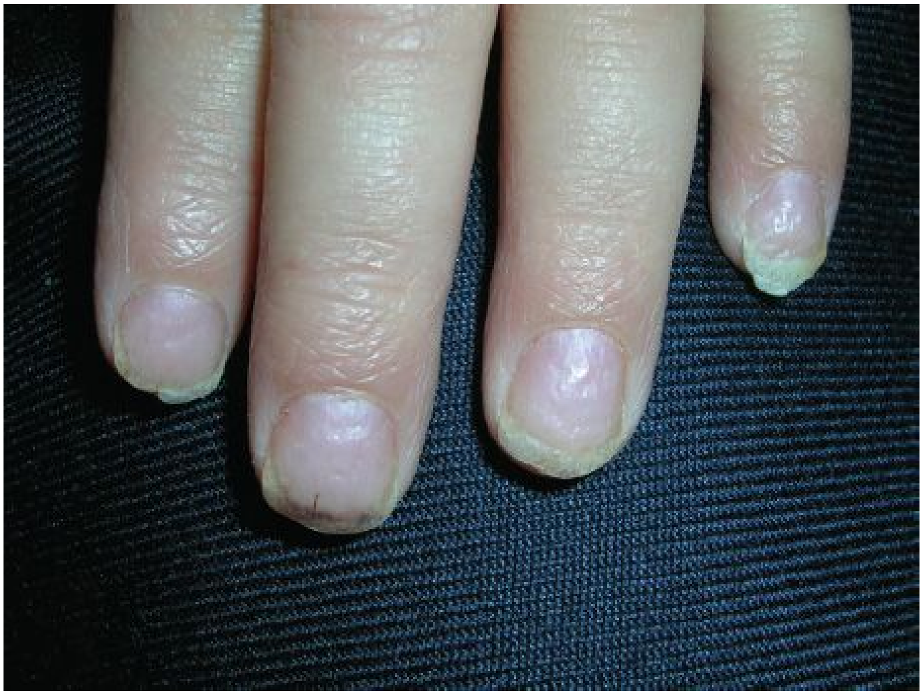

FIGURE 136-10 Nail pitting from psoriasis in a 3-year-old girl. This is the same girl with plantar psoriasis in **Figure 136-7**. (*Used with permission from Richard P. Usatine, MD.*)

9. Psoriatic arthritis (**Figure 136-11**).

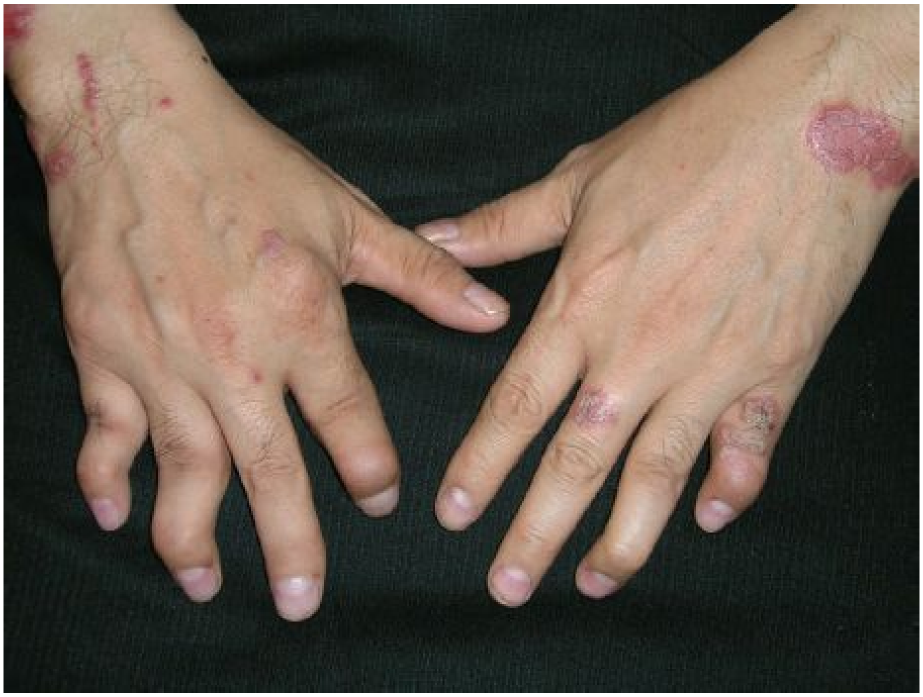

FIGURE 136-11 Psoriatic arthritis that has become crippling to this patient. Note the swan-neck deformities. Psoriatic arthritis should be diagnosed and treated before it gets to this stage. (*Used with permission from Richard P. Usatine, MD.*)

Typical distribution involves: elbows, knees, extremities, trunk, scalp, face, ears, hands, feet, genitalia, and intertriginous areas, and nails.

▶ Plaque psoriasis

- White scale on an erythematous raised base with well-demarcated borders (**Figures 136-2**).

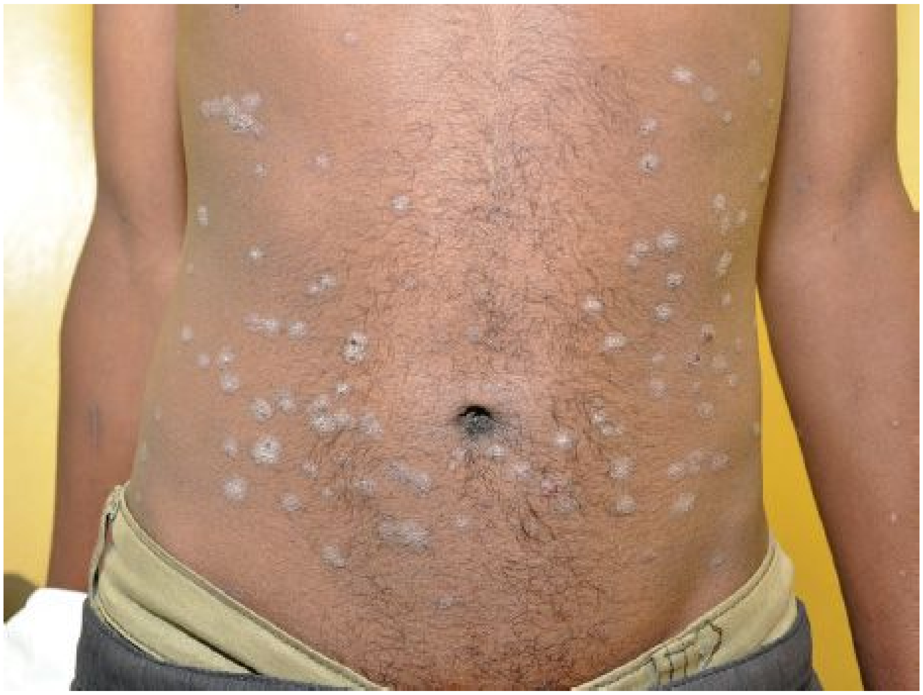

FIGURE 136-12 Guttate psoriasis in a 17-year-old young African teen following an episode of strep pharyngitis. Note how the small plaques are a silvery gray color rather than the erythema seen in lighter pigmented individuals. (*Used with permission from Richard P. Usatine, MD.*)

- Plaques can appear in different colors including silvery gray (**Figure 136-12**) and hypopigmented (**Figure 136-13**).

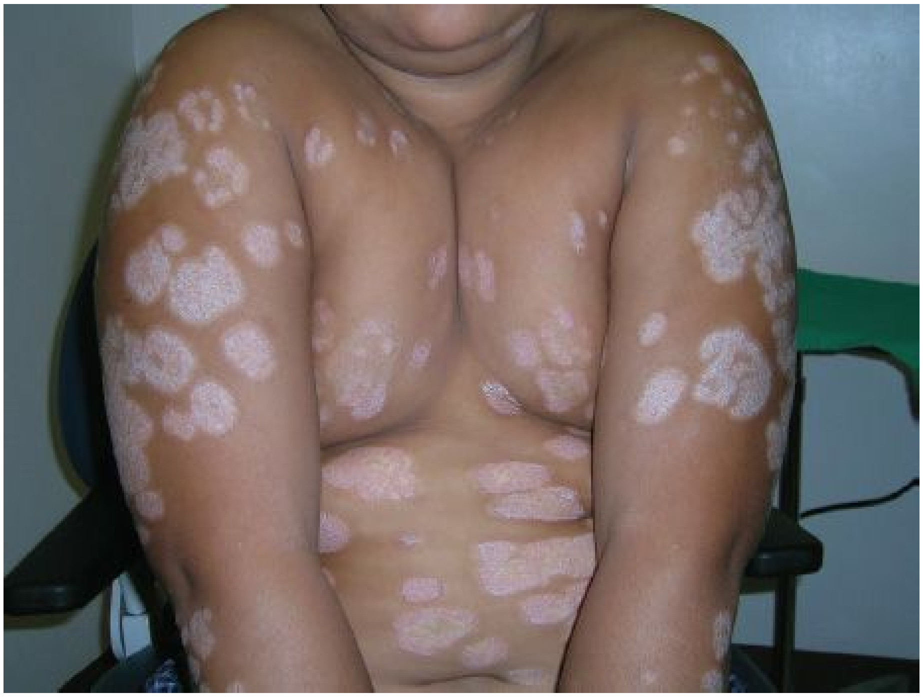

FIGURE 136-13 Plaque psoriasis with hypopigmentation in this 12-year-old obese boy. (*Used with permission from Richard P. Usatine, MD*.)

- Positive Auspitz sign in which the peeling of the scale produces pinpoint bleeding on the plaque below.
- Typical distribution includes the elbows and knees and other extensor surfaces. The plaques can be found from head to toe including the umbilicus, vulva, and penis. In children, plaques are more likely to be seen on the face than in adults (**Figure 136-14**).

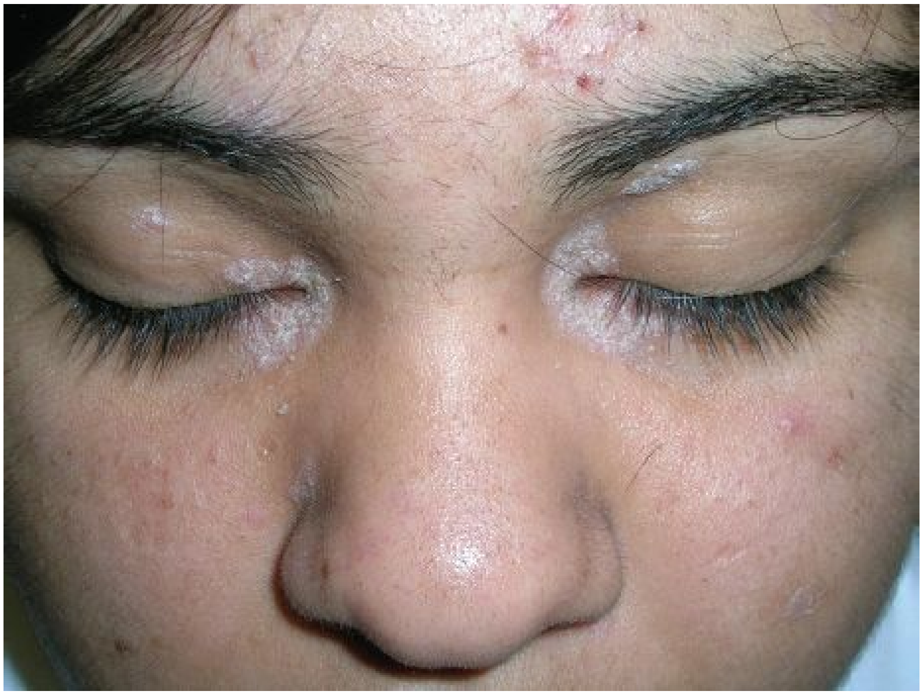

FIGURE 136-14 Plaque psoriasis on the face of a 15-year-old girl. She also has scalp psoriasis. (*Used with permission from Richard P. Usatine, MD*.)

- Plaques tend to be symmetrically distributed.
- Plaques can be annular with central clearing (**Figure 136-15**).

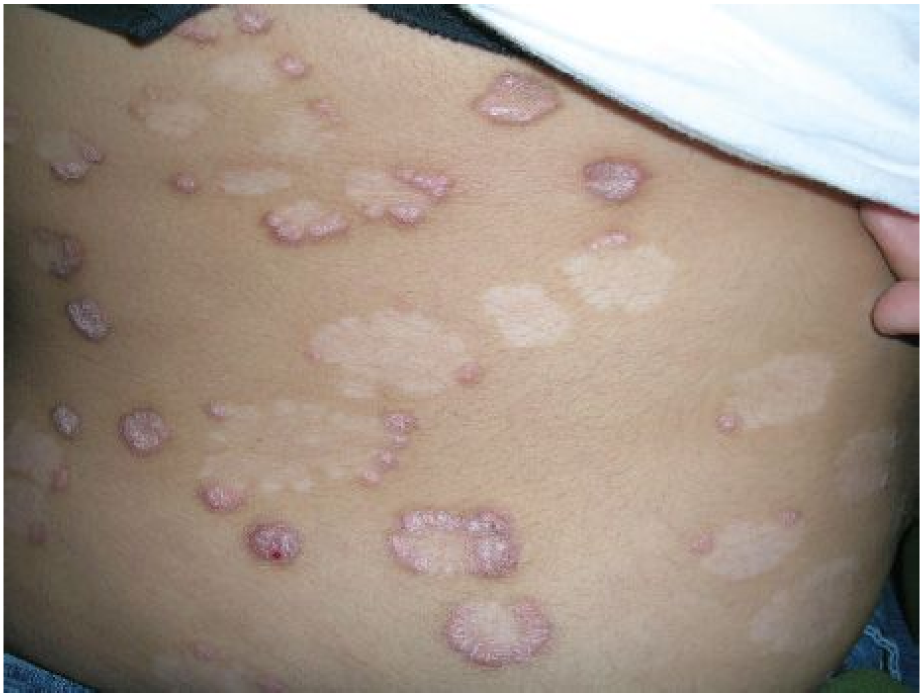

FIGURE 136-15 Plaque psoriasis with annular patterns on the trunk of a 15-year-old girl. Some of the healed plaques have left postinflammatory hypopigmentation. (*Used with permission from Richard P. Usatine, MD.*)

- When plaques occur at a site of injury, it is known as the Koebner phenomenon.

▶ Scalp psoriasis

- Plaque on the scalp that may be seen at the hairline and around the ears (**Figure 136-3**).
- The thickness and extent of the plaques are variable as seen in plaque psoriasis.

▶ Guttate psoriasis

- Small round plaques that resemble water drops (guttate means like a water drop; **Figure 136-16**).

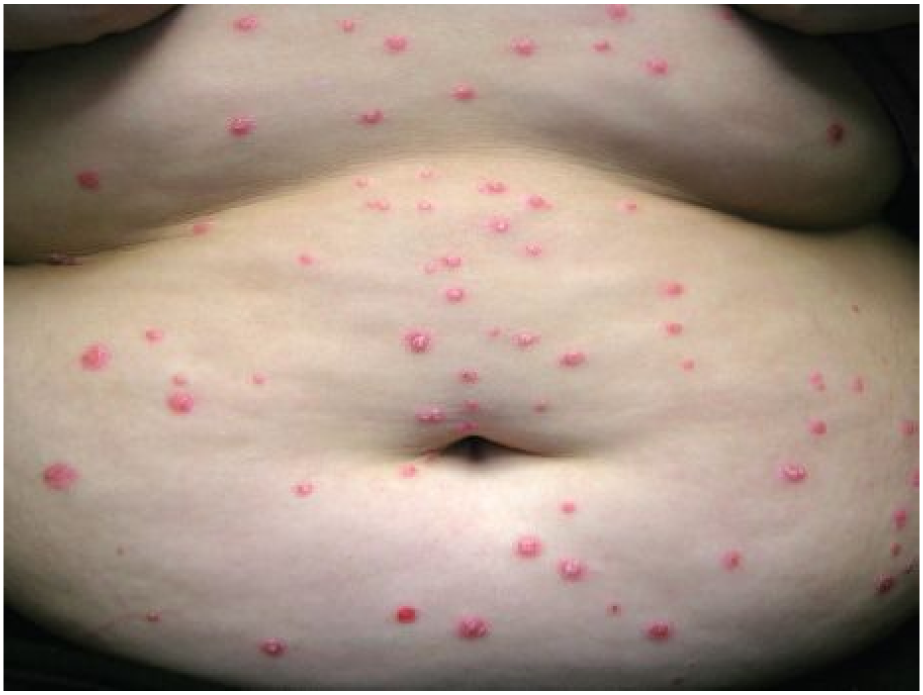

FIGURE 136-16 Guttate psoriasis in an obese 8-year-old girl. After many attempts to treat this with topical corticosteroids and ultraviolet light therapy

she finally cleared with etanercept. (*Used with permission from Richard P. Usatine, MD.*)

- Classically described as occurring after strep pharyngitis or another bacterial infection. This is one type of psoriasis that occurs in childhood.
- Typical distribution—The trunk and extremities but may include the face and neck (**Figures 136-1** and **136-5**).

► Inverse psoriasis

- Found in the intertriginous areas of the axilla, groin, inframammary folds, and intergluteal fold (**Figure 136-6**). It can also be seen within adipose folds in obese individuals.
- The term *inverse* refers to the fact that the distribution is not on extensor surfaces but in areas of body folds.
- Morphologically the lesions have little to no visible scale.
- Color is generally pink to red but can be hyperpigmented in dark-skinned individuals.

► Palmar-plantar (palmoplantar) psoriasis

- Psoriasis that occurs on the plantar aspects of the hands and feet (palms and soles) (**Figure 136-7**). The psoriasis can also be seen on other parts of the hands and feet.
- Patients with this type of psoriasis often experience severe foot and hand pain that can impair walking and other daily activities of living. Hand involvement can result in pain with many types of work.
- Morphologically this can be plaque-like, vesicular, or pustular. Brown spots may be present as macules or flat papules. These are called mahogany spots and although they are not always present, they are characteristic of palmar-plantar psoriasis. Exfoliation of the skin can occur on the palms and soles.

► Erythrodermic psoriasis

- Erythrodermic psoriasis is widespread and erythematosus covering most of the skin (**Figure 136-8**).
- Morphologically, it can have plaques and erythema or the erythroderma can appear with the desquamation of pustular psoriasis.
- Widespread distribution can impair the important functions of the skin and this can be a dermatologic urgency requiring hospitalization and IV fluids. Chills, fever, tachycardia, and orthostatic hypotension are all signs that the patient may need hospitalization.

► Pustular psoriasis

- Pustular psoriasis comes in localized and generalized types. **Figure 136-9** is an example of localized pustular psoriasis on the lower legs.
- In the generalized type (**Figure 136-17**), the skin initially becomes fiery red and tender, and the patient experiences constitutional signs and symptoms such as headache, fever, chills, arthralgia, malaise, anorexia, and nausea. The desquamation that occurs in the generalized form can impair the important functions of the skin predisposing to dehydration and sepsis. This is a dermatologic emergency requiring hospitalization and IV fluids, preferably in a monitored bed with good nursing care.

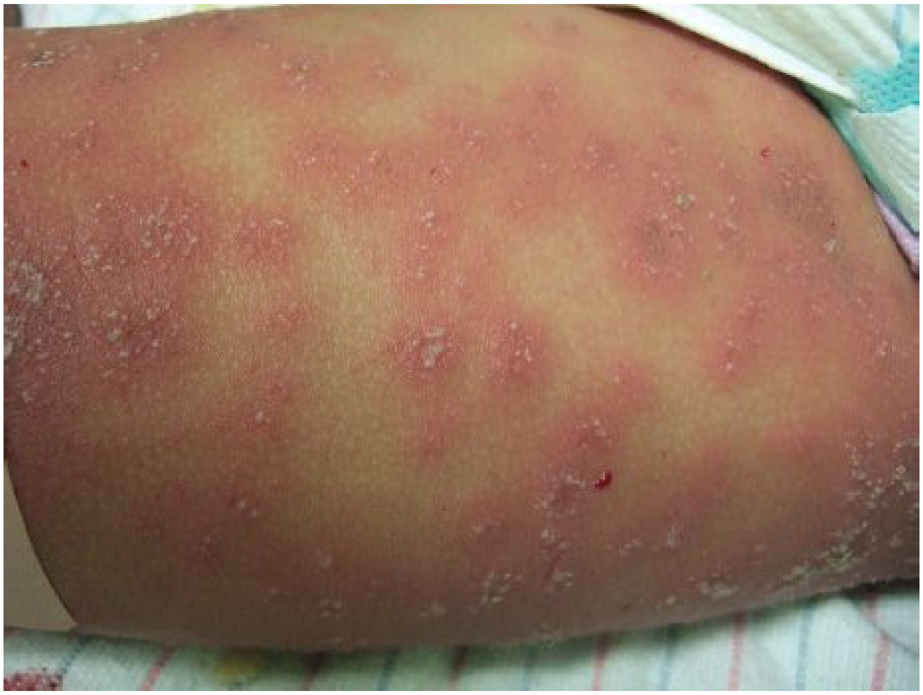

FIGURE 136-17 Generalized pustular psoriasis in a 2-year-old boy not known to have psoriasis before this presentation. The child had fever and was hospitalized for diagnosis and treatment. Note the large areas of erythema and the many pustules present. In some areas, the pustules are beginning to coalesce into lakes of pus and there is desquamation starting to occur. (*Used with permission from John C. Browning, MD*.)

- Typical distribution—Flexural and anogenital. Less often, facial lesions occur. Pustules may occur on the tongue and subungually, resulting in dysphagia and nail shedding, respectively.
- Time course—Within hours, clusters of nonfollicular, superficial 2- to 3-mm pustules may appear in a generalized pattern. These pustules coalesce within 1 day to form lakes of pus that dry and desquamate in sheets, leaving behind a smooth erythematous surface on which new crops of pustules may appear. These episodes of pustulation may occur for days to weeks causing the patient severe discomfort and exhaustion. Upon remission of the pustular component, most systemic symptoms disappear; however, the patient may be in an erythrodermic state or may have residual lesions.[1]

▸ Nail psoriasis

- Nail involvement in psoriasis can lead to pitting, onycholysis, subungual keratosis, splinter hemorrhages, oil spots, and nail loss (**Figure 136-10**; see Chapter 165, Psoriatic Nails).

▸ Psoriatic arthritis

- Asymmetric oligoarthritis typically involving the hands, feet, and knees. The arthritis can also be symmetric and in children is a form of juvenile idiopathic arthritis (see Chapter 172, Juvenile Idiopathic Arthritis). Distal interphalangeal joint (DIP) involvement is a classic finding, but DIP predominance is present in the minority of cases. The fingers may be swollen like sausages, which is called dactylitis.
- Hand involvement can become disabling (**Figure 136-11**). X-rays should be ordered when a patient with psoriasis has joint pains suggesting psoriatic arthritis. At first, the x-rays will be negative other than soft-tissue swelling. Over time, untreated psoriatic arthritis will demonstrate juxtaarticular erosions and pencil-cup deformities seen with the interphalangeal joints.
- There may be inflammation at the insertion of tendons onto bone (enthesopathy). This may occur at the Achilles tendon.
- Patients with psoriatic arthritis need to be treated with systemic agents (methotrexate or biologics) to prevent advancement of the disease.

DISEASE SEVERITY

- Moderate-to-severe disease is defined by psoriasis of the palms, soles, head and neck, or genitalia, and in patients with more than 5 percent body surface area (BSA) involvement. A person’s palm is approximately 1 percent BSA and can be used to estimate BSA.
- Another grading system for severity uses the following numbers:
  - Mild—Up to 3 percent BSA.
  - Moderate—3 to 10 percent BSA.

- Severe—>10 percent BSA (**Figure 136-18**).

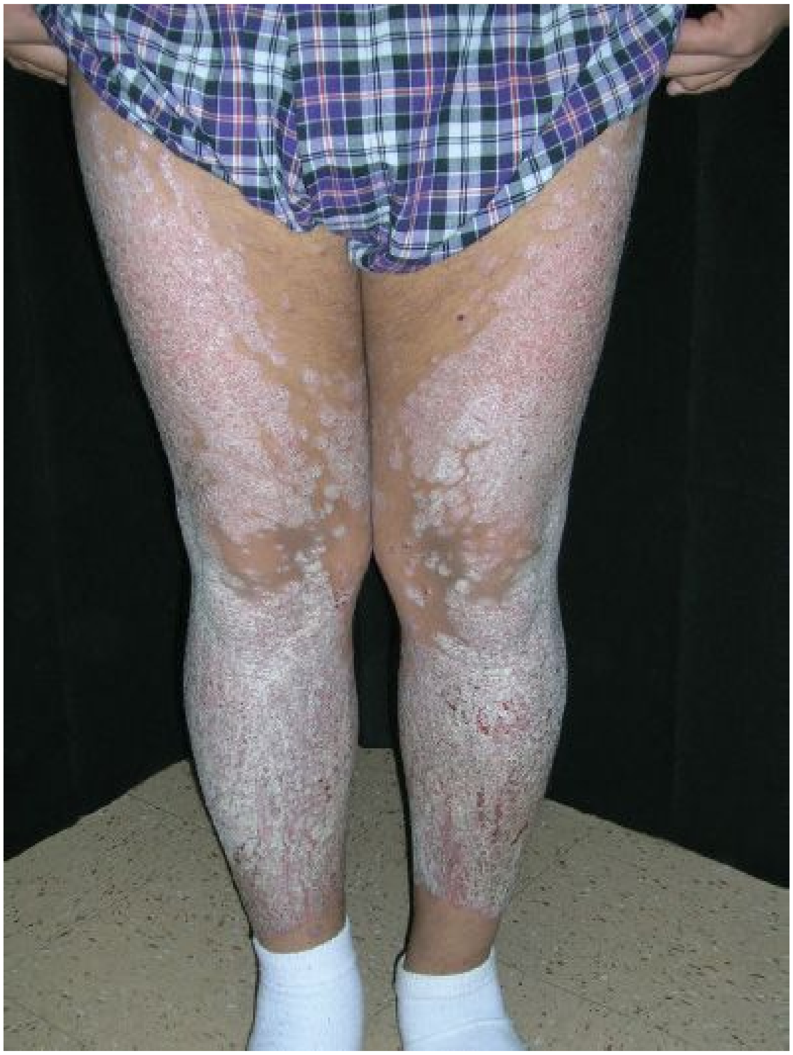

FIGURE 136-18 Widespread plaque psoriasis in the initial presentation of psoriasis in a teenage male. He also had severe pain in his feet and ankles from psoriatic arthritis. His disease was ultimately controlled with a biologic agent. (*Used with permission from Richard P. Usatine, MD.*)

- Patients with psoriatic arthritis may have limited skin disease but require more aggressive systemic therapies.
- Note that palmoplantar psoriasis is considered moderate-to-severe even if the BSA involved is not above 3 or 5 percent because of its disabling effect on the patient.

LABORATORY STUDIES

Laboratory studies are rarely needed. A punch biopsy or deep shave is used for evaluating atypical cases. For pustular psoriasis, a 4-mm punch around an intact pustule is preferred.

IMAGING

Plain films should be ordered when a person with psoriasis has joint pains suggesting psoriatic arthritis. Early psoriatic arthritis often has no bone findings on plain films, but if history and physical exam suggest the diagnosis, one should not wait for irreversible visible joint damage to initiate therapy.

DIFFERENTIAL DIAGNOSIS

- Tinea corporis or cruris can resemble inverse psoriasis in the intertriginous areas as both conditions tend to have erythema and thinner plaques without central clearing in these regions. Tinea corporis in nonintertriginous areas typically presents with annular plaques with central clearing. Tinea corporis usually does not have as many plaques as psoriasis but a KOH preparation can be used to look for fungal elements to distinguish between these two conditions (see Chapter 123, Tinea Corporis).
- Lichen planus is a papulosquamous disease similar to psoriasis. Its distribution is more on flexor surfaces and around the wrists and ankles than the elbows and knees (see Chapter 138, Lichen Planus). It is very uncommon in children.
- Lichen simplex chronicus is a hyperkeratotic plaque with lichenification. It usually presents with fewer plaques than psoriasis and is typically found on the posterior neck, ankle, wrist, or lower leg. There is usually more lichenification than thick scale and it is always pruritic (**Figure 136-19**).

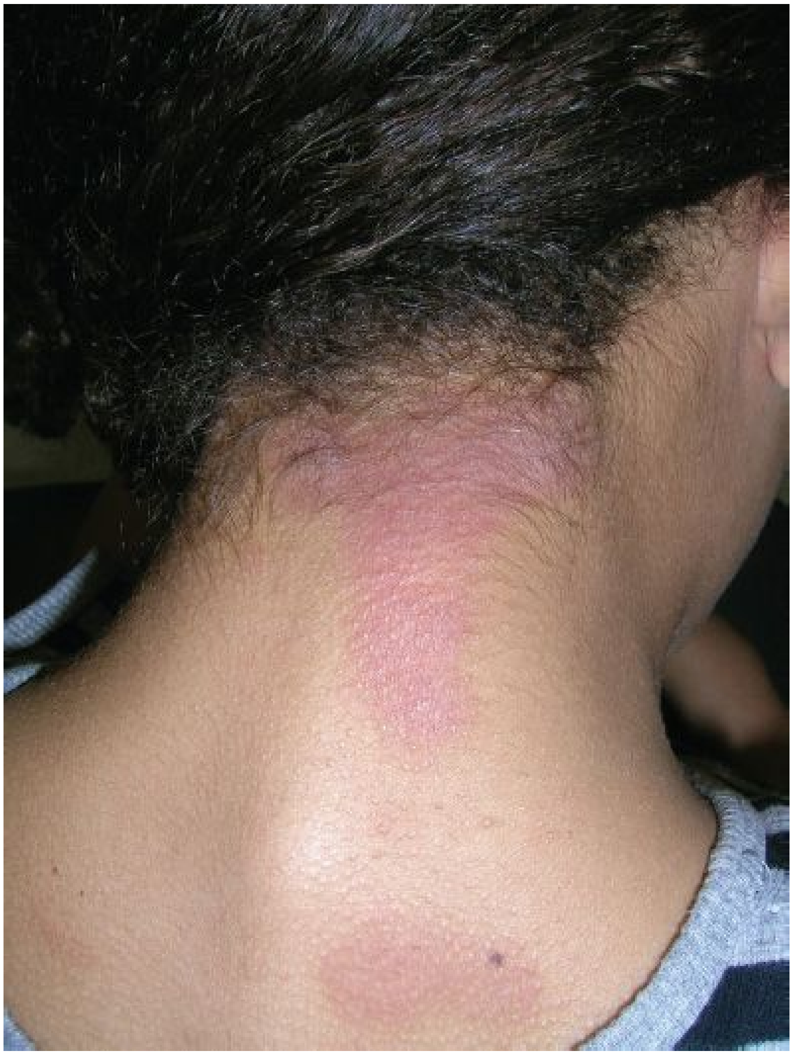

FIGURE 136-19 Lichen simplex chronicus on the neck of a 13-year-old Hispanic female. (*Used with permission from Richard P. Usatine, MD.*)

- Nummular eczema presents with coin-like plaques. These are most commonly found on the legs and are usually not as thick as the plaques of psoriasis. Nummular eczema may also have vesicles and bullae. Psoriasis has a different distribution and often includes nail changes (see Chapter 133, Nummular Eczema).
- Pityriasis rosea is a self-limited process that has papulosquamous plaques. These plaques are less keratotic and have a collarette scale. Pityriasis rosea frequently has a herald patch (see Chapter 137, Pityriasis Rosea).
- Seborrheic dermatitis of the scalp can closely resemble psoriasis of the scalp, especially when it is severe. Psoriasis generally has thicker plaques

on the scalp and the plaques often cross the hairline. Seborrhea and psoriasis can both involve the ear. Both conditions respond to topical steroids (see Chapter 135, Seborrheic Dermatitis).

- Syphilis is the great imitator and secondary syphilis can have a papulosquamous eruption similar to psoriasis. Secondary syphilis often involves the palms and soles and the rapid plasma reagin (RPR) will be positive (see Chapter 181, Syphilis).
- Cutaneous candidiasis appears similar to inverse psoriasis when found in intertriginous areas (see Chapter 121, Candidiasis). A KOH prep should be positive and satellite lesions may be visible.

MANAGEMENT

Treat precipitating and underlying factors when these are known. Encourage smoking cessation to all who smoke. Avoid alcohol use. Stress management techniques can be suggested in children and teens who admit that stress is an important factor in worsening their condition. Use preventive techniques as much as possible by avoiding known precipitants.

Patient perception of their disease and expectations for therapy are as important as the evidence and recommendations that follow. Some patients and their parents are willing to live with some skin changes rather than go on systemic treatment, whereas others want everything done with a goal of 100 percent clearance. Consequently, therapeutic choices are made in conjunction with patient and the parent’s values and their life situation (economics and time issues surrounding treatment options).

▶ Choice of topical vehicles

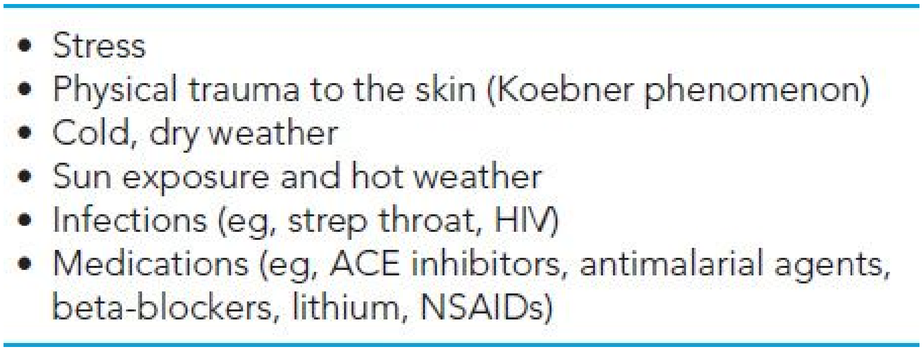
- An ointment has a petrolatum base and will penetrate thick scale best.
- An emollient cream has some of the advantages of an ointment but is cosmetically more appealing to patients who find a basic ointment to be too greasy.

- Some patients prefer cream to avoid the oily feel of ointment even though it is less effective in general than an ointment. However, in most cases the most effective vehicle is the one the patient will use as directed.
- Lotions and foams are good for hair-bearing areas when some moisturizing is desired.
- Steroid solutions work well for psoriasis of the scalp.
- New foam preparations have rapid absorption and are cosmetically appealing. These tend to be more expensive and are less likely to be covered by insurance.

Topical treatments

- **Table** 136-2 summarizes the strength of recommendations for the treatment of psoriasis using topical therapies. Most studies have been performed in adults, so evidence is extrapolated to children when adult data is all that is available.

TABLE 136-2 Strength of Recommendations for the Treatment of Psoriasis Using Topical Therapie



- Stress
- Physical trauma to the skin (Koebner phenomenon)
- Cold, dry weather
- Sun exposure and hot weather
- Infections (eg, strep throat, HIV)
- Medications (eg, ACE inhibitors, antimalarial agents, beta-blockers, lithium, NSAIDs)

- Research supports potent topical steroids as first-line therapy.[10] SOR Ⓐ Clobetasol is an ultrahigh-potency steroid that is generic and comes in many vehicles for use on the body and scalp. Clobetasol has FDA approval for children greater than 12 years of age. A meta-analysis of the studies with clobetasol demonstrated 68 to 89 percent of patients had clear improvement or complete healing.[11] SOR Ⓐ

- In one study, clobetasol foam was found to be safe and effective for treatment of mild-to-moderate plaque-type psoriasis in patients aged 12 years or older.[12] SOR Ⓑ Reversible hypothalamic-pituitary-adrenal axis suppression secondary to topical clobetasol was observed in 47 percent of participants aged 6 to 12 years.[12]
- Topical 0.1 percent triamcinolone is a moderate strength corticosteroid and can be used on children of any age.
- There are two vitamin D analogs available for topical use: calcipotriene (Dovonex and generic) and calcitriol (Vectical). These vitamin D preparations are recommended as first-line therapy with or without topical corticosteroids for the treatment of childhood psoriasis.[13] SOR Ⓐ
- Comparable efficacy has been shown for topical calcipotriene (vitamin D analog) and tazarotene (retinoid) with a slight increase in adverse effects for tazarotene.[10] SOR Ⓐ
- Using topical steroids and calcipotriene or tazarotene is an effective regimen. It has increased efficacy and fewer side effects.[10–11] SOR Ⓐ However, in monotherapy studies of topical agents in psoriasis, steroids caused fewer adverse reactions compared to vitamin D analogs and tazarotene.[14] SOR Ⓐ
- Clobetasol in the morning and tazarotene in the evening is a good combination to reduce irritation and increase efficacy.[10] SOR Ⓐ
- Two trials randomized potent steroid treatment responders to either an intermittent maintenance regime (three applications each weekend) or to no maintenance. The results of more than 6 months indicate that patients receiving maintenance therapy were more than three times as likely to stay in remission.[15] SOR Ⓑ
- Older treatments still in use include topical coal tar.[11] Evidence does not support the use of coal tar alone or in combination at this time.[11] SOR Ⓐ
- Topical calcineurin inhibitors previously approved for eczema are being studied for use in psoriasis. Tacrolimus ointment seems most effective in treating psoriasis of the face and intertriginous areas where the skin is thin. Clinical trials suggest that tacrolimus (0.1%) ointment twice a day

produces a good response in a majority of patients with facial and intertriginous (inverse) psoriasis (**Figures 136-6** to **136-14**). SOR Ⓑ

- Emollients and keratolytics are safe and probably beneficial as adjunctive treatment. SOR Ⓒ
- Intralesional steroids may help small plaques resolve in older children if they will allow these injections. Use triamcinolone acetonide 5 to 10 mg/mL injected with a 27-gauge needle into the plaque. SOR Ⓒ

Phototherapy

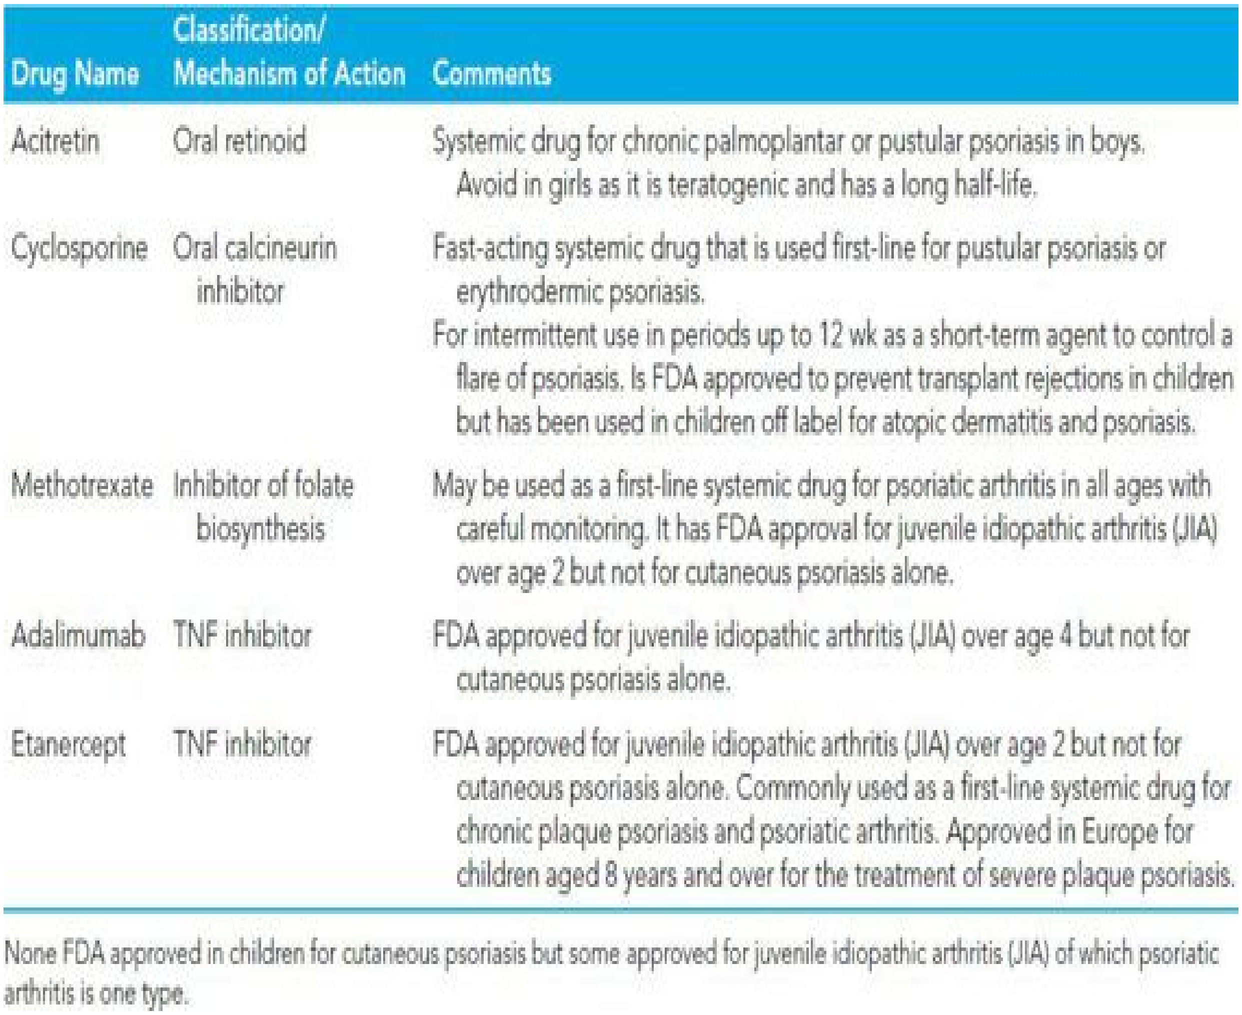
- Is indicated in the presence of extensive and widespread disease (practically defined as more lesions than can be easily counted) and psoriasis not responding to topical therapy.
- Phototherapy is only safe in children old enough and mature enough to sit in a small light box alone with protective eyewear for a number of minutes. They have to understand that the eyewear must be worn the whole time to protect their vision from the damage of the intense ultraviolet light.
- Narrowband UVB is more effective than broadband UVB and approaches psoralen and UVA (PUVA) in efficacy for the treatment of psoriasis in patients with skin types I to III (lighter skin).[19] SOR Ⓐ
- At present, there are no predictors of the type(s) of psoriasis most responsive to narrowband UVB.[19]
- Of adult patients with psoriasis, 63 to 80 percent will clear with a course of narrowband UVB with equivalent relapse rates compared with PUVA.[19]
- Methotrexate pretreatment (15 mg per week × 3) allowed physicians to clear psoriasis in fewer phototherapy sessions than when phototherapy was administered alone in one study.[20] SOR Ⓑ
- According to one consensus conference, acitretin combined with UV therapy is safe and effective and limits treatment frequency, duration, and cumulative doses of both agents. They state this combination is better tolerated, more convenient, less costly, and, perhaps, safer during long-term treatment than phototherapy alone.[21] SOR Ⓒ

- Avoid use of cyclosporine with UV therapy because of an increased risk of skin cancer.[22]

Systemic

- When topical agents (and/or phototherapy fail), systemic agents (including biologic agents) are the next step. **Table** 136-3 summarizes the systemic drugs used in treatment of psoriasis.[23]

TABLE 136-3 Systemic Drugs Used in Treatment of Psoriasis.[29]



Drug Name	Classification/ Mechanism of Action	Comments
Acitretin	Oral retinoid	Systemic drug for chronic palmoplantar or pustular psoriasis in boys. Avoid in girls as it is teratogenic and has a long half-life.
Cyclosporine	Oral calcineurin inhibitor	Fast-acting systemic drug that is used first-line for pustular psoriasis or erythrodermic psoriasis. For intermittent use in periods up to 12 wk as a short-term agent to control a flare of psoriasis. Is FDA approved to prevent transplant rejections in children but has been used in children off label for atopic dermatitis and psoriasis.
Methotrexate	Inhibitor of folate biosynthesis	May be used as a first-line systemic drug for psoriatic arthritis in all ages with careful monitoring. It has FDA approval for juvenile idiopathic arthritis (JIA) over age 2 but not for cutaneous psoriasis alone.
Adalimumab	TNF inhibitor	FDA approved for juvenile idiopathic arthritis (JIA) over age 4 but not for cutaneous psoriasis alone.
Etanercept	TNF inhibitor	FDA approved for juvenile idiopathic arthritis (JIA) over age 2 but not for cutaneous psoriasis alone. Commonly used as a first-line systemic drug for chronic plaque psoriasis and psoriatic arthritis. Approved in Europe for children aged 8 years and over for the treatment of severe plaque psoriasis.

None FDA approved in children for cutaneous psoriasis but some approved for juvenile idiopathic arthritis (JIA) of which psoriatic arthritis is one type.

- Methotrexate and biologic agents are especially valuable in patients with psoriatic arthritis and may be started early in the course of treatment to prevent permanent joint damage.

- Do not use systemic corticosteroid therapy for psoriasis. Pustular flares of disease may be provoked and these flares can be fatal.
- Methotrexate and oral retinoids can cause birth defects so appropriate counseling, contraception, and testing should accompany therapy with these agents.
- In one systematic literature review of the efficacy and safety of treatments for childhood psoriasis, methotrexate was considered to be the systemic treatment of choice.[24] In a consensus statement of pediatric rheumatologists in Germany, the primary treatment of choice for psoriasis and psoriatic arthritis in childhood was methotrexate followed by etanercept.[5] SOR Ⓒ
- Methotrexate (MTX) is given as a weekly dose titrated to response and side effects.[25] SOR Ⓐ Tuberculosis screening with purified protein derivative (PPD) or QuantiFERON-TB Gold blood test should precede treatment (if positive results, then the tuberculosis [TB] needs treatment before starting this therapy). Pretreatment laboratories should include a complete blood count (CBC), differential, liver function tests (LFTs), a chemistry profile, and hepatitides B and C serologies. A CBC and LFTs should be followed regularly. Patients should take folic acid daily to prevent some of the possible adverse effects of MTX. For MTX, reliable contraceptive methods should be used during and for at least 3 months after therapy in both males and females.[24]
- The major risk of MTX is liver damage. Type 2 diabetes and obesity appear to be significant risk factors for hepatic fibrosis.[23] The question of whether or when to do a liver biopsy and/or stop MTX is controversial. The National Psoriasis Foundation has published that liver “biopsies are now advocated after a cumulative dose of 3.5 g in low-risk patients and 1.5 g in high-risk patients.” The same recommendations are cited in the 2009 National Psoriasis Foundation Consensus Conference on MTX and psoriasis.[26] SOR Ⓒ
- Cyclosporine (oral) is a T-cell inhibitor and is very effective in rapidly treating psoriasis. The recommended starting dose is 2.5 to 6 mg/kg per day (actual body weight) divided twice a day.[22] SOR Ⓒ Serum creatinine and blood pressure should be monitored monthly. Also CBC, uric acid,

potassium, lipids, LFTs, and magnesium should be monitored monthly. Cyclosporine can be used for long-term therapy in patients with severe psoriasis for up to 2 years life-time maximum based on European guidelines and 1 year maximum based upon the US guidelines.[11,22] SOR Ⓒ Cyclosporine is pregnancy category C, with several studies indicating an increased risk of premature birth but no major malformations.[22]

- Oral retinoids—Acitretin is a potent systemic retinoid used for psoriasis.[27] SOR Ⓐ Acitretin appears to provide better efficacy in pustular psoriasis (including palmoplantar psoriasis) than in plaque-type psoriasis as a single agent treatment.[28] SOR Ⓐ Acitretin is known to cause fetal malformations just like isotretinoin so it is best to avoid use in women capable of pregnancy, especially as it may remain in the body for up to 3 years after stopping therapy.

▸ Biologic agents

There are 4 biologic agents available and FDA approved for treating psoriasis in adults. See **Table 136-3** for the 2 biologic agents that have been FDA approved for treating children with JIA of which psoriatic arthritis is one type. In Europe, etanercept was approved for children aged 8 years and over for the treatment of severe plaque psoriasis.[29]

- Before starting therapy, obtain a PPD or QuantiFERON-TB *Gold* blood test. These agents can reactivate dormant TB. Screening for TB should continue yearly during biologic therapy.[30]
- The TNF inhibitors (adalimumab, etanercept) share a common mechanism of action that leads to safety concerns. Safety concerns include serious infections (e.g., sepsis, tuberculosis, and viral infections), autoimmune conditions (lupus and demyelinating disorders), and lymphoma.[31]
- Etanercept was studied in 211 children (4 to 17 years of age) in a 48-week study and found to significantly reduce disease severity in children and adolescents with moderate-to-severe plaque psoriasis.[32] The children were given once-weekly subcutaneous injections of placebo or 0.8 mg of etanercept per kilogram of body weight (to a maximum of 50 mg). A subgroup analysis of the original study concluded that etanercept provided

significant, sustained improvement in disease severity and was well tolerated in children > or = 8 years with severe plaque psoriasis.[33]

- While the biologic agents are all very expensive, insurance may cover them and there are patient assistance programs for uninsured patients with limited resources.

Methotrexate versus biologic agents[25]

- MTX is a very inexpensive medication with more than a 40-year track record, but with known potential for hepatotoxicity. It is very effective, but requires monitoring of the LFTs and the blood count on a regular basis.
- The biologic agents are engineered proteins with a potentially safer profile than MTX. However, they are very expensive and require parenteral administration. Biologics have the advantage of requiring less monitoring with blood tests. The biologic agents are not side-effect free and some of the potential side effects, while rare, are quite dangerous, and include the risks of sepsis, malignancy, and demyelinating disease.

THERAPY BY TYPE OF PSORIASIS

Plaque type

Mild-to-moderate plaque psoriasis: Start with triamcinolone ointment twice daily for 2 to 4 weeks. Consider topical clobetasol, a stronger topical steroid, if needed. Then decrease use of topical steroid when possible and consider adding a steroid-sparing topical agent such as a vitamin D topical product.

Severe plaque form psoriasis: One systematic review found 665 studies dealing with the treatment of severe plaque psoriasis.[20] Photochemotherapy showed the highest average proportion of patients with clearance (70% [6947/9925]) and good response (83% [8238/9925]), followed by UVB (67.9% [620/913]) and cyclosporine (64% [1030/1609]) therapy.[34] SOR Ⓐ Expert consensus in a meeting following data analysis supported the following sequence for the treatments: UVB, photochemotherapy, MTX, acitretin, and cyclosporine.[34] SOR Ⓒ

The Consensus guidelines for the management of plaque psoriasis published in 2012 is based on US National Psoriasis Foundation review and update of the Canadian Guidelines for the Management of Plaque Psoriasis.[29] **Table 136-3** summarizes the systemic treatments for plaque type psoriasis.

Scalp

One head-to-head trial (no pun intended) in scalp psoriasis demonstrated no therapeutic difference between a topical vitamin D derivative and a topical potent steroid.[15] Generic fluocinonide solution daily to the scalp is effective. Derma-smooth is another affordable scalp product that combines a high-potency steroid with a peanut oil. Calcipotriene daily to scalp also helps but is more expensive. Mineral oil may be used to moisturize and remove scale. Shampoos with tar and/or salicylic acid (T-Gel and T-Sal) can help to dissolve and wash away some of the scale. Of course, systemic therapies for more severe psoriasis will help clear scalp psoriasis.

Guttate psoriasis

Phototherapy works particularly well for guttate psoriasis in patients old enough to be able to use phototherapy safely.[9] SOR C Narrow-band UVB therapy may produce clearing in less than one month. Topical therapies are a reasonable option when phototherapy is not available.[9] SOR C Although both antibiotics and tonsillectomy have frequently been advocated for patients with guttate psoriasis, there is no good evidence that either intervention is beneficial.[35]

Inverse psoriasis

Mid- to high-potency topical steroids can be used for inverse psoriasis even though the disease occurs in skinfolds (**Figure 136-6**). A number of studies have shown that tacrolimus works well to treat inverse psoriasis when applied twice daily.[16–18] SOR B Some patients did report a warm sensation or pruritus upon application so patients should be warned of this and told not to stop using the tacrolimus as this may improve over time.[13–15]

▶ Palmar-plantar psoriasis

For mild disease, start with topical treatments as in plaque psoriasis. For moderate to severe cases, systemic therapy such as oral acitretin, MTX, or one of the biologics may be needed.

▶ Erythrodermic/generalized psoriasis

Treatment considerations include hospitalization for dehydration and close monitoring, cyclosporine, MTX, oral retinoids, or phototherapy.[9] SOR Ⓒ Cyclosporine is very effective in rapidly treating the most severe erythrodermic psoriasis.

▶ Pustular psoriasis

Options include oral retinoids such as isotretinoin or acitretin (depends on sex and age of the patient), MTX, cyclosporine, phototherapy, and hospitalization as needed.[9] SOR Ⓒ Cyclosporine is very effective in rapidly treating pustular psoriasis.[22]

REFERRAL

Children with psoriasis that is more than mild and/or requiring more than topical therapy should be referred to a dermatologist. Children with psoriatic arthritis should be referred to a pediatric rheumatologist and/or a pediatric dermatologist.

PROGNOSIS

In one study, the first signs of psoriasis occurred before the age of 18 in 37 percent of patients. The type of childhood onset psoriasis often remained the same from childhood to adulthood. They found no evidence that getting psoriasis before the age of 18 years influences disease severity in later life.

The authors concluded that the age of onset of psoriasis essentially does not influence the subsequent course of the disease.[36]

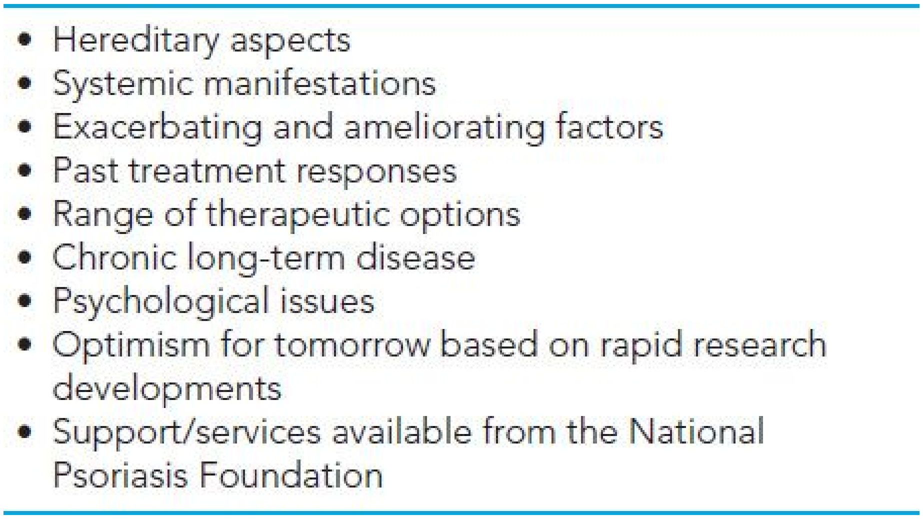
FOLLOW-UP

- Follow-up may need to be frequent for various therapies including cytotoxic drugs, the biologics, and light therapy.
- While there are many safety concerns with the biologic agents a recent integrated safety analysis of short- and long-term safety profiles of etanercept in patients with psoriasis concluded that rates of noninfectious and infectious adverse events were comparable between placebo and etanercept groups.[37] Also, there was no increase in overall malignancies with etanercept therapy compared with the psoriasis population.[37]
- Well-controlled psoriasis on topical agents does not require frequent follow-up.

PATIENT EDUCATION

This is a chronic disease that cannot be cured. There are many methods to control psoriasis. Patients and their families need to develop a relationship with the dermatologist to control the psoriasis for maximum quality of life. **Table 136-4** lists discussion points.

TABLE 136-4 Discussion Points for Health care Provider and Patient/Parents at Initial Visits



- Hereditary aspects
- Systemic manifestations
- Exacerbating and ameliorating factors
- Past treatment responses
- Range of therapeutic options
- Chronic long-term disease
- Psychological issues
- Optimism for tomorrow based on rapid research developments

137 PITYRIASIS ROSEA

David Henderson, MD
Richard P. Usatine, MD

PATIENT STORY

A 17-year-old is brought to the office by her mom because of a rash that appeared 3 weeks ago for no apparent reason (**Figures 137-1** to **137-3**). She was feeling well and the rash is only occasionally pruritic. With and without mom in the room, the patient denied sexual activity. The diagnosis of pityriasis rosea was made by the clinical appearance even though there was no obvious herald patch. The collarette scale was visible and the distribution was consistent with pityriasis rosea. The patient and her mom were reassured that this would resolve spontaneously. At a subsequent visit for a college physical, the skin was found to be completely clear with no scarring.

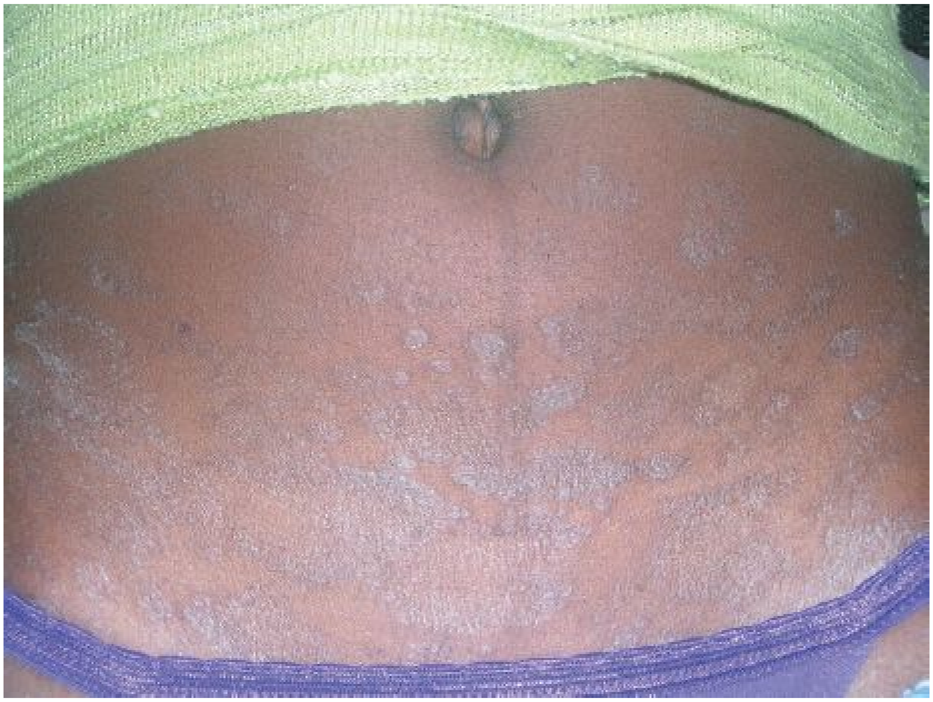

FIGURE 137-1 Pityriasis rosea in a 17-year-old. Lesions are often concentrated in the lower abdominal area. (*Used with permission from Richard P. Usatine, MD*.)

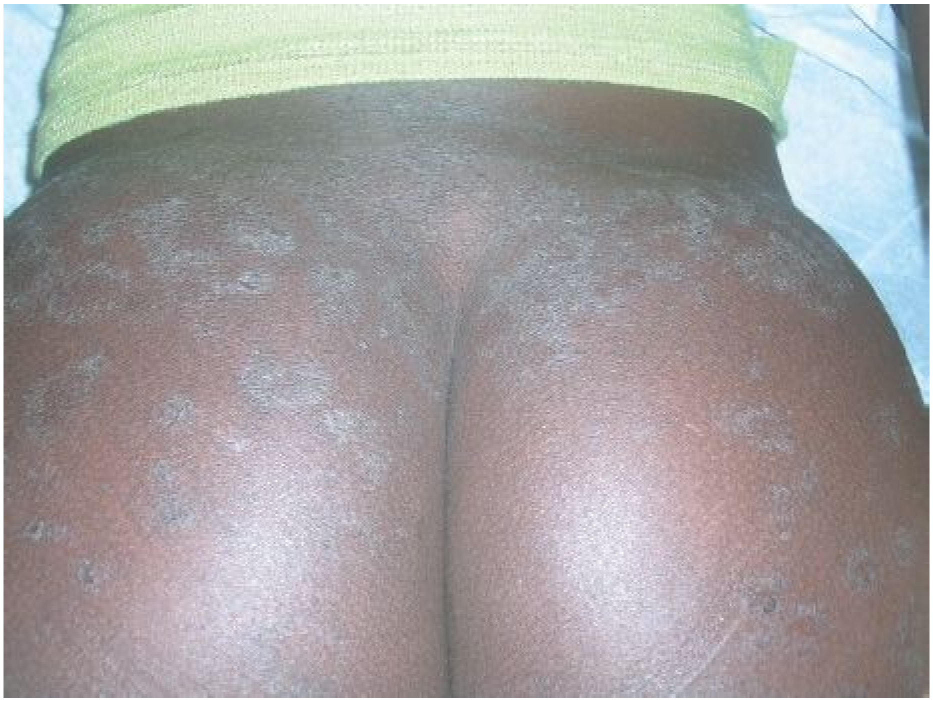

FIGURE 137-2 Scaling lesions seen on the buttocks of the same teen as in Figure 137-1. Note how some of the lesions are annular. (*Used with permission from Richard P. Usatine, MD*.)

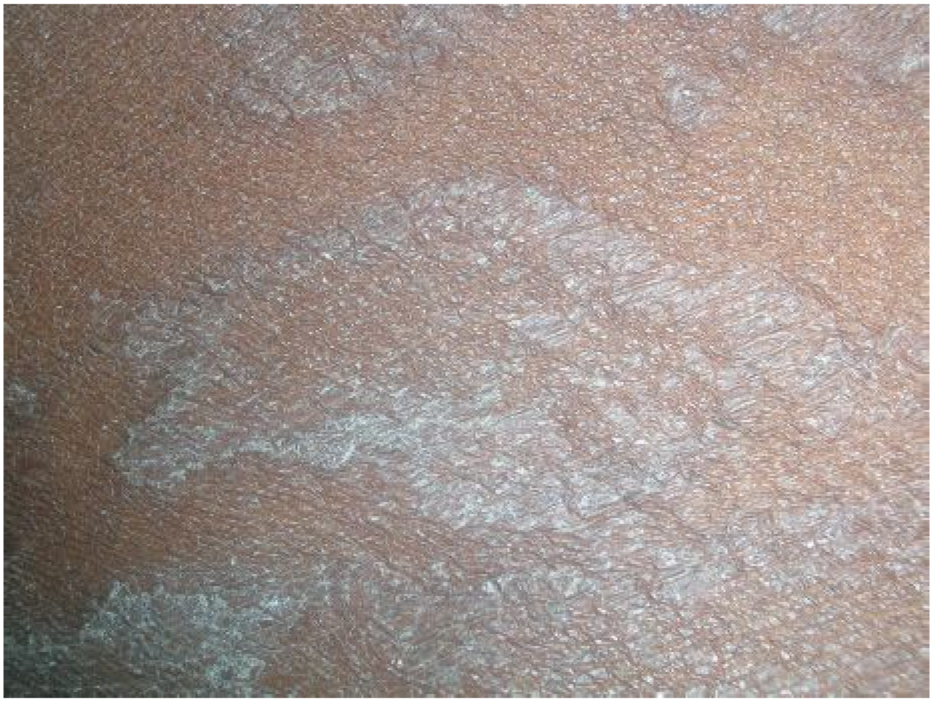

FIGURE 137-3 Close-up of lesion showing collarette scale. Note how the lesions can be annular with some central clearing. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Pityriasis rosea is a common, self-limited, papulosquamous skin condition originally described in the 19th century. It is seen in children and adults. Despite the long history, its etiology remains elusive. A number of infectious etiologies have been proposed, but at present, supporting evidence is inconclusive. Pityriasis rosea has unique features including a herald patch in many cases and collarette scale that are useful in distinguishing it from other papulosquamous eruptions.

EPIDEMIOLOGY

- Pityriasis rosea is a papulosquamous eruption of unknown etiology.[1]
- It occurs throughout the life cycle. It is most commonly seen between the ages of 10 and 35 years.[3]
- The peak incidence is between 20 and 29 years of age.[1]
- The gender distribution is essentially equal.[1]
- The rash is most prevalent in winter months.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- The cause of pityriasis rosea is unknown, although numerous causes have been proposed.
- It has long been suspected that it may have a viral etiology because a viral-like prodrome often occurs prior to the onset of the rash. Human herpesviruses 6 and 7 have been proposed as causes, but numerous studies have failed to demonstrate conclusive supportive evidence.[1,2]
- *Chlamydophila pneumoniae*, *Mycoplasma pneumoniae*, *and Legionella pneumophila* have been proposed as potential etiologic agents, but studies have not demonstrated any significant rise in antibody levels against any of these pathogens in patients with pityriasis rosea.[1]
- Pityriasis rosea has also been associated with negative pregnancy outcomes, particularly premature birth. The risk seems to be greatest when the condition occurs in the first 15 weeks of gestation.[2]
- Pityriasis rosea may rarely occur as the result of a drug reaction. Documented drug reactions that have produced a pityriasis rosea-like eruption include barbiturates, captopril, clonidine, interferon, bismuth, gold, and the hepatitis B vaccine.[1,2]

DIAGNOSIS

CLINICAL FEATURES

- In approximately 20 to 50 percent of cases, the rash of pityriasis rosea is preceded by a viral-like illness consisting of upper respiratory or GI symptoms.
- This is followed by the appearance of a *herald patch* in 17 percent of cases (**Figures 137-4** to **137-6**).[4]

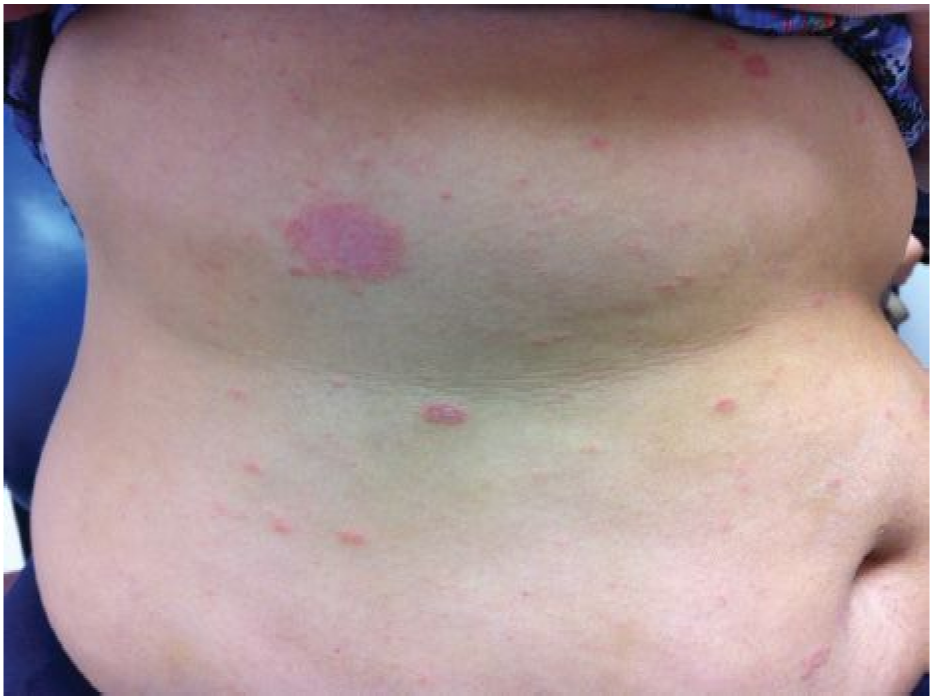

FIGURE 137-4 Pityriasis rosea with prominent pink herald patch on the abdomen of this overweight teenager. (*Used with permission from Richard P. Usatine, MD*.)

- The herald patch is a solitary, oval, flesh-colored to salmon-colored lesion with scaling at the border. It often occurs on the trunk, and is generally 2 to 10 cm in diameter (**Figures 137-4** and **137-5**).

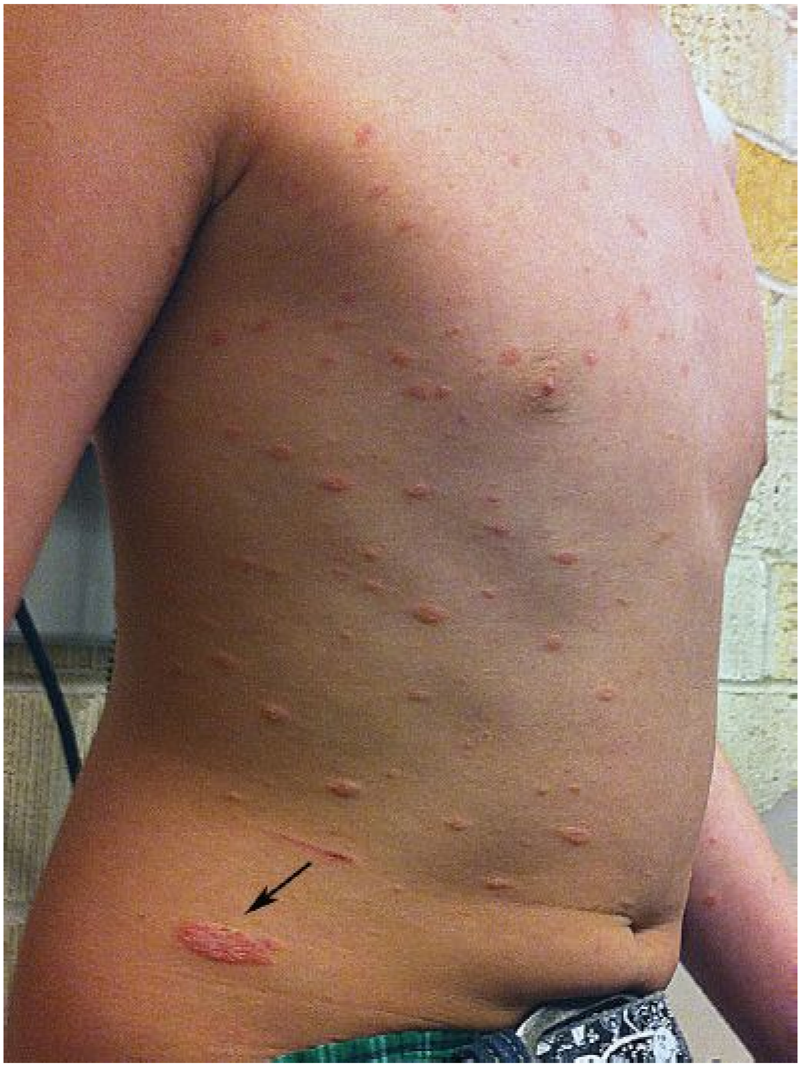

FIGURE 137-5 Pityriasis rosea in a 13-year-old boy. Arrow points to herald patch. (*Used with permission from Richard P. Usatine, MD.*)

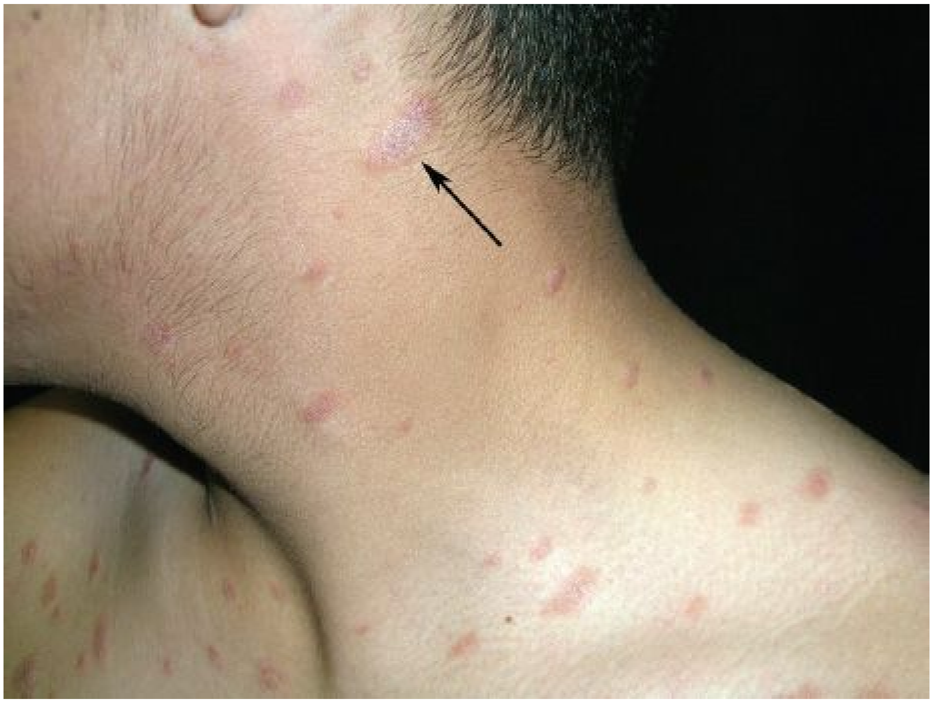

FIGURE 137-6 Pityriasis rosea in a 15-year-old boy with the herald patch on the neck near the hairline. (*Used with permission from Richard P. Usatine, MD.*)

- One to two weeks after the appearance of the herald patch, other papulosquamous lesions appear on the trunk and sometimes on the extremities.
- These lesions vary from oval macules to slightly raised plaques, 0.5 to 2 cm in size. They are salmon colored (or hyperpigmented in individuals with dark skin), and typically have a collarette of scaling at the border (**Figure 137-3**). It is common for some of the lesions to appear annular with central clearing.
- In many cases, the herald patch has resolved by the time the rest of the exanthem erupts which can make the diagnosis more difficult.
- There are no systemic symptoms.
- Itching occurs in approximately 25 percent of patients.
- The exanthem resolves in 8 weeks in 80 percent of patients.[1] However, it can last up to 3 to 5 months.[3]

TYPICAL DISTRIBUTION

- The rash is bilaterally symmetrical, generally most dense on the trunk, but also involves the upper and lower extremities.
- The lesions follow the cleavage, or Langer lines, and may create the typical *fir* or *Christmas tree* pattern over the back (**Figure 137-7**). Do not expect to always see a Christmas tree pattern.

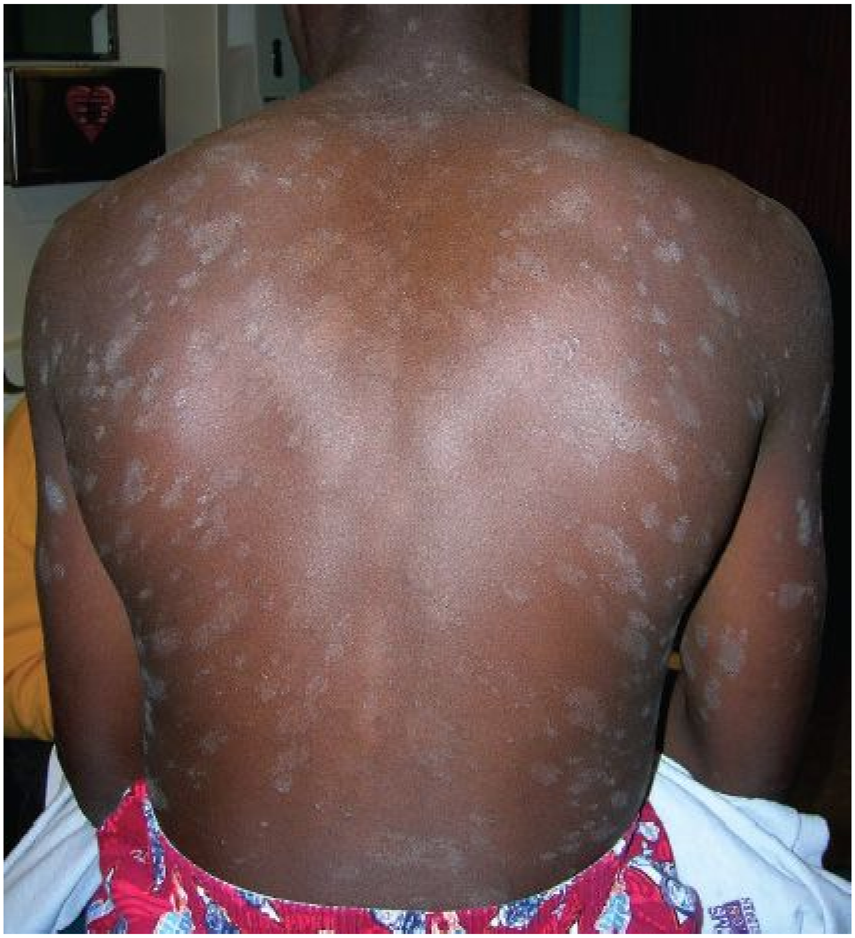

FIGURE 137-7 Pityriasis rosea in a 16-year-old boy. The scaling lesions follow skin lines and resemble a Christmas tree. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

- Over the chest, the lesions create a V-shaped pattern, and run transversely over the abdomen (**Figures 137-8** and **137-9**).

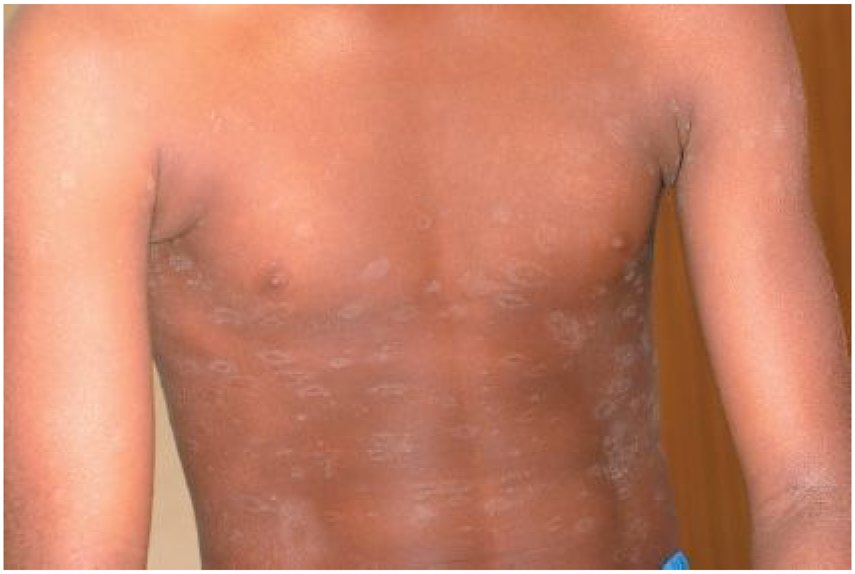

FIGURE 137-8 Pityriasis rosea in a 12-year-old boy showing classic scaling lesions across the chest and abdomen. Small annular lesions are visible. (*Used with permission from Jeffrey Meffert, MD*.)

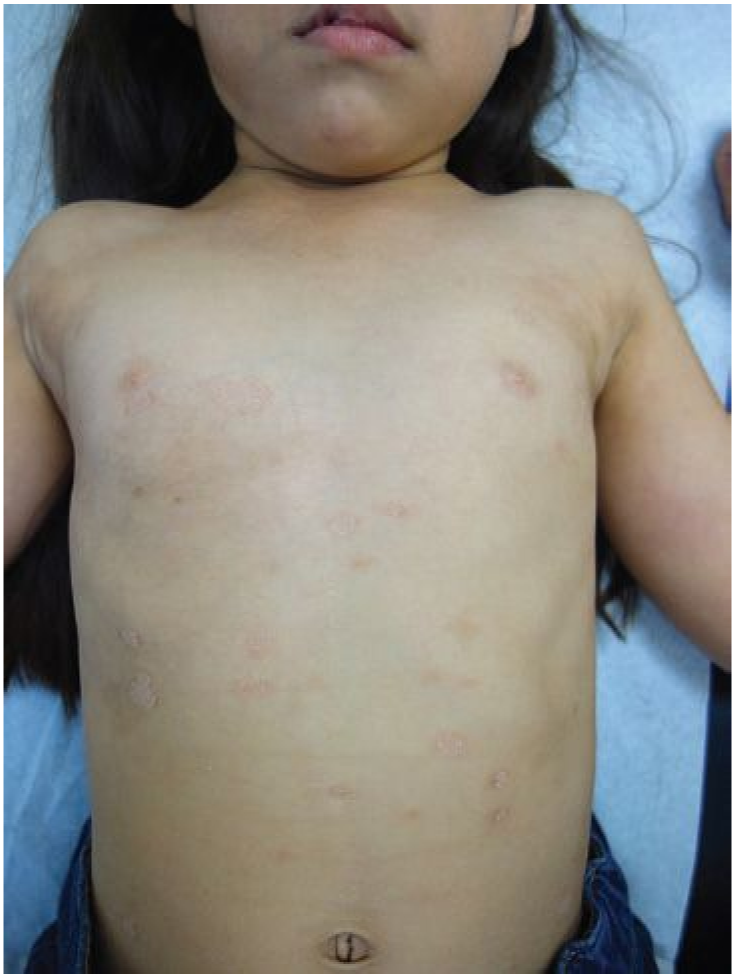

FIGURE 137-9 Pityriasis rosea on the chest and abdomen of this young girl. While the lesions are subtle, close-up examination reveals a trailing scale pattern. (*Used with permission from Emily Becker, MD.*)

- An inverse form has been described, characterized by more intense involvement of the extremities and relative sparing of the trunk (**Figures 137-10** and **137-11**).

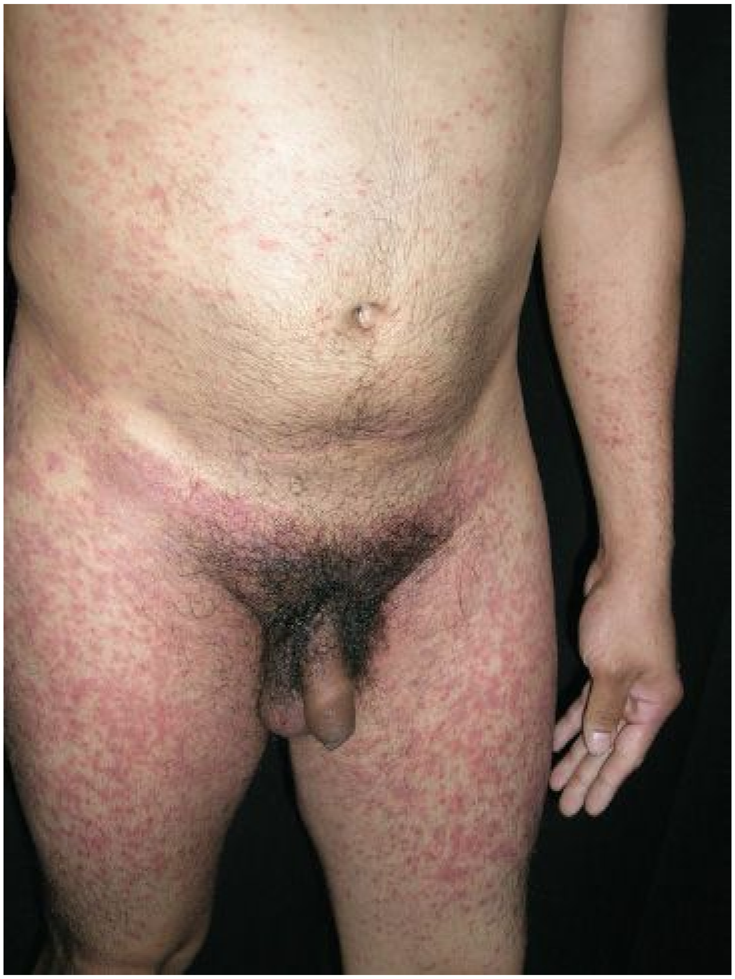

FIGURE 137-10 Pityriasis rosea with an inverse pattern. Note how there is a higher density of lesions on the legs. Rapid plasma reagin (RPR) was negative and the diagnosis was confirmed with a punch biopsy. (*Used with permission from Richard P. Usatine, MD*.)

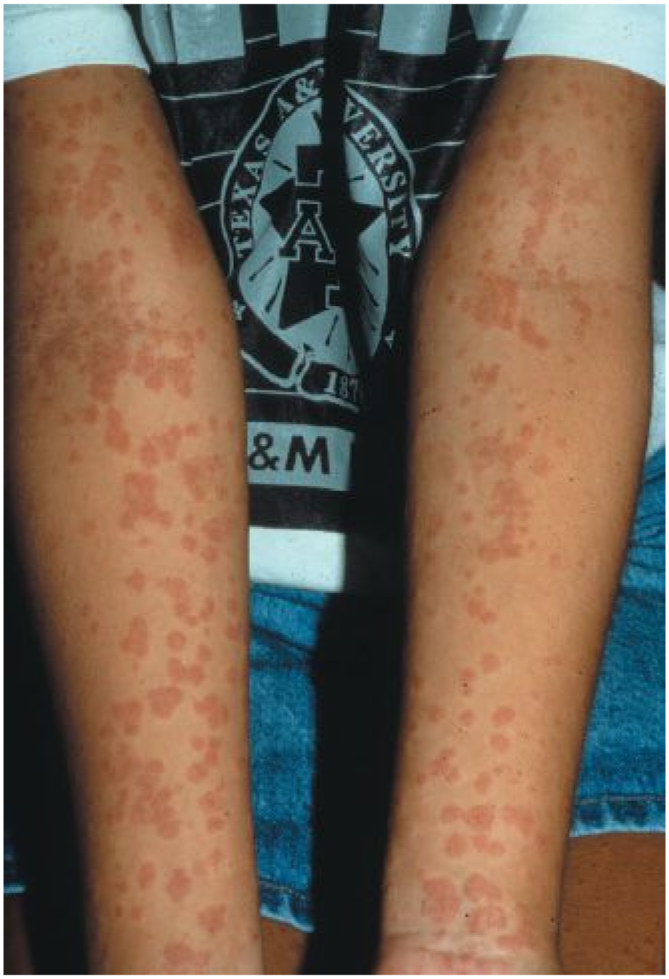

FIGURE 137-11 Pityriasis rosea with an inverse pattern on the arms with prominent erythematous lesions. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

LABORATORY STUDIES

Pityriasis rosea is a clinical diagnosis. There are no laboratory tests that aid in the diagnosis. Biopsy of lesions typically reveals only nonspecific inflammatory changes. Because secondary syphilis is also a papulosquamous eruption and can be difficult to distinguish from pityriasis rosea on clinical grounds, taking a sexual history is important when a diagnosis of pityriasis rosea is being considered. In patients with a history of sexually transmitted diseases, or sexual practices that place them at risk, a blood test for syphilis should be considered (**Figures 137-10**) (see Chapter 181, Syphilis).

DIFFERENTIAL DIAGNOSIS

- Tinea corporis is usually more localized than pityriasis rosea. However, the annular patterns, scale, and central clearing of some lesions in pityriasis rosea can mislead the clinician to misdiagnose tinea corporis. Tinea corporis tends to have fewer annular lesions and may have concentric circles rather than a single ring. Microscopy with KOH usually demonstrates branching hyphae (see Chapter 123, Tinea Corporis).
- Tinea versicolor has a distribution similar to pityriasis rosea, but is not associated with a herald patch. The pattern of scaling noted is generally more diffuse and not annular. Microscopy with KOH demonstrates the *spaghetti-and-meatball* pattern typical of *Pityrosporum* (see Chapter 126, Tinea Versicolor).
- Secondary syphilis is also a papulosquamous eruption. Lesions are often found on the palms and soles, which is not the case in pityriasis rosea; however, because the two conditions cannot always be accurately distinguished on clinical grounds, a blood test for syphilis is indicated if there is a significant doubt in the diagnosis (see Chapter 181, Syphilis).
- Nummular eczema has coin-like areas of scale that can resemble pityriasis rosea. The scale is not collarette and nummular eczema has a predilection for the legs, an area that is less often involved with pityriasis rosea (see Chapter 130, Atopic Dermatitis).
- Guttate psoriasis generally presents as oval to round, scaly macules on the trunk, and so can be confused with pityriasis rosea. However, the scaling is generally thicker and more adherent than in pityriasis rosea (see Chapter 136, Psoriasis).

MANAGEMENT

- Pityriasis rosea often requires no treatment at all other than reassurance.

- Topical steroids and oral diphenhydramine may be used to relieve itching when there is pruritus involved. SOR Ⓒ
- One study found oral erythromycin to be effective in treating patients with pityriasis rosea,[5] although a subsequent study did not find erythromycin to be better than placebo.[6] SOR Ⓑ
- Azithromycin did not cure pityriasis rosea in a study of children with this condition.[7]
- A Cochrane systematic review found inadequate evidence for efficacy for most treatments for pityriasis rosea.[8] Based on one small randomized controlled trial (RCT), the review authors noted that oral erythromycin may be effective in treating the rash and decreasing the itch.[5,8] The authors stated that this result should be treated with caution as it comes from only one small RCT.[5,8] SOR Ⓑ

FOLLOW-UP

- Patients should be instructed to follow up if the rash persists for longer than 3 months as reevaluation and consideration of an alternate diagnosis may be prudent.

PATIENT EDUCATION

- Patients are often concerned about the duration of the rash and whether they are contagious. They should be reassured that pityriasis rosea is self-limited and not truly contagious. Although there have been reported clusters of pityriasis rosea in settings where people are living in close quarters (e.g., dormitories), it is not considered to be contagious. It has a reported recurrence rate of only 2 percent.[5]

138 LICHEN PLANUS

Robert Kraft, MD
Richard P. Usatine, MD

PATIENT STORY

A 12-year-old boy presents with a rash on his wrists, forearms and ankle for one month (**Figure 138-1**). The rash itches and he does not know where it comes from. The father states that there are no other members of the family with such a rash now or in the past. The pediatrician recognized the morphology and distribution as that of lichen planus. The papules and plaques on the wrist were pink and purple, planar, pruritic and polygonal. The pediatrician looked inside the mouth and the mucosa was clear with no Wickham's striae. The boy was started on a mid-potency topical steroid ointment and a follow up appointment was scheduled.

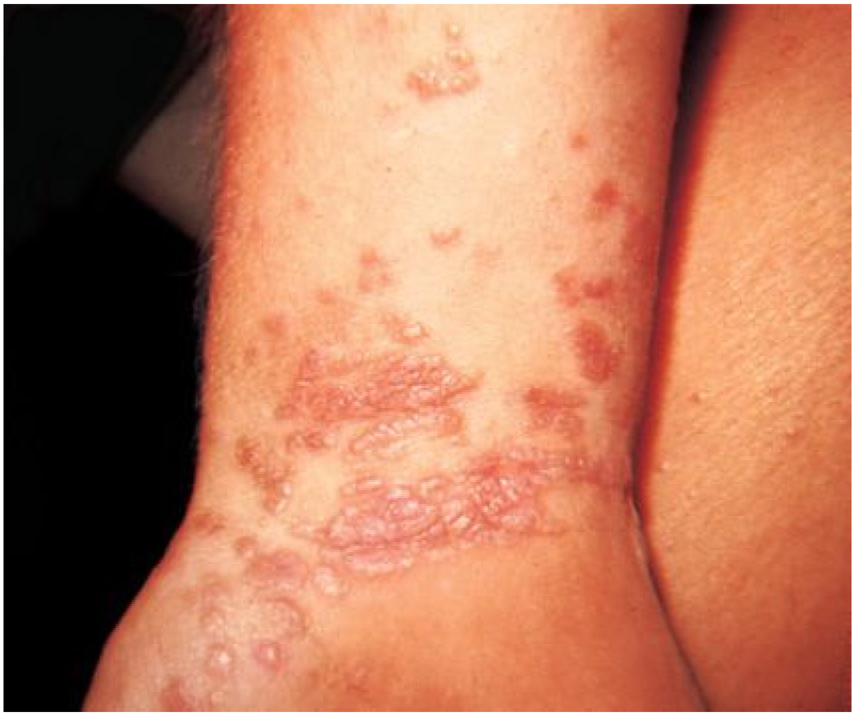

FIGURE 138-1 Lichen planus on the flexor surface of the wrist of a 12-year-old boy. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 9-40, New York, NY: McGraw-Hill, 2008*.)

INTRODUCTION

Lichen planus (LP) is a self-limited, recurrent, or chronic autoimmune disease affecting the skin, oral mucosa, and genitalia. LP is generally diagnosed clinically with lesions classically described using the six Ps (planar, purple, polygonal, pruritic, papules, and plaques).

EPIDEMIOLOGY

- LP is an inflammatory dermatosis of skin or mucous membranes that occurs in approximately 1 percent of all new patients seen at health care clinics.[1]
- Although most cases occur between ages 30 and 60 years, LP can occur at any age with fewer than 4 percent of cases in patients under age 20.[1–4]
- There may be a slight female predominance.[2,5–7]

ETIOLOGY AND PATHOPHYSIOLOGY

- Usually idiopathic, thought to be a cell-mediated immune response to an unknown antigen.[2,5,8]
- Possible human leukocyte antigen (HLA)-associated genetic predisposition.[2]

- Lichenoid-type reactions may be associated with medications (e.g., angiotensin-converting enzyme inhibitors [ACEIs], thiazide-type diuretics, tetracycline, and chloroquine), metals (e.g., gold and mercury), or infections (e.g., secondary syphilis).[2,8]
- Associated with liver disease, especially related to hepatitis C virus.[2,8,9]
- A few cases of LP after hepatitis B vaccination have been reported.[10]
- LP may be found with other diseases of altered immunity (e.g., ulcerative colitis, alopecia areata, myasthenia gravis).[1]
- Malignant transformation has been reported in ulcerative oral lesions in men.[1]

RISK FACTORS

- Possible HLA-associated genetic predisposition; however, a positive family history is not consistently found.[11]
- Hepatitis C virus infection, and possibly hepatitis B vaccination, although causal relationship is not established.[6,12]
- Certain drugs (see the previous section “Etiology and Pathophysiology”).

DIAGNOSIS

CLINICAL FEATURES[2,8]

- Classically, the six Ps of LP are planar, purple, polygonal, pruritic, papules, and plaques (**Figure 138-2**). These well-demarcated flat-topped violaceous lesions are often covered by lacy, reticular white lines (called Wickham striae or Wickham lines; **Figure 138-3**).

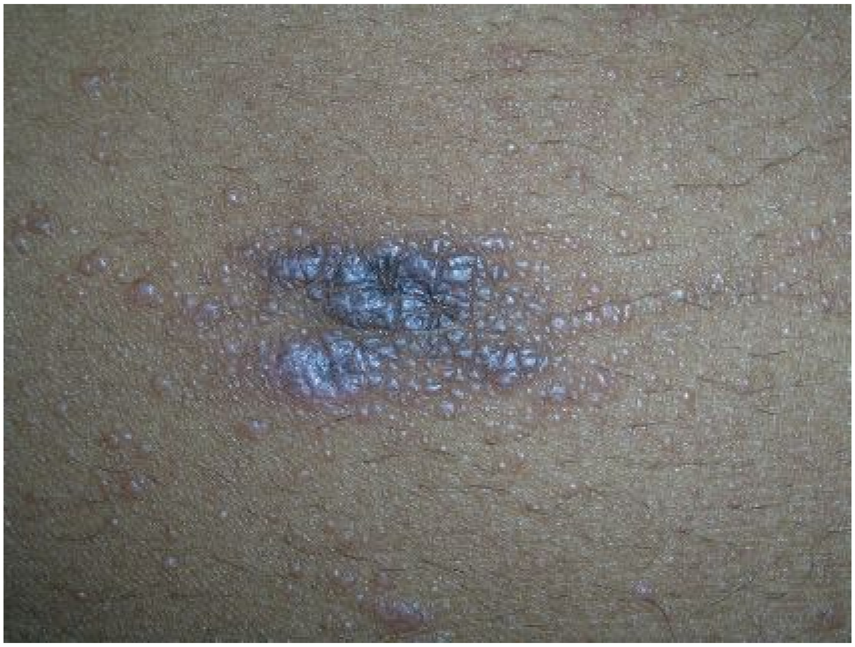

FIGURE 138-2 Lichen planus on the back with all the 6 Ps (planar, purple, polygonal, pruritic, papules, and plaques). Some of the papules are also pink and follow a linear pattern. (*Used with permission from Richard P. Usatine, MD*.)

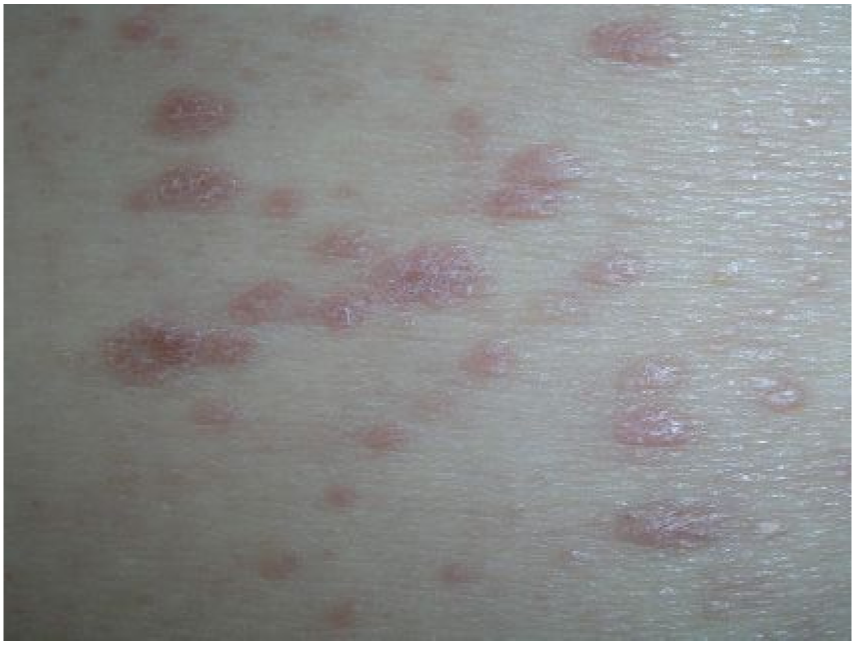

FIGURE 138-3 Close-up of lesions on the back showing Wickham striae crossing the flat papules of lichen planus. These lines are white and reticular like a net. (*Used with permission from Richard P. Usatine, MD*.)

- An initial lesion is usually located on the flexor surface of the limbs, such as the wrists, followed by a generalized eruption with maximal spreading within 2 to 16 weeks.[1]
- Lesions may demonstrate the Koebner phenomenon (linear distribution) from scratching (**Figure 138-4**).

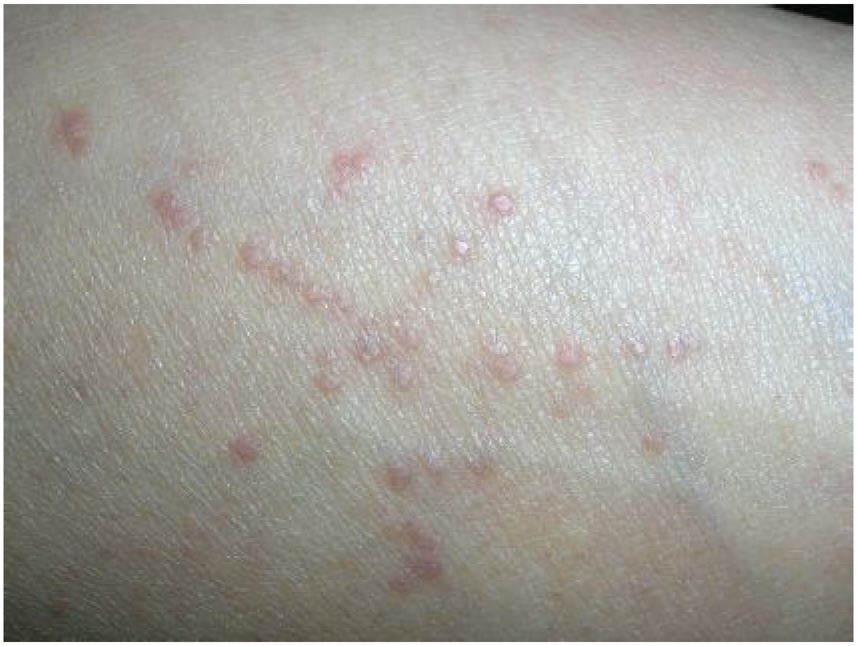

FIGURE 138-4 Close-up of wrist showing linearity of the lesions on the flexor surface secondary to the Koebner phenomenon. Lesions may be pink rather than purple. (*Used with permission from Richard P. Usatine, MD.*)

- Lesions are often hyperpigmented rather than purple or pink in dark-skinned persons, and skin may remain hyperpigmented after lesions resolve (**Figure 138-5**).

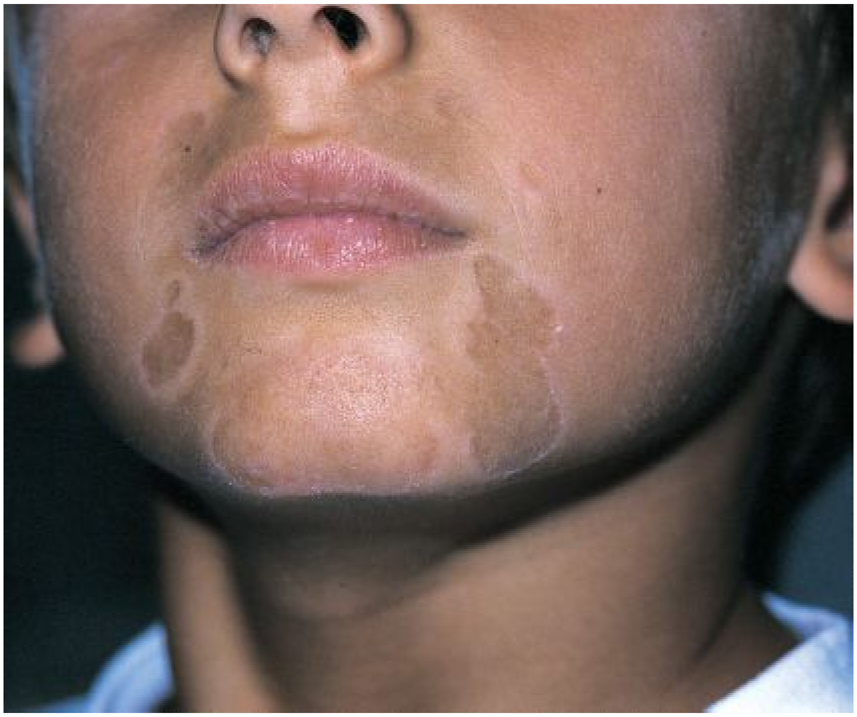

FIGURE 138-5 Annular lichen planus on the face of a young boy. Note how the lesion is hyperpigmented rather than purple or pink. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 9-47, New York, NY: McGraw-Hill, 2008.*)

- Lesions can also be annular (**Figure 138-5**).
- Skin variants:
  - Hypertrophic (**Figure 138-6**)—Typical papules develop into thicker reddish-brown to purple plaques most commonly on the foot and shins.

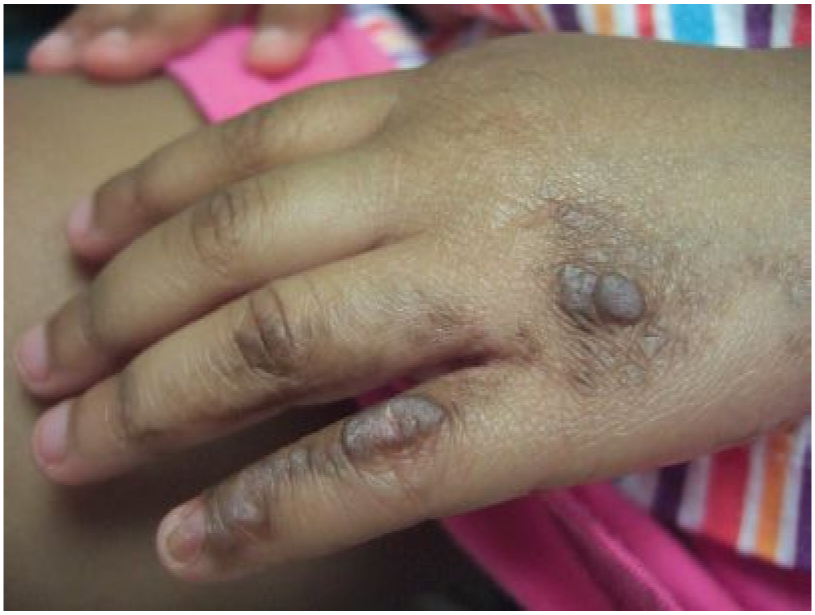

FIGURE 138-6 Hypertrophic lichen planus on the hand of a child. As this also resembles verruca vulgaris a shave biopsy was performed to determine the diagnosis. (*Used with permission from John C. Browning, MD*.)

- Follicular—Pinpoint hyperkeratotic projections often on scalp, may lead to cicatricial alopecia (**Figure 138-7**).

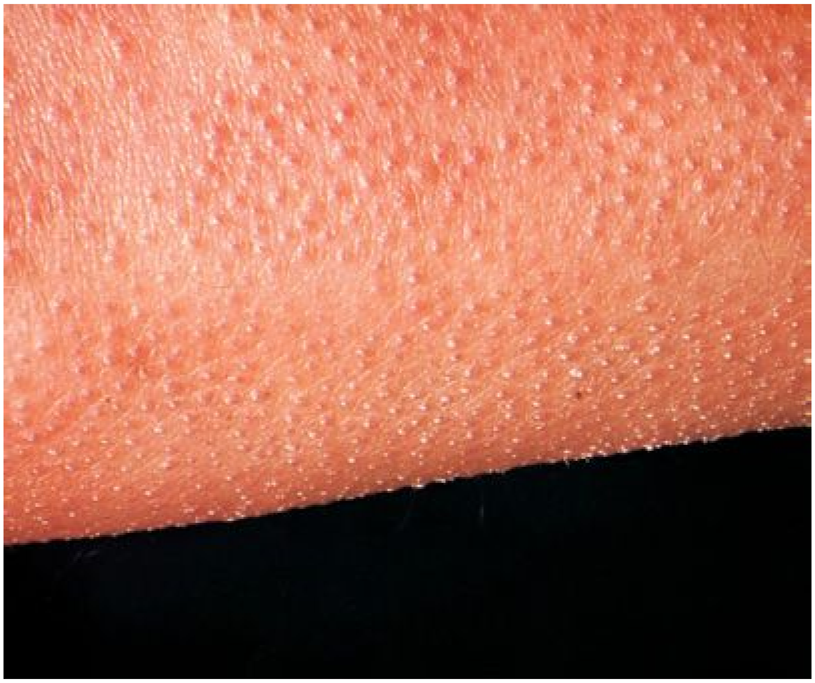

FIGURE 138-7 Lichen planopilaris (follicular lichen planus) primary involvement is around hair follicles and this is more common in females. When it involves the scalp it can cause scarring alopecia. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 9-48, New York, NY: McGraw-Hill, 2008.*)

  - Vesicular—Vesicles or bullae occur alongside the more typical LP lesions (**Figure 138-8**).

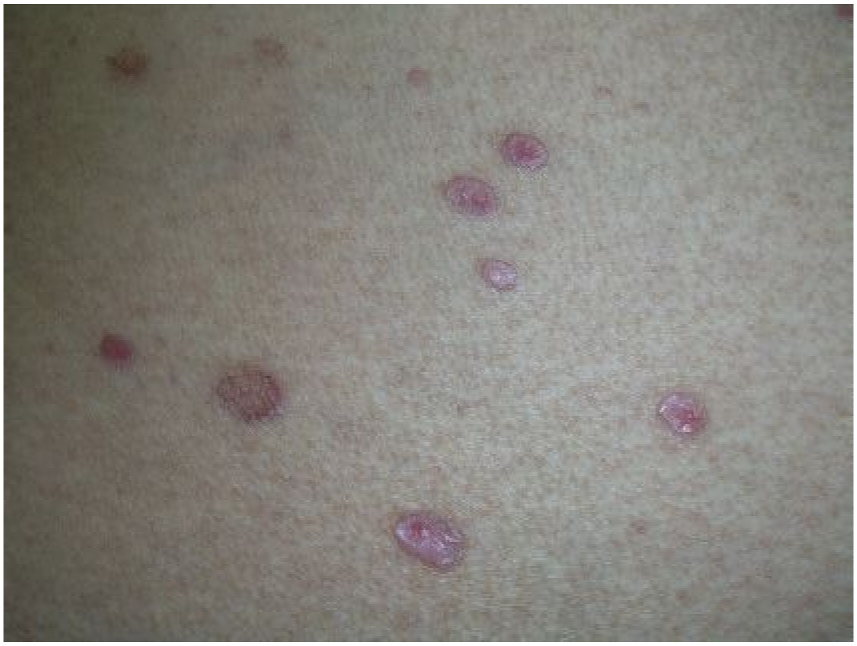

FIGURE 138-8 Bullous lichen planus on the lower back. (*Used with permission from Richard P. Usatine, MD.*)

  - Actinic—Typical lesions in sun-exposed areas, such as the face, back of hands and arms.
  - Atrophic—The lesions are atrophic rather than standard plaques.
  - Ulcerative—Ulcers develop within typical lesions or start as waxy semitranslucent plaques on palms and soles; may require skin grafting.

- Mucous membrane variants:
  - May be reticular (net-like; **Figure 138-9**), atrophic, erosive, or bullous. It is almost always bilateral.

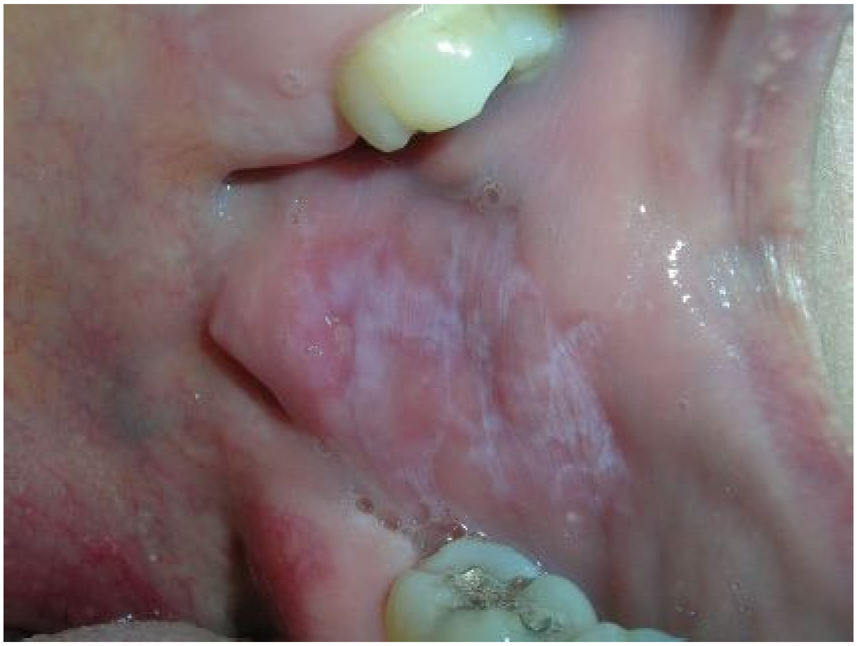

FIGURE 138-9 Asymptomatic white keratotic striae of lichen planus on left buccal mucosa. The patient had similar involvement of the right buccal mucosa and gingivae. Lichen planus in the mouth is bilateral. (*Used with permission from Richard P. Usatine, MD*.)

  - Oral lesions may be asymptomatic or have a burning sensation; pain occurs with ulceration.[1,6,9]
  - Found in up to 40 percent of pediatric patients.[13]
  - Oral LP is often associated with extraoral LP.[4,14,15]
- Genitalia variants:
  - Reticular, annular, papular, or erosive lesions on penis, scrotum, labia, or vagina.
  - Vulvar/vaginal lesions may be associated with dyspareunia, a burning sensation, and/or pruritus.[1,14]
  - Vulvar and urethral stenosis can also be present.[1,14]
- Hair and nail variants (**Figure 138-10**); the latter present in 10 percent of adult patients, but less commonly in pediatric patients:[1,11,13]

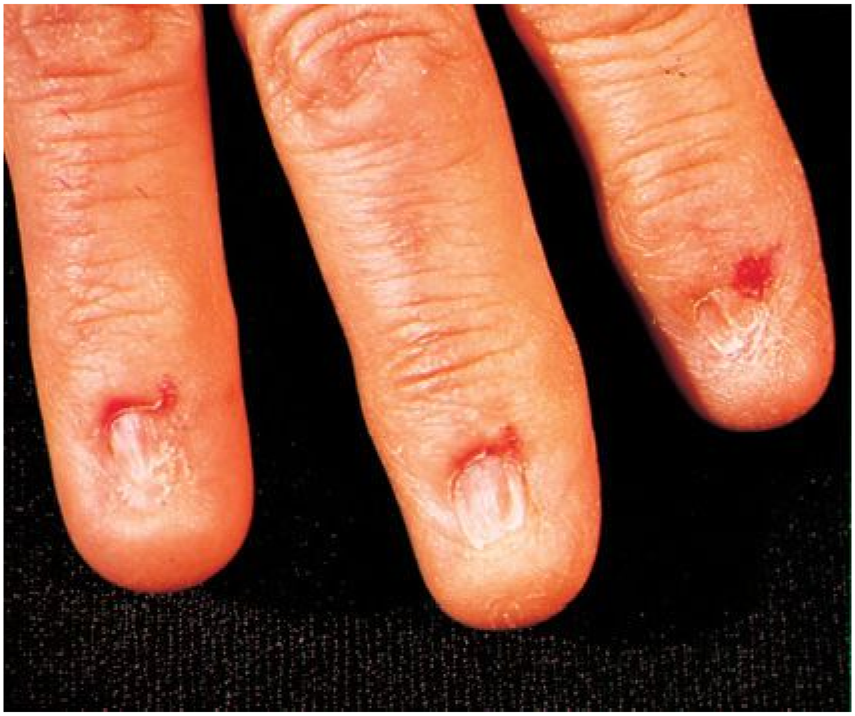

FIGURE 138-10 Lichen planus of the nails with pterygium formation and permanent nail loss. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 9-46, New York, NY: McGraw-Hill, 2008*.)

- Violaceous, scaly, pruritic papules on the scalp can progress to scarring alopecia. Lichen planopilaris (LP of the scalp) can cause widespread hair loss.[16]
- Nail plate thinning results in longitudinal grooving and ridging; rarely destruction of nailfold and nail bed with splintering (**Figure 138-9**).
- Hyperpigmentation, subungual hyperkeratosis, onycholysis, and longitudinal melanonychia can result from LP.[1]

TYPICAL DISTRIBUTION

Wrists (**Figure 138-1**), ankles, lower back, eyelids, shins, scalp, penis, or mouth (i.e., buccal mucosa, lateral tongue, and gingiva).[2,8]Lesions can also appear on the dorsum of the hand (**Figures 138-6** and **138-11**) and on the legs (**Figure 138-12**).

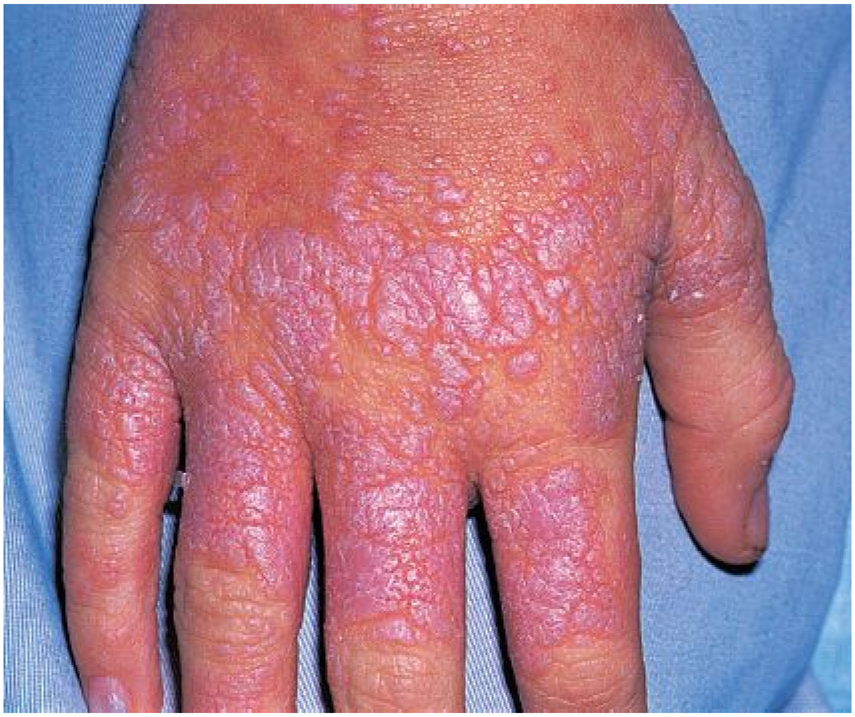

FIGURE 138-11 Lichen planus on the dorsum of the hand and fingers of a child. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 9-39, New York, NY: McGraw-Hill, 2008*.)

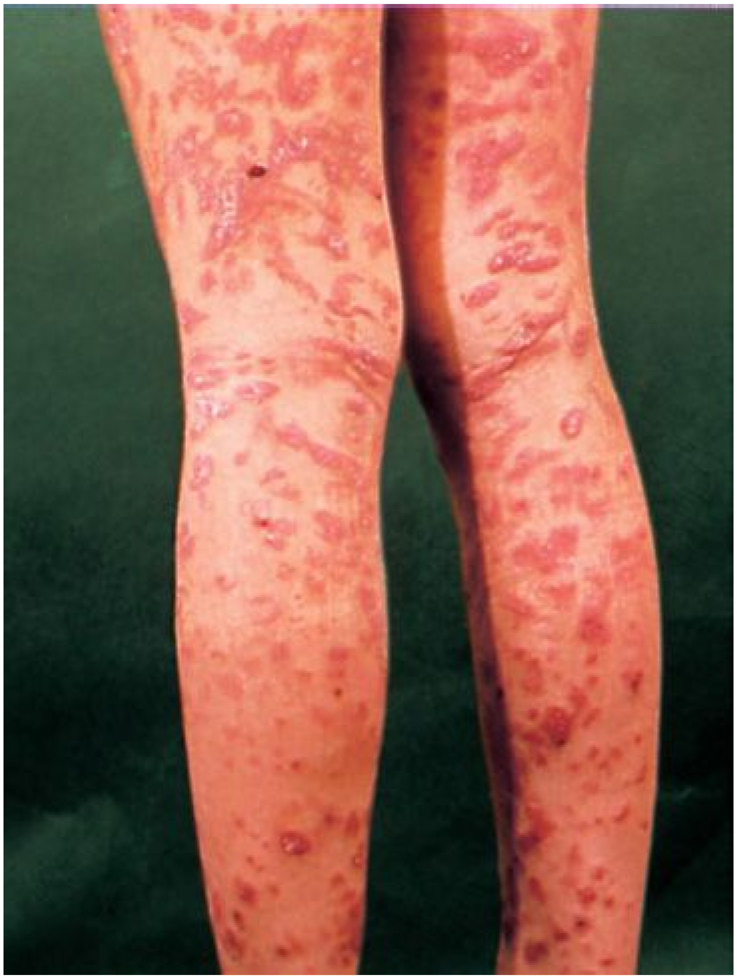

FIGURE 138-12 Severe lichen planus on the legs of a child. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 9-41, New York, NY: McGraw-Hill, 2008*.

LABORATORY STUDIES

- Wickham striae can be accentuated by a drop of oil on the skin plaque and magnification.[8] Not all LP has visible Wickham striae. This study is rarely needed. If the diagnosis is uncertain, a punch biopsy should be performed.

BIOPSY

- A punch biopsy is a valuable method to make as initial diagnosis if the clinical picture is not certain. A biopsy is rarely needed to evaluate for malignant transformation.[8,17]
- Mainly lymphocytic immunoinflammatory infiltrate with hyperkeratosis, increased granular layer and liquefaction of basal cell layer.[2,8]
- Linear fibrin and fibrinogen deposits along basement membrane.[2,8]
- Direct immunofluorescence on biopsy specimen reveals globular deposits of immunoglobulin (Ig) G, IgM, IgA, and complement at dermal–epidermal junction.[8]

DIFFERENTIAL DIAGNOSIS

Skin lesions that may be confused with LP:

- Eczematous dermatitis—“The itch that rashes”: dry skin, itching, often excoriations and lichenification of skin with predilection for flexor surfaces (see Chapter 130, Atopic Dermatitis).
- Psoriasis has more prominent silvery scale and is generally located on extensor surfaces.[8] A punch biopsy can be used to distinguish between these two when the clinical picture is not clear (see Chapter 136, Psoriasis).
- Pityriasis rosea—Herald patch and subsequent pink papules and plaques with long axes along skin lines (Christmas tree pattern) (see Chapter 137, Pityriasis Rosea).
- Chronic cutaneous lupus erythematosus—Bright red sharply demarcated papules with adherent scale. Tend to regress centrally and can be light induced. Generally located on face, scalp, or forearms, and hands. Biopsy may be necessary to differentiate (see Chapter 173, Lupus: Systemic and Cutaneous).[8]

Other mucous membrane lesions that may appear similar:[8]

- Thrush—Removable whitish plaques over an erythematous mucosal surface caused by *Candida* infection, confirmed by KOH preparation (see Chapter 121, Candidiasis).
- Bite trauma in the mouth—May result in white areas of the lip or buccal mucosa. Persons may have a white bite line where the upper and lower molars occlude and this can be confused with oral LP. If in doubt, a biopsy may be needed.

Genital lesions that may be differentiated from LP:[8]

- Psoriasis on the penis can look like LP on the penis. A shave biopsy can be used to differentiate between these two diagnoses (see Chapter 136, Psoriasis).

MANAGEMENT

LP may persist for months to years. Hypertrophic LP and oral LP can last for decades.[2] Any type of LP can recur. Antihistamines can be used for symptomatic pruritus.[8] SOR Ⓒ Symptomatic and severe cases can be treated as follows:

- Localized/topical treatment.
  - Topical corticosteroids twice a day.[18–20] SOR Ⓑ Mid- to high-potency steroids are usually needed. Clobetasol cream or ointment may be used on the skin and clobetasol ointment or gel may be used in the mouth.
  - Topical aloe vera gel has demonstrated efficacy against oral LP.[21,22] SOR Ⓑ
  - Intralesional triamcinolone (3 to 5 mg/mL) for hypertrophic or mucous membrane lesions, may repeat every 3 to 4 weeks.[2,8,17,18,23] SOR Ⓑ
  - Tacrolimus, pimecrolimus, retinoids, or cyclosporine in mouthwash or adhesive base for oral disease unresponsive to topical corticosteroids.[5,6,17,19,24–27] SOR Ⓑ
  - Topical corticosteroids, tacrolimus, and aloe vera gel have demonstrated efficacy for vulvar LP.[28,29] SOR Ⓑ

- Systemic treatment can be considered for resistant, widespread, or severe cases.
    - Oral steroids may be used starting with a 3-week tapered course of oral prednisone.[2,17,18,30,31] SOR Ⓑ
    - Systemic retinoids, that is, acitretin 25 mg/day. Monitor serum creatinine, liver function tests (LFTs), and fasting lipids.[5,8,31] SOR Ⓑ Contraindicated in women of childbearing potential.
    - Cyclosporine (5 mg/kg per day). Monitor complete blood count, serum creatinine, LFTs, and blood pressure.[2] SOR Ⓑ
    - Azathioprine may be used as a steroid-sparing agent. Monitor complete blood count and LFTs.[8,17] SOR Ⓒ
    - Psoralen UVA (PUVA) phototherapy may be effective but can cause phototoxic reactions and has long-term risks, including the development of squamous cell carcinoma.[32] SOR Ⓒ
    - Carbon dioxide laser and low-level laser therapy have reports of treatment success against oral LP.[33,34] SOR Ⓒ

PROGNOSIS

- Generally self-limiting and spontaneous resolution may occur in 12 to 18 months.
- Recurrences are common.
- Mucosal LP is generally more persistent than cutaneous forms.
- Malignant transformation of LP is rare.

FOLLOW-UP

- Follow-up depends on severity and treatment course.
- Oral and vaginal disease may be most challenging to treat.

- Follow oral or vaginal lesions for possible malignant transformation. Because of low risk of transformation even with oral LP (best estimate: 0.2% per year), routine screening and biopsy is not recommended.[17] Biopsy if suspecting malignancy; lesion becomes larger, ulcerated, nodular, or lose reticular pattern.

PATIENT EDUCATION

- Patients should understand that LP is often self-limiting and may resolve in 12 to 18 months.
- There is a significant chance of recurrence.

139 LICHEN NITIDUS AND LICHEN STRIATUS

Michaela R. Marek, MD
Catherine Kowalewski, DO

PATIENT STORY

An 8-year-old Hispanic boy presents for evaluation of mildly itchy, pinpoint bumps that have been present for 2 to 3 months. The “rash” is primarily involving the patient’s trunk. Patient is otherwise healthy, and no one else at home has a similar eruption. The mother of the patient has tried some over-the-counter hydrocortisone, which has helped some with the mild itching, but the lesions persist. The pediatrician noted the linear pattern of the pinpoint papules and made the clinical diagnosis of lichen nitidus (**Figure 139-1**). These lines represent the Koebner phenomenon caused by scratching done by the child in areas that are reachable.

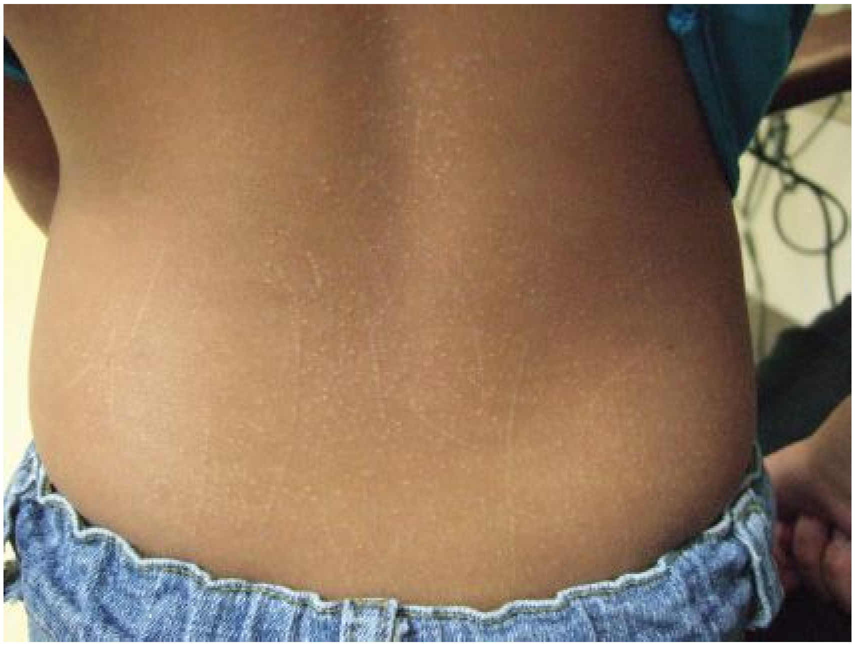

FIGURE 139-1 Lichen nitidus with several linearly arranged groups of tiny, skin-colored papules amidst a background of scattered pinpoint papules on the trunk of a child. The linearly arranged groups of papules are secondary to scratching (Koebner phenomenon). (*Used with permission from John Browning, MD.*)

INTRODUCTION

Lichen nitidus and lichen striatus are two distinct entities under the umbrella of lichenoid dermatoses, a grouping that is based on clinical findings resembling lichen planus, the prototypical lichenoid dermatosis, and the characteristic histologic findings of a band-like inflammatory infiltrate with or without vacuolar alteration of the dermoepidermal junction. Both conditions can present in a linear array; lichen nitidus because it exhibits the Koebner phenomenon (**Figure 139-1**) and lichen striatus (**Figure 139-2**) because it follows the lines of Blaschko. We will further discuss some of the similarities and distinguishing features of these two entities.

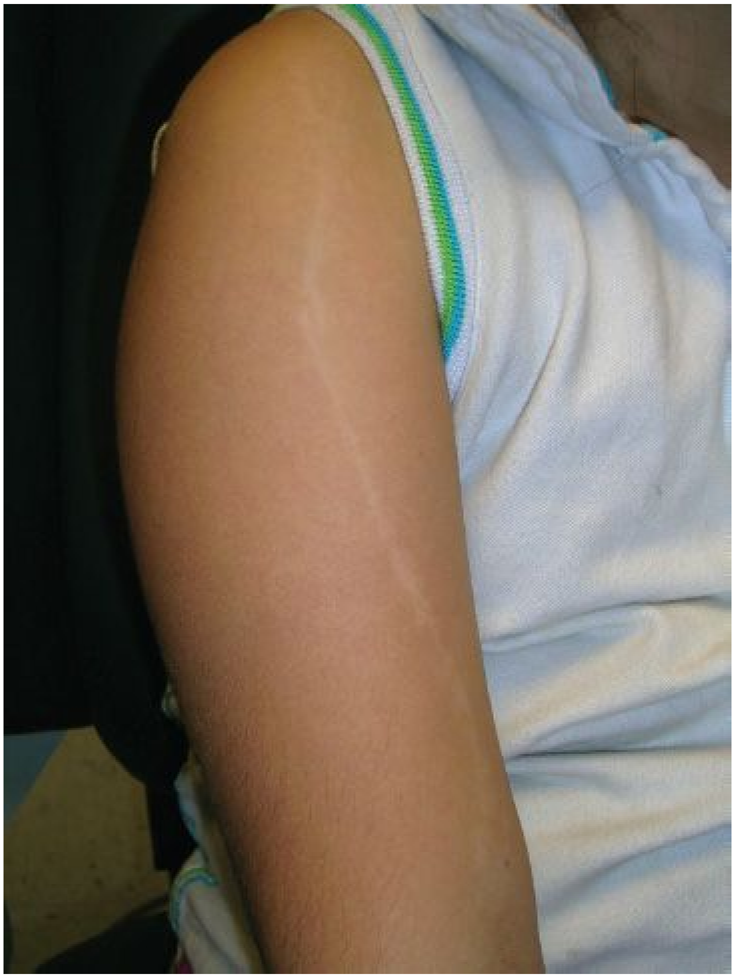

FIGURE 139-2 Lichen striatus with a curvilinear configuration of pink, slightly scaly, flat-topped papules on the upper extremity of a young girl. (*Used with permission from Richard P. Usatine, MD.*)

SYNONYMS

Lichen striatus—Linear lichenoid dermatosis, *B*laschko *l*inear *a*cquired *i*nflammatory *s*kin *e*ruption (BLAISE).

EPIDEMIOLOGY

LICHEN NITIDUS

- Lichen nitidus is a relatively rare disorder, more common in children and young adults.
- Lichen nitidus often presents in preschool and school-aged children.
- There does not seem to be a race or sex predilection.

LICHEN STRIATUS

- Lichen striatus is seen primarily in children 5 to 15 years of age.[1]
- Females are more often affected than males, with some reports of a female to male ratio as great as 2-3:1 (**Figure 139-3**).

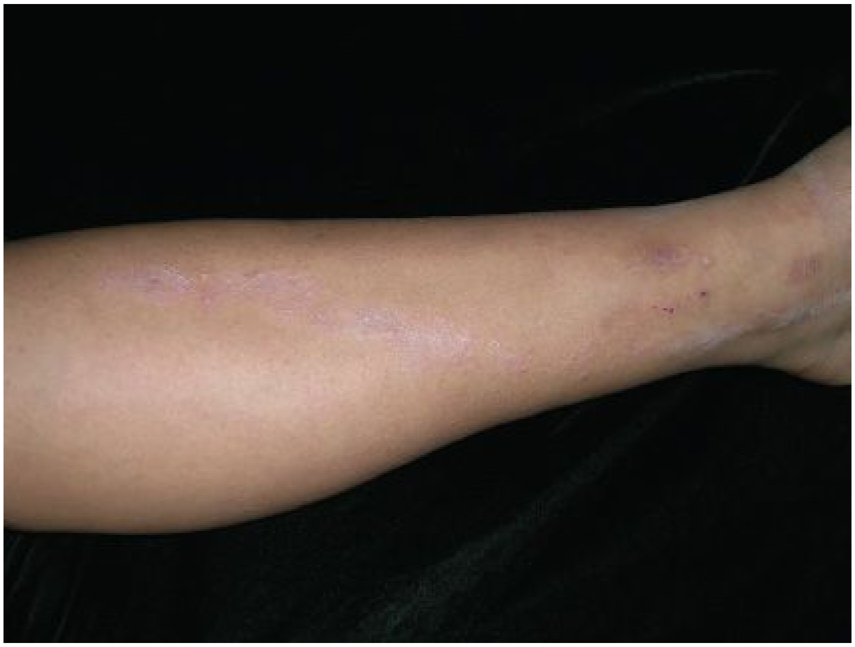

FIGURE 139-3 Lichen striatus with a Blaschkoid distribution of pink, slightly scaly papules on the leg of an 11-year-old girl. (*Used with permission from Richard P. Usatine, MD.*)

ETIOLOGY AND PATHOPHYSIOLOGY

LICHEN NITIDUS

- Lichen nitidus was once thought to be a tuberculous reaction because of its distinctive histologic findings of a lymphohistiocytic infiltrate, but no infectious agents have ever been elucidated.

LICHEN STRIATUS

- Lichen striatus is also thought to be related to infectious agents, viruses in particular. This postulation is based on the predominance of lichen striatus in children and its tendency to appear more commonly in the spring and summer.
- The Blaschkoid distribution of lesions in lichen striatus point to a somatic mutation as another potential cause, but no gene association has been established.
- Some hypothesize that a combination of the two previously mentioned processes may be required for development of lichen striatus.
- Still, lichen striatus may be related to atopy.

RISK FACTORS

LICHEN NITIDUS

There are no proven risk factors, but some authors do believe that lichen nitidus is a cutaneous manifestation of Crohn’s disease.[2]

LICHEN STRIATUS

Atopy may be a predisposing factor for lichen striatus, but it is suspected that an infectious agent is still a necessary trigger.

DIAGNOSIS

LICHEN NITIDUS

CLINICAL FEATURES

Lichen nitidus is characterized by numerous, discrete, skin-colored, shiny, flat-topped 1 to 2mm papules, clustered in groups (**Figures 139-4** and **139-5**). If inflammatory, the papules may appear more red.

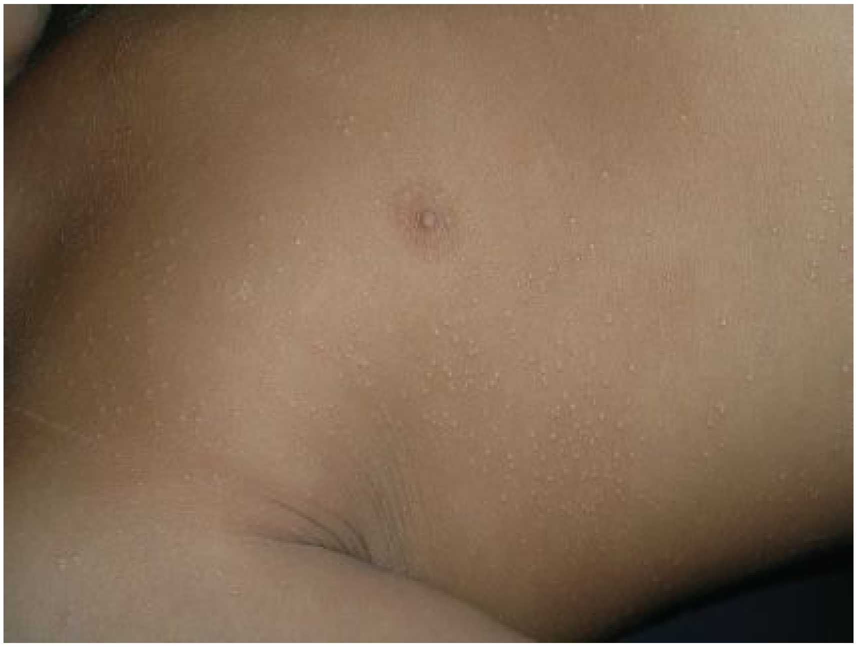

FIGURE 139-4 Lichen nitidus with scattered 1 to 2mm shiny, skin-colored, flat-topped papules of the trunk of a 7-year-old Hispanic boy. (*Used with permission from Richard P. Usatine, MD*.)

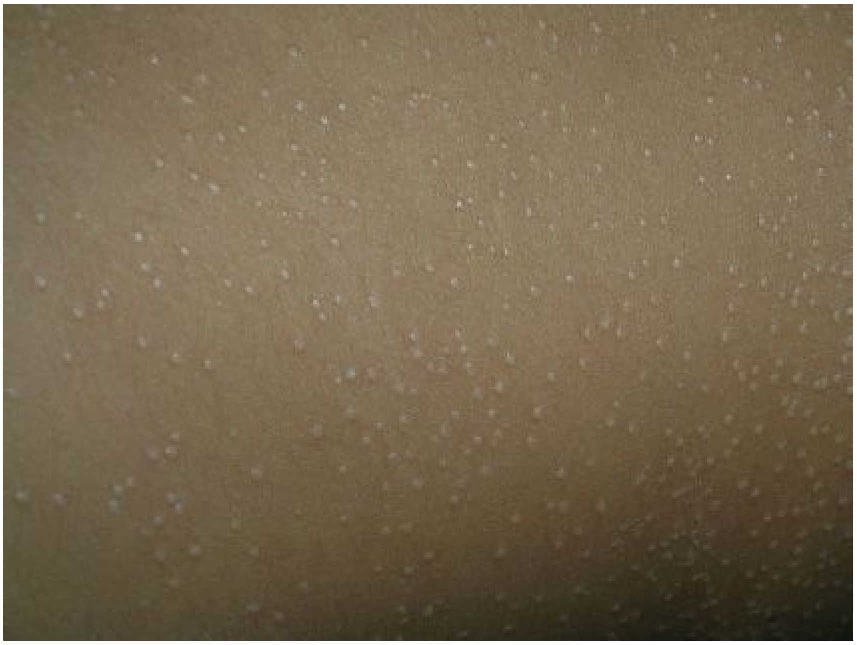

FIGURE 139-5 Close-up view of lichen nitidus with scattered skincolored, flat-topped papules on the trunk. (*Used with permission from Richard P. Usatine, MD*.)

Sometimes the pinhead-sized papules are more yellow or red-brown.

In dark-skinned persons, the papules are most often hypopigmented, but can also be hyperpigmented.

Tiny grey-white papules can be seen on the buccal mucosa, along with grey-white plaques involving the tongue and hard palate.

Nail changes are seen in approximately 10 percent of patients, more often in adults, and consist of pitting, longitudinal ridging, and rippling.

Often seen in a linear pattern, secondary to koebnerization (**Figure 139-6**).

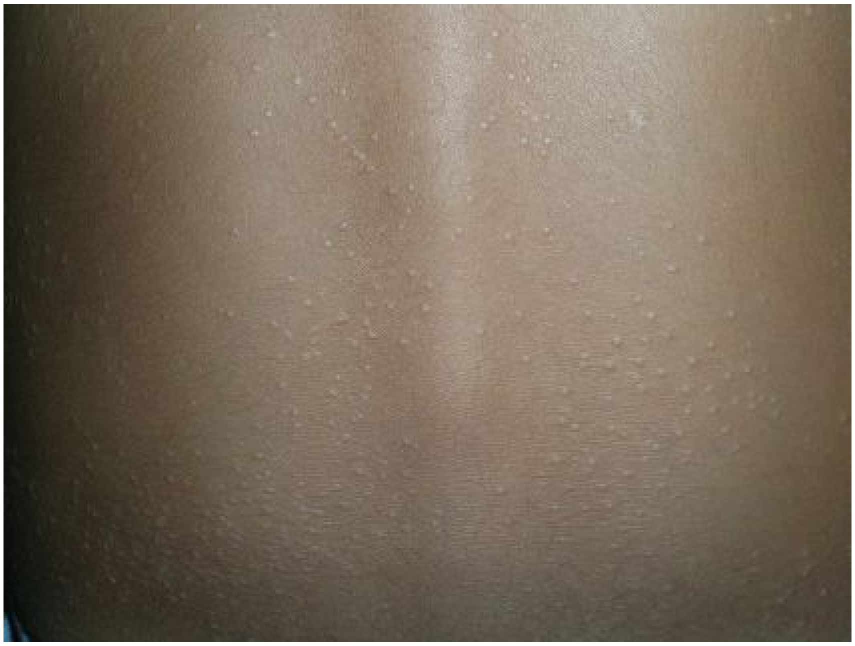

FIGURE 139-6 Lichen nitidus showing skin-colored, flat-topped papules in a linear array across mid-back of an adolescent. This is an example of Koebnerization. (*Used with permission from Richard P. Usatine, MD.*)

Lesions can be pruritic, with pruritus more common in the generalized form.

SALE (summertime actinic lichenoid eruption) or lichen nitidus actinicus has similar clinical appearance as lichen nitidus, but is seen in type IV and V skin, and is pruritic and photodistributed.

DISTRIBUTION

Flexor aspects of the upper extremities, dorsal hands, anterior trunk, and genitalia are sites most often involved.

Lichen nitidus has also been reported to occur on the palms of pediatric patients, albeit rarely.[3]

LABORATORY TESTING AND IMAGING

Other than skin biopsy, labs and imaging studies are typically not useful in the diagnosis of lichen nitidus. Biopsy shows a distinctive pattern of “ball in claw” consisting of lymphs, histiocytes, and epitheloid cells clutched in hyperplastic rete.

LICHEN STRIATUS

CLINICAL FEATURES

Clinically lichen striatus presents as a band of clustered, skin-colored to pink, slightly scaly, flat-topped papules (**Figure 139-7**).

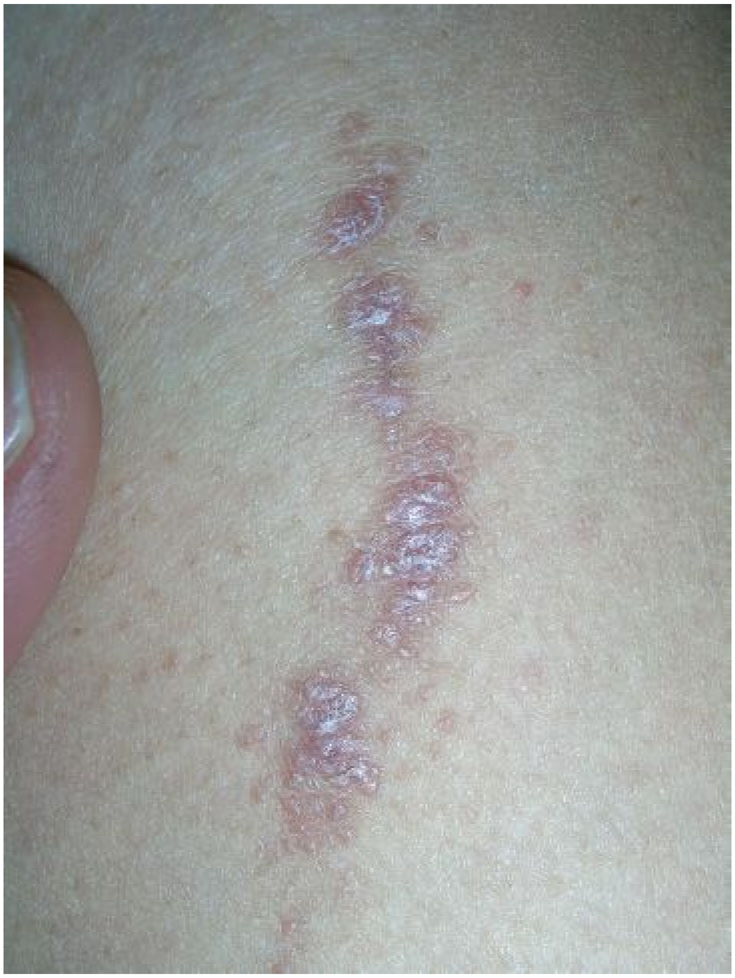

FIGURE 139-7 Lichen striatus close-up showing a linear band of pink, scaly papules. (*Used with permission from Richard P. Usatine, MD.*)

The individual papules are usually larger than that seen in lichen nitidus, ranging from 2 to 4 mm in size. They can be smooth or scaly.

Occasionally vesicles may be present.

Nail changes may be the only clinical finding and present as thickened nails with ridges and/or longitudinal split. The nail changes can occur before, after, or simultaneous with appearance of skin lesions.[4]

Lichen striatus can also be intensely pruritic.

DISTRIBUTION

Lichen striatus usually presents as a single, unilateral streak along Blaschko's lines (**Figures 139-8** and **Figure 139-9**).

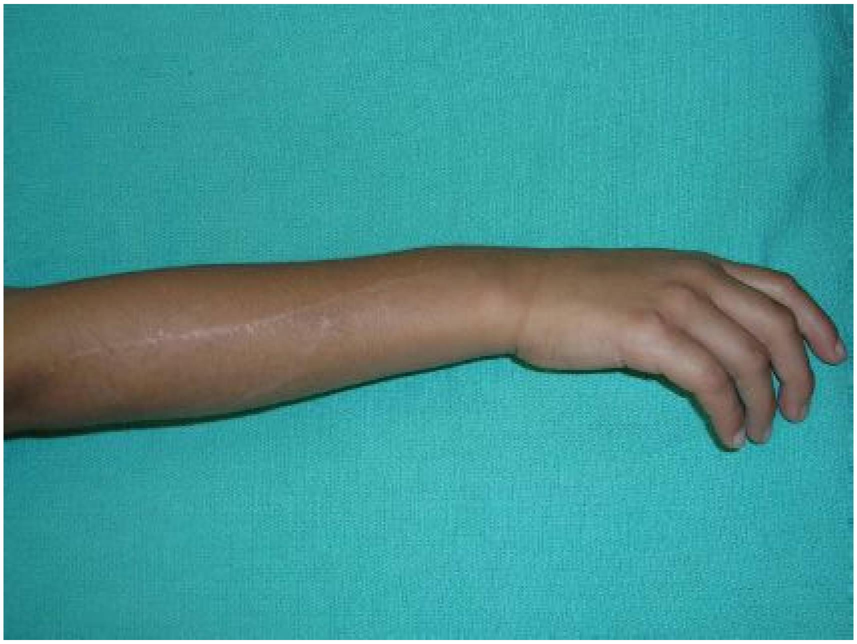

FIGURE 139-8 Lichen striatus with skin-colored to pink, slightly scaly papules coalescing into a linear plaque on the upper extremity of a young girl. (*Used with permission from Richard P. Usatine, MD.*)

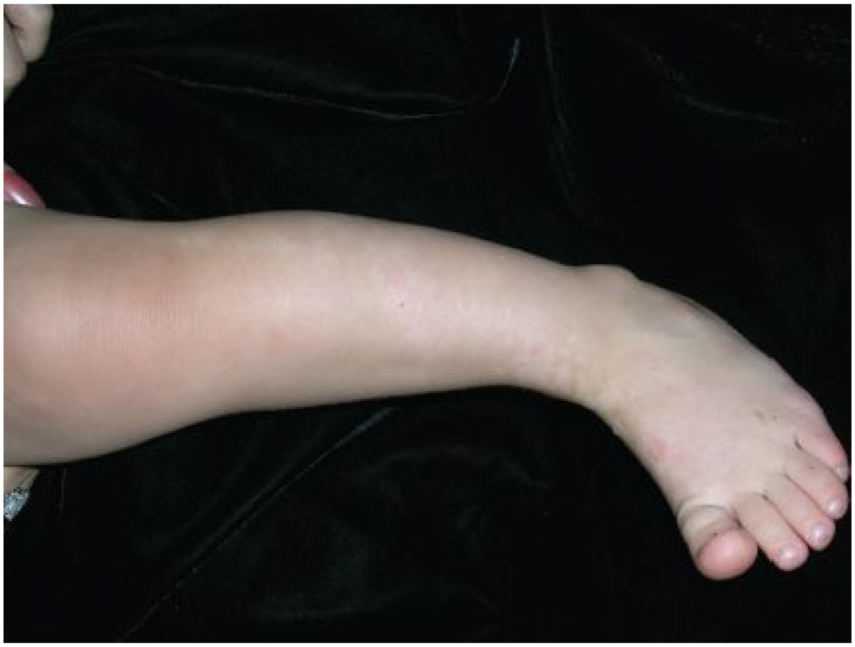

FIGURE 139-9 Lichen striatus with hypopigmented to pink, flattopped papules in a Blaschkoid distribution on the leg of an infant. (*Used with permission from Richard P. Usatine, MD*.)

The eruption tends to affect a single extremity (**Figure 139-10**), but can be seen bilaterally and involving the face1 or the trunk (**Figure 139-11**).

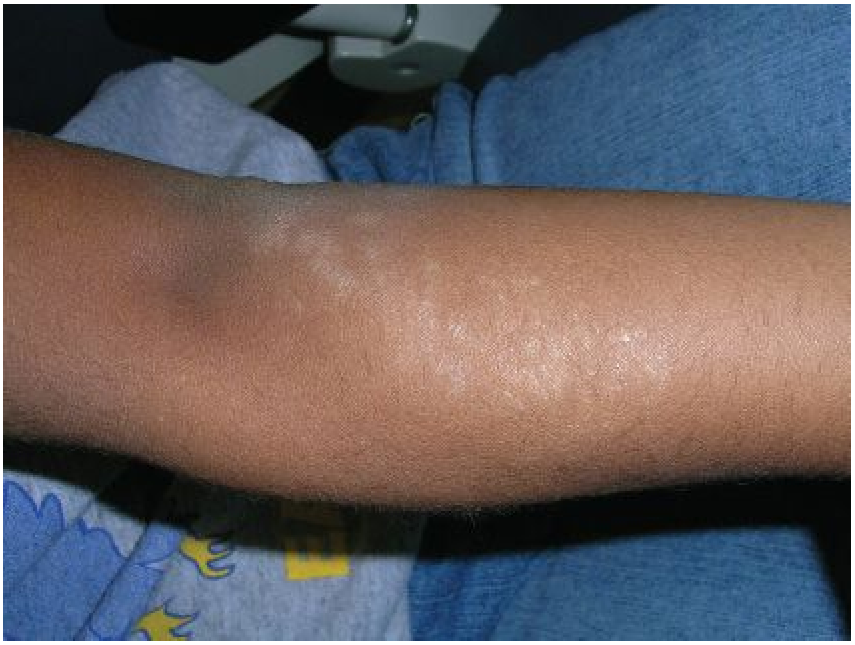

FIGURE 139-10 Lichen striatus on one arm with hypopigmented to pink, flat-topped papules in a Blaschkoid distribution. (*Used with permission from Richard P. Usatine, MD*.)

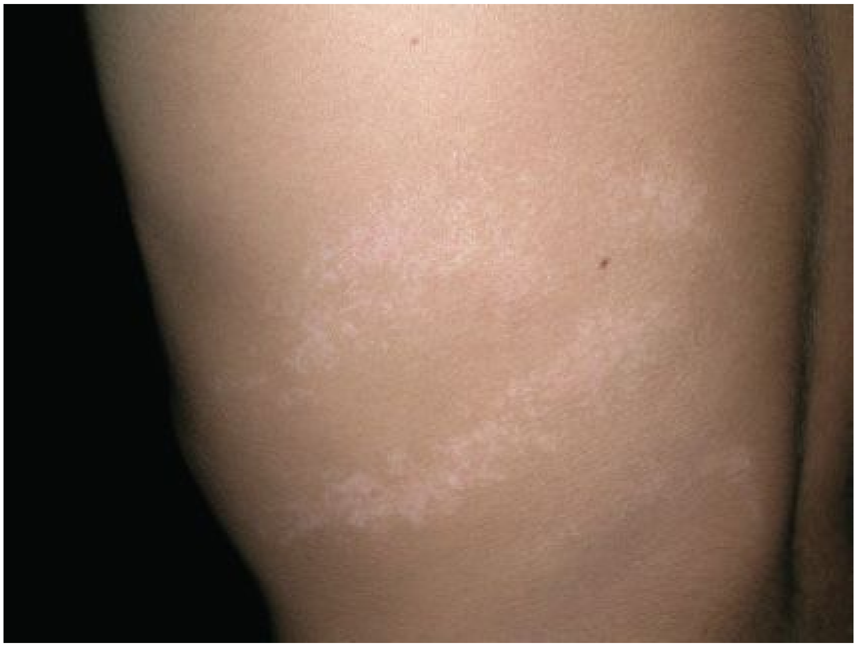

FIGURE 139-11 Lichen striatus with hypopigmented to pink, flattopped papules in a Blaschkoid distribution on the trunk of a 13-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY TESTING AND IMAGING

Usually a clinical diagnosis, labs do not play a significant role in diagnosing lichen striatus except for possible conformational skin biopsy. Imaging studies are not indicated.

DIFFERENTIAL DIAGNOSIS

LICHEN NITIDUS

- Lichen planus—Purple, polygonal, planar papules, more pruritic and larger than papules of lichen nitidus (see Chapter 138, Lichen Planus).
- Molluscum contagiosum—Smooth, skin-colored to pink, dome-shaped papules with central umbilication (see Chapter 115, Molluscum Contagiosum).
- Atopic dermatitis (popular form)—Scattered pin-head sized erythematous papules, frequently in the flexures (see Chapter 130, Atopic Dermatitis).
- Lichen spinulosus—Multiple discrete, follicular-based, skin-colored papules with central keratin spine, coalescing into circumscribed plaques, usually bilateral and symmetric.
- Keratosis pilaris—Monomorphic, roughly 1mm folliculocentric papules, most often affecting the extensor arms and thighs (**Figures 139-12** and **139-13**).

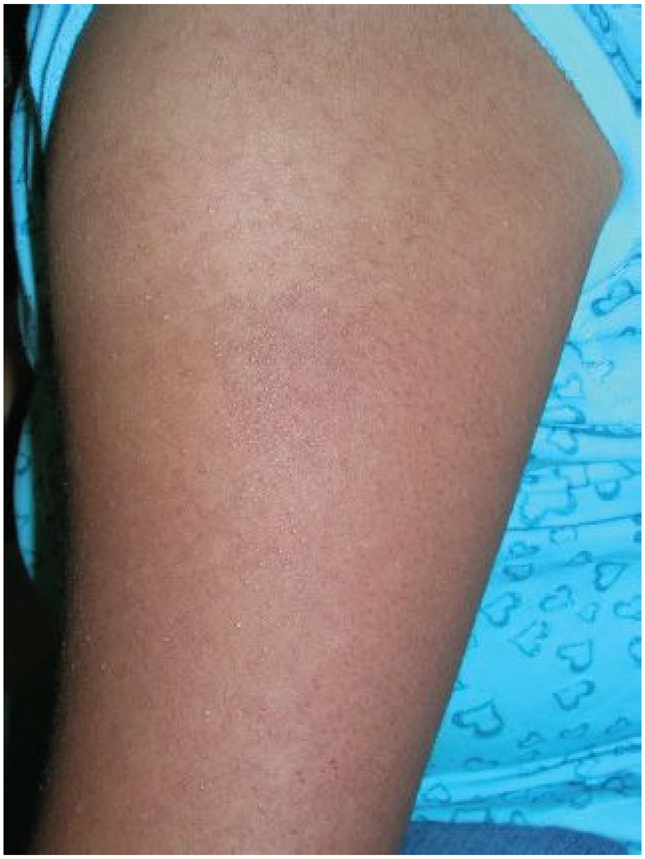

FIGURE 139-12 Keratosis pilaris on the upper arm of this young girl. Keratosis pilaris most often affects the extensor surface of the extremities,

unlike lichen nitidus, which has a predilection for the flexural surfaces of the arms. (*Used with permission from Richard P. Usatine, MD.*)

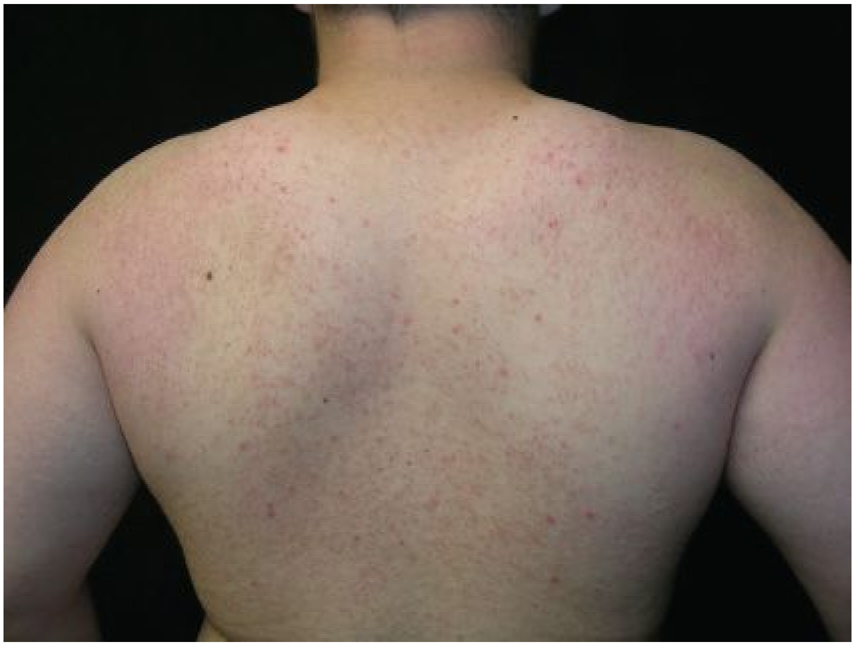

FIGURE 139-13 Keratosis pilaris on the back of this 17-year-old boy. The folliculocentric skin-colored to pink papules of keratosis pilaris can also be seen on the back. Lichen nitidus is more likely to occur on the anterior trunk although it too can occur on the back. (*Used with permission from Richard P. Usatine, MD.*)

- Pearly penile papules—Skin-colored to pink, regular papules arranged in rows on the coronal ring or at the frenulum, usually presenting after puberty.

LICHEN STRIATUS

- Linear lichen planus—Purple, polygonal, planar papules in a linear distribution.
- Linear epidermal nevus—Flesh-colored to tan to brown verrucous papules coalescing into linear plaques.
- Blaschkitis—Relapsing papulovesicular eruption in a Blaschkoid distribution.

- Inflammatory linear verrucous epidermal nevus—Erythematous, verrucous papules grouped together in a linear distribution.
- Linear Darier's disease—Autosomal dominantly inherited linear grouping of yellow-brown, greasy, hyperkeratotic papules.
- Incontinentia pigmenti—X-linked recessive found almost exclusively in females, usually presenting within a few weeks of birth. Four stages including vesicular, verrucous, hyperpigmented and hypopigmented (see Chapter 228, Incontinentia Pigmenti).

MANAGEMENT

Both lichen nitidus and lichen striatus are self-limited conditions so treatment is usually indicated for symptomatic cases only. Although more common in lichen nitidus, both entities can cause significant pruritus that generally responds well to topical corticosteroids. Aggressive measures such as surgery should be avoided as the natural history of both conditions is for spontaneous regression.

LICHEN NITIDUS

MEDICATIONS

Topical corticosteroids are usually first line in the treatment of significant pruritus. In children, it is important to use a low potency corticosteroid and avoid use to face and intertriginous areas as much as possible to avoid the potential side effects of atrophy, striae and telangiectasia.

Topical calcineurin inhibitors (TCI), such as tacrolimus and pimecrolimus, have also been shown to be effective. TCI affect the cutaneous immune response by preventing the transcription of proinflammatory cytokines, which may explain its effectiveness in lichen nitidus.[4]

- Oral antihistamines may help to abate intense itching. Children's dosing of a sedating antihistamine can be used at bedtime, but a non-sedating antihistamine would be preferred during the day.
- Generalized lichen nitidus not responding to topical corticosteroids may do well with narrowband UVB or PUVA.
- Acitretin, isotretinoin, and other retinoids have been used rarely.
- Immunomodulatory treatments that have been reported in severe cases include cyclosporine, dinitrochlorobenzene, itraconazole, and isoniazid.[5]

REFERRAL

- Referral may be indicated for confirmation of diagnosis. One may also seek dermatology referral for generalized pruritus that has not responded to topical medications and/or oral antihistamines. In that scenario, narrowband UVB or PUVA or other systemic therapy may be necessary, and this therapy should be facilitated and monitored by a dermatologist.

LICHEN STRIATUS

MEDICATIONS

- Topical corticosteroids are also the mainstay of treatment for lichen striatus. They have been used under occlusion to accelerate its spontaneous resolution. As per the preceding, precautions must be taken to avoid unwanted side effects.
- Topical calcineurin inhibitors have been reported to be effective as well.

REFERRAL

- As with lichen nitidus or any other cutaneous eruption, dermatology consult may be appropriate to confirm a diagnosis. In lichen striatus in particular, it would be of benefit to rule out some of the other entities in the differential, such as incontinentia pigmenti and linear epidermal nevus, which can present with or develop additional findings, including systemic findings.

PREVENTION AND SCREENING

- As the exact etiology and pathogenesis of both conditions remains theoretical at best, prevention and screening measures are not practical at this time.

PROGNOSIS

Lichen nitidus and lichen striatus purport excellent prognoses as an eventual spontaneous resolution is the natural progression of both conditions, usually within a few years.

FOLLOW-UP

Follow-up should be made on an as needed basis for symptomatic patients to ensure that their pruritus is adequately controlled.

PATIENT EDUCATION

- Reassure patients and parents that lichen nitidus and lichen striatus are self-limited.
- Offer low potency topical steroids if pruritus is a problem.

SECTION 9 BENIGN NEOPLASMS

140 JUVENILE XANTHOGRANULOMA

Olvia Revelo, MD
Richard P. Usatine, MD

PATIENT STORY

A 2-year-old healthy Caucasian male is brought in by his mother for evaluation of a solitary mass-like lesion that developed on his scalp over the past couple of months. The nodule was asymptomatic. His mother denies other symptoms or medical problems. Physical examination was normal except for a 1cm yellow, dome-shaped, smooth nodule on scalp apex (**Figure 140-1**). Clinical diagnosis of juvenile xanthogranuloma was made and mother was given reassurance that lesion would regress spontaneously over the next months.

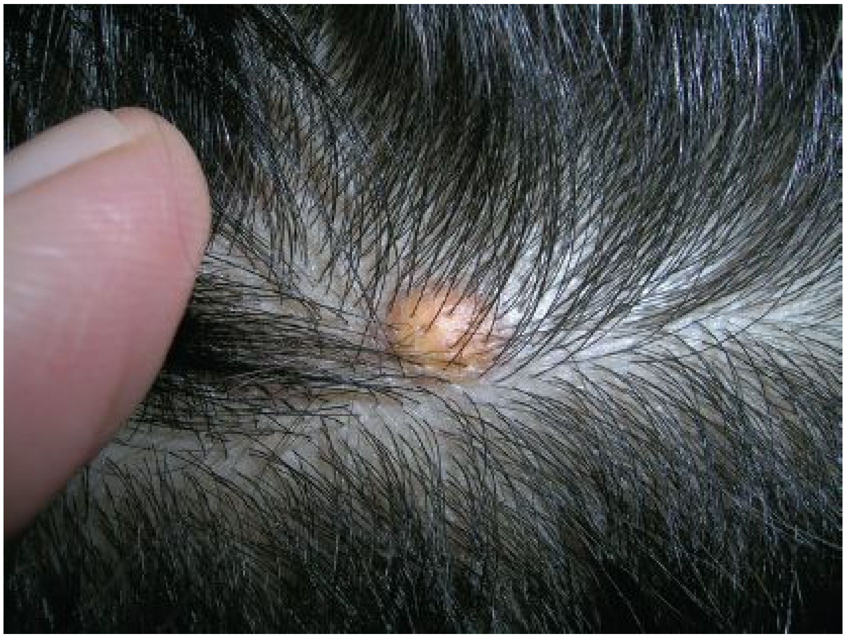

FIGURE 140-1 Juvenile xanthogranuloma on the scalp of a 2-year-old boy. Note the yellow color. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

- Juvenile Xanthogranuloma (JXG) is considered a benign, non-Langerhan cell, histiocyte proliferation disorder.
- It usually presents as a solitary or few dome shaped red to yellow papules involving the upper body, although many variants are known to exist.
- Juvenile Xanthogranuloma usually only involves the skin. These lesions generally resolve spontaneously within months to years.
- Rarely JXG may be associated with systemic findings such as involvement of the central nervous system, liver, spleen, lungs, eyes, oropharynx, and muscle.[1] Only 5 patients (3.9%) of 129 patients were found to have systemic involvement in a retrospective review of a German pediatric tumor registry.[2]
- There is a 0.3–0.5 percent incidence of ocular JXG. Children at maximum risk are 2 years of age or younger, have multiple skin lesions, and are newly diagnosed JXG.[3] Two percent of JXG involving the eye are complicated by blindness usually from hyphema or glaucoma.[4]
- Juvenile Xanthogranuloma may also be associated with other disorders including neurofibromatosis 1, juvenile chronic myelogenous leukemia (CML), urticaria pigmentosa, insulin-dependent diabetes mellitus, aquagenic pruritis, and possibly cytomegalovirus infection. Children with JXG associated with NF1 have a 20 time increased risk of developing CML.[1]
- The xanthomas of JXG are not associated with primary hyperlipidemia.[4]

SYNONYMS

Nevoxanthoendothelioma, xanthoma multiplex, juvenile xanthoma, congenital xanthoma tuberosum, xanthoma neviforme, and juvenile giant-cell granuloma.

EPIDEMIOLOGY

- Disease incidence is unknown. JXG may be under recognized and under reported. The relative incidence from a retrospective review of 26,400 patients was 0.52 percent.[2,5]
- It commonly affects children 2 years or younger with 75 percent of cases diagnosed by age 1, and 15 percent of cases presenting at birth.[4]
- There may be a slight male predilection in children. Estimates run between 1.5 to 4: 1 male to female ratio.[1]
- It may rarely present in adults.

ETIOLOGY AND PATHOPHYSIOLOGY

- The pathogenesis is unknown.
- There is still controversy about the origin of the cell involved and histiologic criteria since there is a mixed pattern among the non-Langerhans cell histiocyte proliferation disorders with many authorities considering them all a spectrum of the same disorder.[2,4]

DIAGNOSIS

CLINICAL FEATURES

- There are two distinct variants in presentation. First there is a small nodular form with multiple pink, 2 to 5mm, dome-shaped papules that become red-brown and later turn yellow. They mainly affect the upper trunk (**Figure 140-2**).

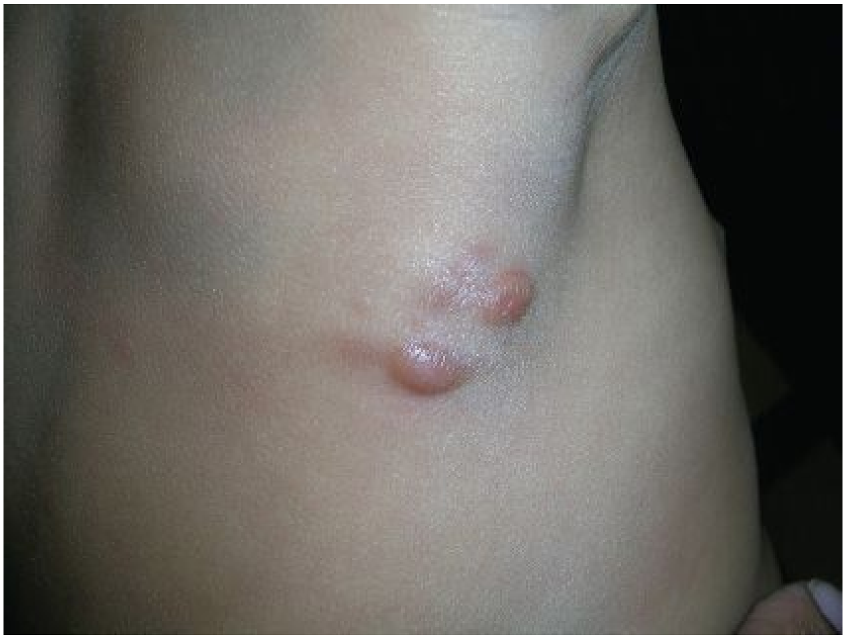

FIGURE 140-2 Multiple nodular juvenile xanthogranuloma on the trunk of a 20-month-old African American boy. Note the pink coloration at an early stage of development. (*Used with permission from Richard P. Usatine*, *MD*.)

- The second variant is the large nodular form in which a solitary or a couple of 1 to 2 cm nodules develop (**Figure 140-3**).

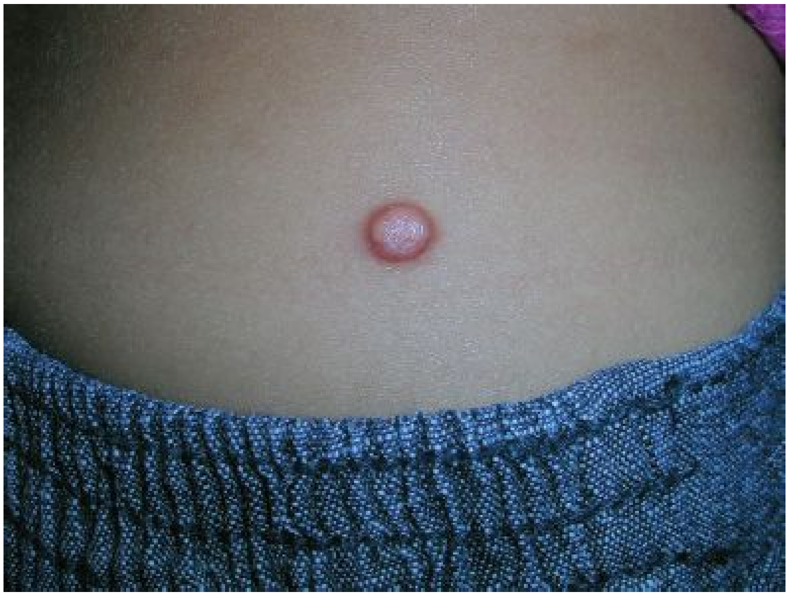

FIGURE 140-3 Solitary juvenile xanthogranuloma on the trunk with overlying scale and a red-brown color. Dermatofibroma is on the differential diagnosis. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th Edition, Figure 15-29, McGraw-Hill, 2008*.)

- Both variants may coexist at the same time.

DISTRIBUTION

- Areas most commonly involved include head, face (**Figure 140-4**), neck, upper torso, upper and lower extremities, and rarely in the oral mucosa.[2,4–7]

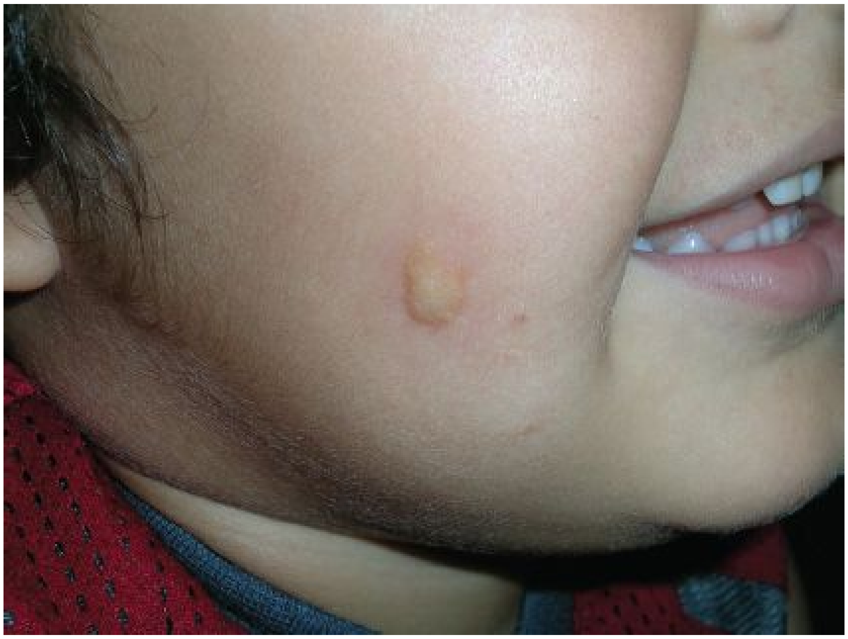

FIGURE 140-4 Solitary juvenile xanthogranuloma on the face of a 2.5 year old boy with obvious yellow coloration. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY TESTING

- Clinical diagnosis can be supplemented by biopsy (**Figures 140-5** and **140-6**) and histologic examination for definitive diagnosis.

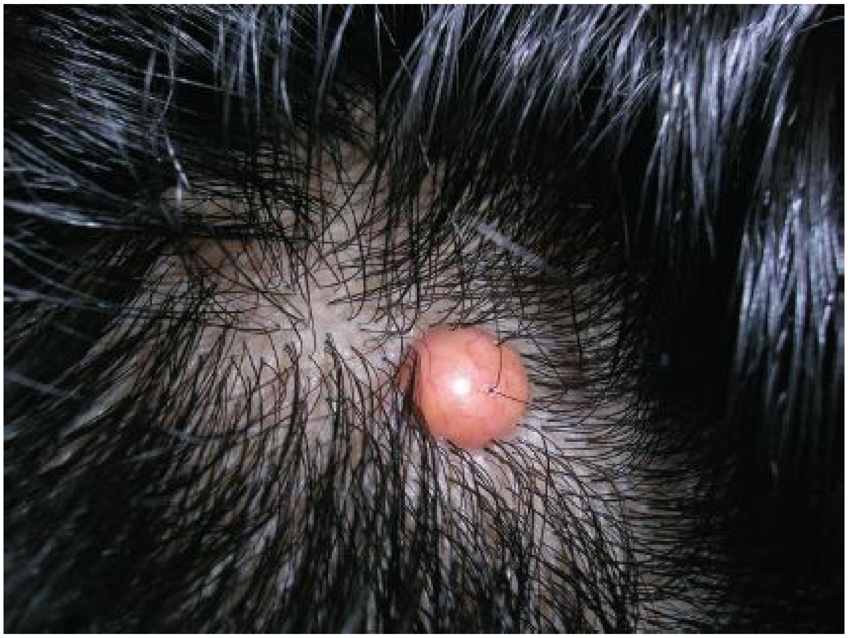

FIGURE 140-5 Juvenile xanthogranuloma on the scalp of a 2-year-old boy. Note the yellow color and the telangiectasias. This was biopsy proven. (*Used with permission from Richard P. Usatine, MD*.)

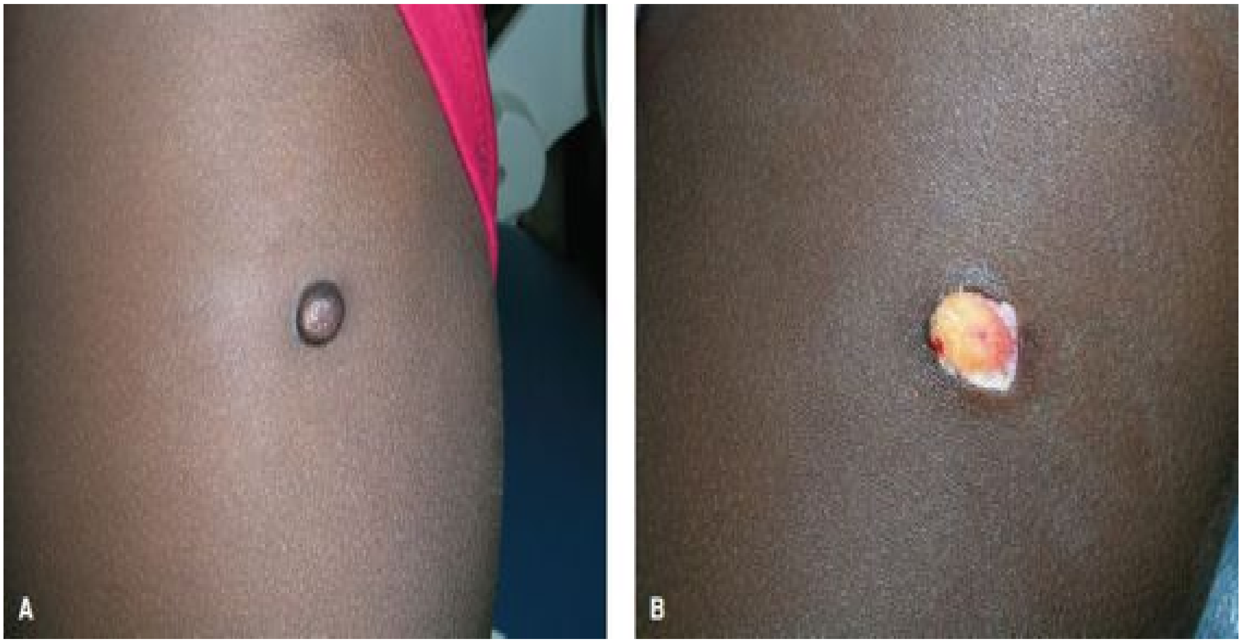

FIGURE 140-6 A. Six-month-old girl presented with growing tumor on her trunk. No yellow color was visible within the dark skin of the tumor. B. Yellow color of juvenile xanthogranuloma visible after shave biopsy using local anesthesia. (*Used with permission from Richard P. Usatine, MD*.)

IMAGING

- Consider imaging if systemic involvement is suspected by clinical symptoms.

DIFFERENTIAL DIAGNOSIS

- Juvenile Xanthogranuloma may be confused with other histiocytic proliferating disorders such as
  - Langerhan Cell Histiocytosis—These infants typically present with refractive scalp seborrheic-like dermatitis associated with diaper dermatitis and cutaneous xanthomatous papules. It is frequently associated with systemic symptoms such as bone lesions, hepatosplenomegaly, and diabetes insipidus (see Chapter 214, Langerhans Cell Histiocytosis).[5,8,9]
  - Generalized Eruptive Histiocytosis—This disorder usually involves older children and even adults and present as recurrent, multiple, red to brown papules over upper trunk, face, and proximal extremities. These lesions may leave a hyperpigmented scar behind.[4,5]
  - Benign Cephalic Histiocytosis—This entity typically involves erythematous macules/papules on the face, and may also appear on the ears, neck, trunk and upper extremities (**Figure 140-7**).[4,5]

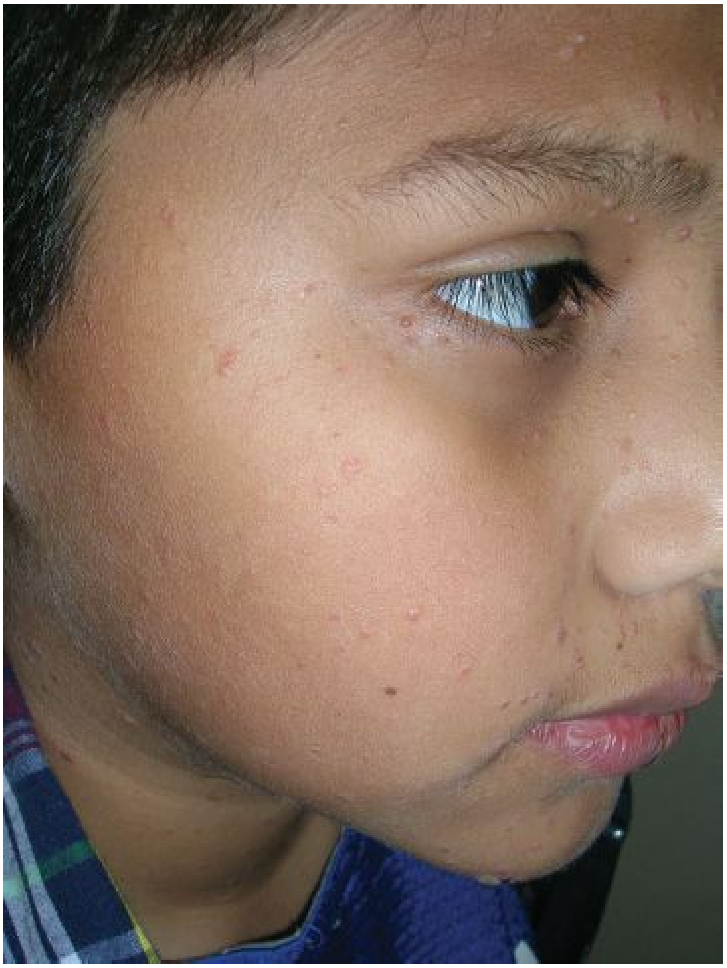

FIGURE 140-7 Benign cephalic histiocytosis on the face of 8-year-old boy, biopsy proven. (*Used with permission from Richard P. Usatine, MD.*)

  - Xanthoma disseminatum—Rare condition including triad of cutaneous and mucous membrane xanthomas along with diabetes insipidus. Xanthomas are usually numerous, symmetric and involve the face along with flexural and intertriginous skin.[4,5]
- It can also look similar to molluscum contagiosum, Spitz nevus, dermatofibroma (**Figure 140-3**), keloid, and pyogenic granuloma.[4] Histologic examination may be the only way to differentiate between entities.

MANAGEMENT

- Juvenile Xanthogranuloma, when only involving the skin, is usually a self-limited proliferation and requires no therapy. Look for systemic involvement or other systemic disorders. If no other organ is involved and there is no other risk associated with other disorders, then patient is given reassurance with good prognosis. Granulomas usually regress in 3 months to 6 years.[2,4–7] SOR Ⓐ
- If systemic involvement is found, then referral to appropriate specialist for monitoring, resection or other ablative therapy is indicated.[1,5,10] SOR Ⓐ
- Isolated cases have reported use of various chemotherapy agents (i.e., Cladribine), high dose prednisone, and cyclosporine or radiation therapy for systemic cases.[4,8] SOR Ⓒ
- Surgical excision may be pursued for cosmetic or compressive indications. SOR Ⓑ
- Routine referral for asymptomatic patients to an ophthalmologist is not recommended. Referral to ophthalmology for eye examination may be consider in patients 2 years old or younger, at time of diagnoses, or in patients that have multiple lesions because they may be at increased risk.[3,5] SOR Ⓐ

PROGNOSIS

Prognosis for cutaneous JXG is good, with high likelihood of spontaneous resolution of lesions without scarring. When there is systemic involvement prognosis is variable depending on degree of disease and organs involved.

FOLLOW-UP

Follow-up for resolution of lesion and development of new systemic or ocular symptoms as needed.

PATIENT EDUCATION

Reassure patient that if this is only confined to the skin there is a good prognosis and only rarely affects other organ systems. Reassure that lesions will resolve with little to no scar. At times nodules may develop superficial scaling or crusting which can be ameliorated with emollients (**Figure 140-3**). Lesions are usually asymptomatic.

141 KELOIDS

Richard P. Usatine, MD
E.J. Mayeaux, Jr., MD

PATIENT STORY

A large keloid (**Figure 141-1A**) has been present on the upper ear of this 14-year-old boy for more than 2 years, since he experienced trauma to this area. The keloid was excised in the office with local anesthetic and the defect sutured using 5-0 Prolene (**Figure 141-1B**). The cosmetic result was excellent and the patient was happy.

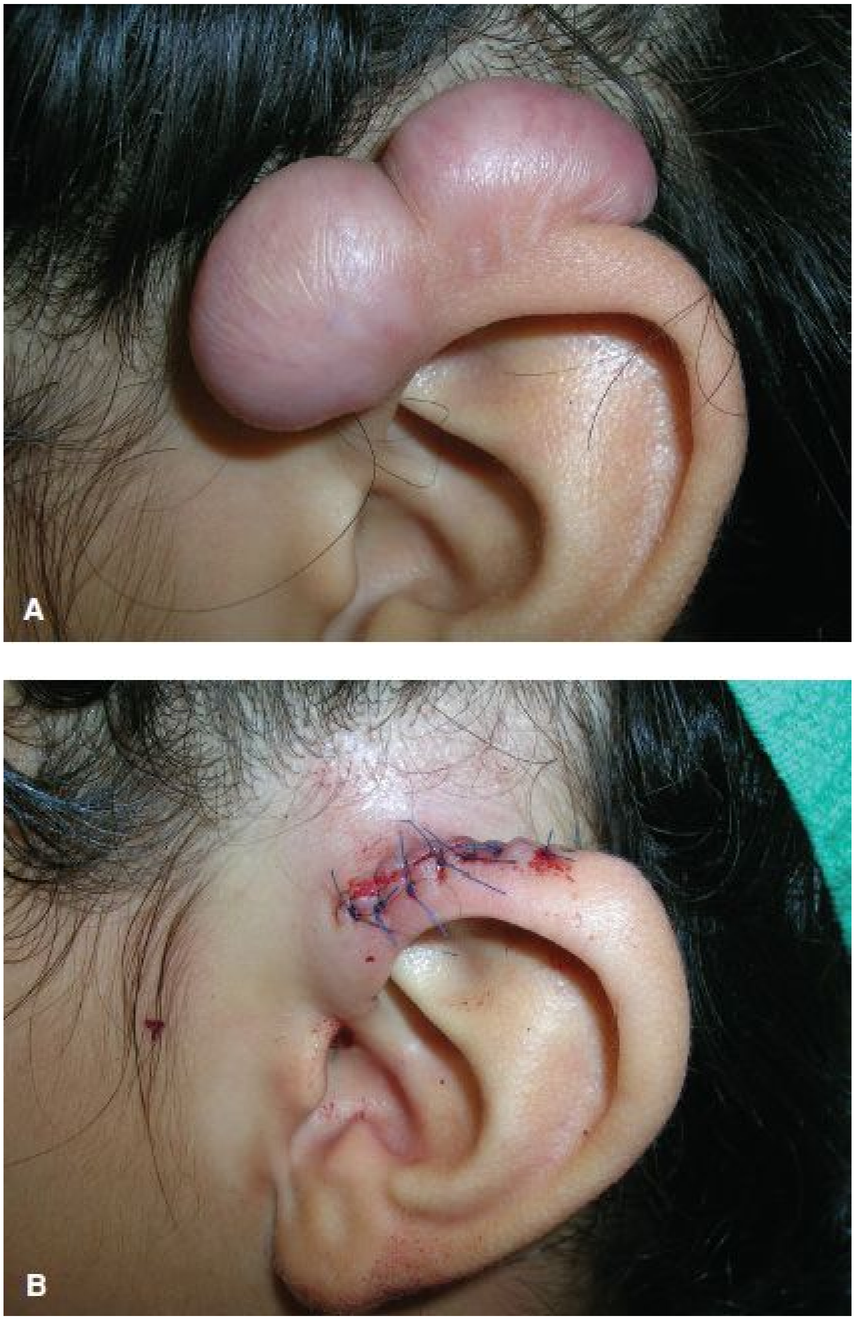

FIGURE 141-1 A. A large keloid has been present on the upper ear of this 14-year-old boy for more than 2 years, since he experienced trauma to this area. B. The keloid was excised in the office with local anesthetic and the defect sutured using 5-0 Prolene. The cosmetic result was excellent. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Keloids are benign dermal fibroproliferative tumors that form in scar because of altered wound healing. They form as a result of overproduction of extracellular matrix and dermal fibroblasts that have a high mitotic rate.

SYNONYMS

Cheloid.

EPIDEMIOLOGY

- Individuals with darker pigmentation are more likely to develop keloids. Sixteen percent of black persons reported having keloids in a random sampling.[1]
- Men and women are generally affected equally except that keloids are more common in young adult women—probably secondary to a higher rate of piercing the ears (**Figure 141-2**).[2]

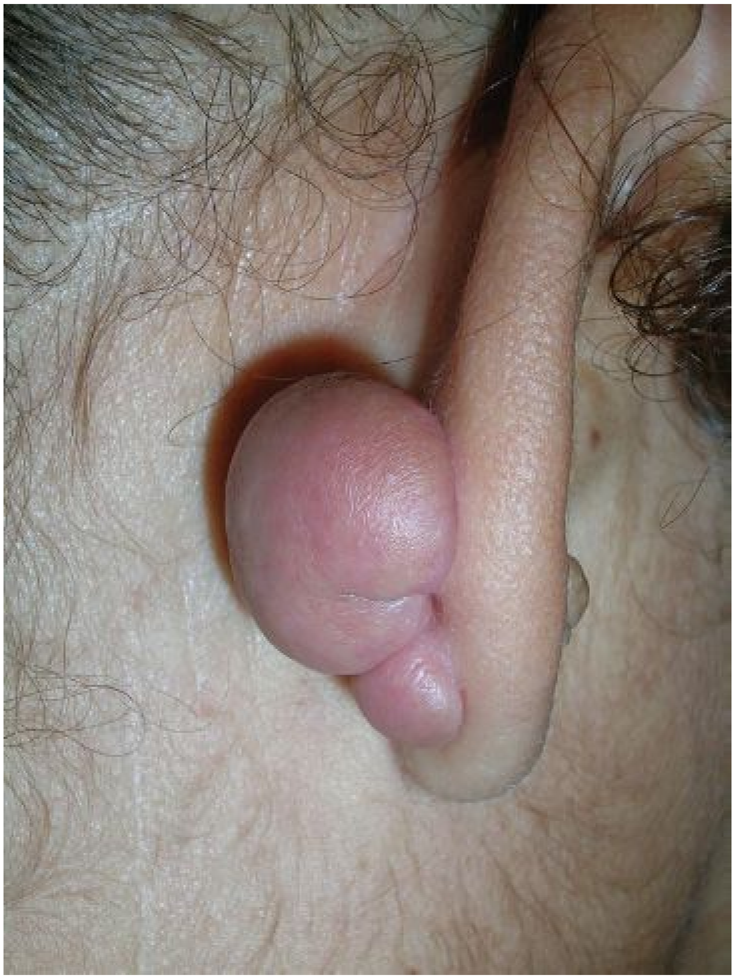

FIGURE 141-2 A keloid on the earlobe that started from piercing the ear. (*Used with permission from Richard P. Usatine, MD*.)

- Highest incidence is in individuals ages 10 to 20 years.[2,3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Keloids are dermal fibrotic lesions that are a variation of the normal wound-healing process in the spectrum of fibroproliferative disorders.
- Keloids are more likely to develop in areas of the body that are subjected to high skin tension such as over the sternum.

- These can occur even up to a year after the injury and will enlarge beyond the scar margin. Burns and other injuries can heal with a keloid in just one portion of the area injured.
- Wounds subjected to prolonged inflammation (acne cysts) are more likely to develop keloids.

RISK FACTORS[3]

- Darker skin pigmentation (African, Hispanic, or Asian ethnicity) (**Figure 141-3**).

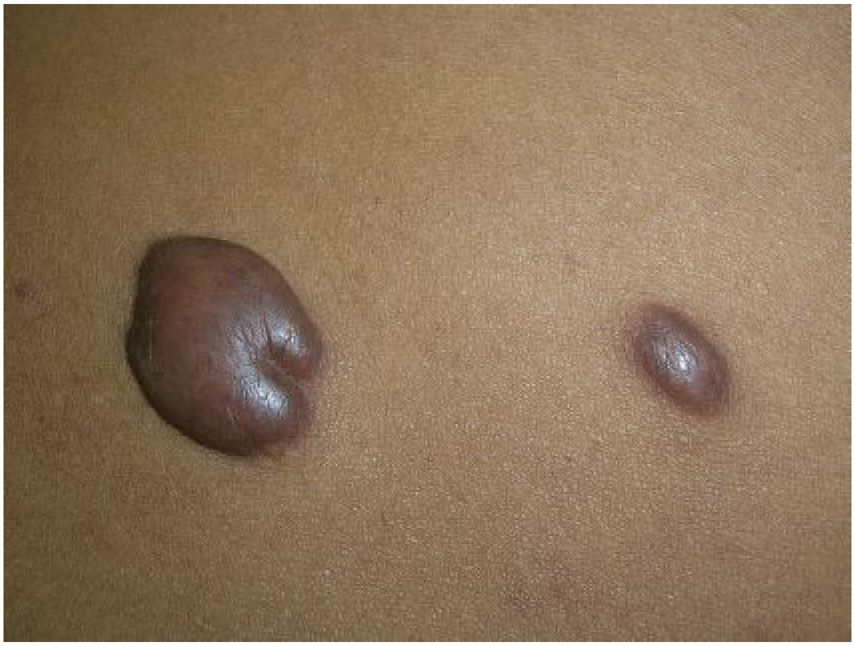

FIGURE 141-3 Two keloids on the back of this young African American woman. (*Used with permission from Richard P. Usatine, MD.*)

- A family history of keloids.
- Wound healing by secondary intention.
- Wounds subjected to prolonged inflammation.
- Sites of repeated trauma.

- Pregnancy.
- Body piercings (**Figure 141-4**).

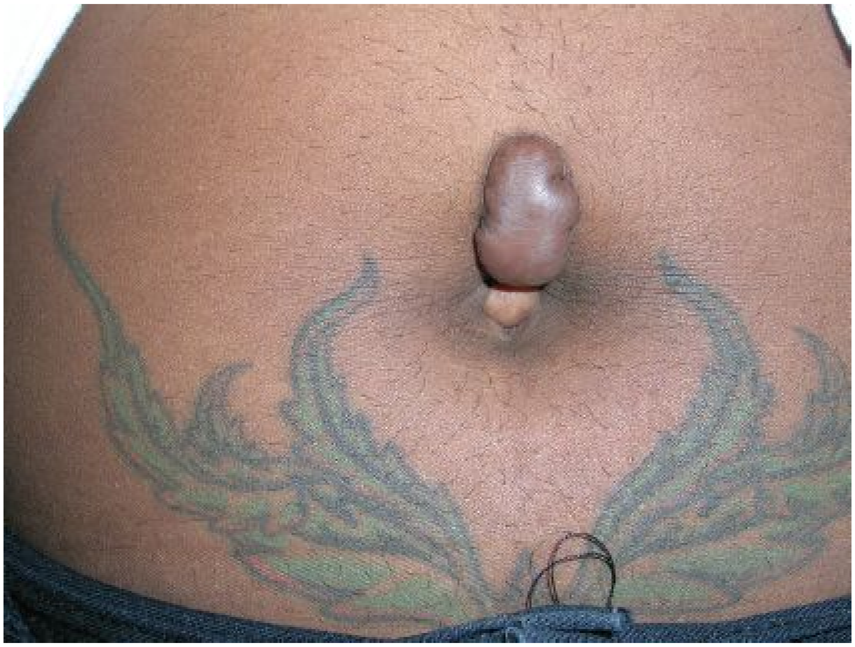

FIGURE 141-4 This keloid formed at the site of a belly button piercing. (*Used with permission from Richard P. Usatine, MD.*)

DIAGNOSIS

CLINICAL FEATURES

- Some keloids present with pruritic pain or a burning sensation around the scar.
- Initially manifest as erythematous lesions devoid of hair follicles or other glandular tissue.
- Papules to nodules to large tuberous lesions.
- Range in consistency from soft and doughy to rubbery and hard. Most often, the lesions are the color of normal skin but can become brownish red or bluish and then pale as they age.[4]

- May extend in a claw-like fashion far beyond any slight injury.
- Lesions on neck, ears, and abdomen tend to become pedunculated.

TYPICAL DISTRIBUTION

- Anterior chest, shoulders, flexor surfaces of extremities, anterior neck, earlobes, and wounds that cross skin tension lines.

LABORATORY TESTING

- Biopsy is rarely needed to make a diagnosis because the clinical appearance is usually distinctive and clear.

DIFFERENTIAL DIAGNOSIS

- Hypertrophic scars can appear similar to keloids but are confined to the site of original injury.
- Acne keloidalis nuchae is an inflammatory disorder around hair follicles of the posterior neck that results in keloidal scarring (**Figure 141-5**). Although the scarring is similar to keloids the location and pathophysiology are unique. This process can also cause alopecia.

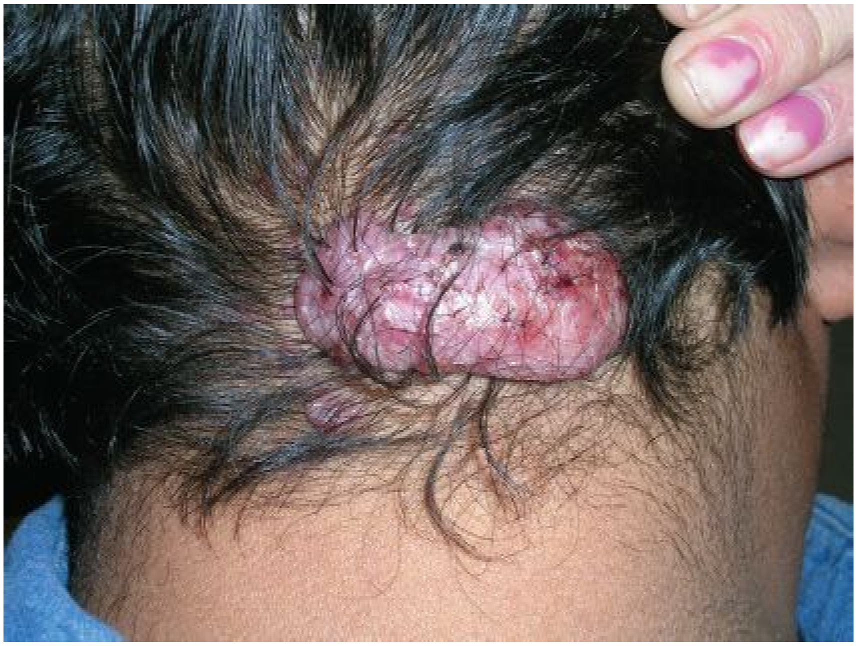

FIGURE 141-5 Acne keloidalis nuchae on the posterior neck of this young Hispanic man. (*Used with permission from Richard P. Usatine, MD.*)

- Dermatofibromas are common button-like dermal nodules usually found on the legs or arms. They may umbilicate when the surrounding skin is pinched. These often have a hyperpigmented halo around them and are less elevated than keloids.

MANAGEMENT

- Patients frequently want keloids treated because of symptoms (pain and pruritus) and concerns about appearance.
- A 2006 systematic review of 396 studies and an accompanying meta-analysis of 36 articles concluded that no optimal evidence-based therapy exists and recommended choosing treatment based on cost and adverse effect profile.[5]

NONPHARMACOLOGIC

- Silicone gel sheeting as a treatment for hypertrophic and keloid scarring is supported by poor-quality trials susceptible to bias. There is only weak evidence of a benefit of silicone gel sheeting as prevention for abnormal scarring in high-risk individuals.[6,7] SOR Ⓑ

MEDICATIONS

- Intralesional steroid injections—Intralesional injection of triamcinolone acetonide (10 to 40 mg/mL) may decrease pruritus, as well as decreasing size and flattening of keloids (**Figure 141-6**). SOR Ⓒ This may be repeated monthly as needed.[5,8]

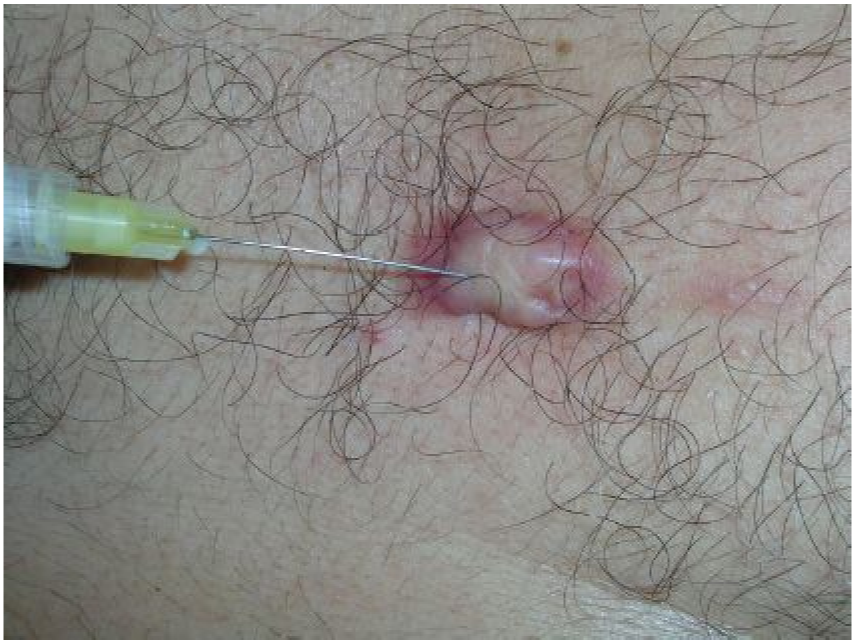

FIGURE 141-6 Triamcinolone injected into this symptomatic keloid on the chest. Note how the keloid is blanching white, demonstrating that the steroid is properly injected into the body of the keloid. A Luer lock syringe is used to avoid the needle popping off during the injection under pressure and a 27-gauge needle is used to minimize patient discomfort. (*Used with permission from Richard P. Usatine, MD.*)

- Earlobe keloids can be treated with imiquimod 5 percent cream following tangential shave excision on both sides of the earlobe.[9,10] SOR Ⓑ Patients were instructed to administer imiquimod 5 percent cream to the excision sites the night of the surgery and daily for 6 to 8 weeks postsurgery. Imiquimod 5 percent cream only temporarily prevented the recurrence of presternal keloids after excision.[11] SOR Ⓒ

COMPLEMENTARY/ALTERNATIVE THERAPY

- No available evidence supports using nonprescription products such as Mederma and other creams, gels, and oils, to treat scars.[7] Limited clinical trials have failed to demonstrate lasting improvement of established keloids and hypertrophic scars with onion extract topical gel (e.g., Mederma) or topical vitamin E.[3] SOR Ⓑ

SURGICAL

- Cryosurgery and intralesional triamcinolone have been used to treat smaller keloids (e.g., secondary to acne) with similar success to other therapies.[3,12] SOR Ⓑ
- Combined cryosurgery and intralesional triamcinolone—The lesion is initially frozen with liquid nitrogen spray and allowed to thaw. Then it is injected with triamcinolone acetate (10 to 40 mg/mL). SOR Ⓒ
- Earlobe keloids can be surgically excised with a shave or excisional technique and then injected with triamcinolone acetate (10 to 40 mg/mL) after hemostasis is obtained. The triamcinolone injection can be repeated in 1 month to decrease the chance of recurrence.[8] SOR Ⓑ
- Keloids on the upper ear can be excised and the skin closed with sutures (**Figure 141-1**). SOR Ⓒ
- Pulsed-dye laser treatment can be beneficial for keloids.[13] Combination treatment with pulsed-dye laser plus intralesional therapy with corticosteroids and/or fluorouracil 50 mg/mL 2 to 3 times per week may be superior to either approach alone.[14] SOR Ⓒ

- Keloids can be treated with cryosurgery alone or in combination with intralesional steroids. In one, small, controlled study, 10 patients with keloids were treated with intralesional steroid and cryosurgery vs. intralesional steroid or cryosurgery alone.[15] SOR B Patients were treated at least 3 times 4 weeks apart. Based upon keloid thickness, the keloids responded significantly better to combined cryosurgery and triamcinolone versus triamcinolone alone or cryotherapy alone. Pain intensity was significantly lowered with all treatment modalities. Pruritus was lowered only with the combined treatment and intralesional corticosteroid alone.[15]
- In another study, 20 patients with hypertrophic and keloidal scars received two 15-second cycles (total 30 seconds) of cryosurgery treatments once monthly for 12 months with intralesional injections of 10 to 40 mg/mL triamcinolone once monthly for 3 months.[16] SOR B Topical application of silicone gel was added 3 times daily for 12 months. The control group included 10 patients who received treatment with silicone sheeting only. After 1 year there was improvement in all the parameters, especially in terms of symptoms, cosmetic appearance, and associated signs, compared to baseline and compared to the control group.[16] SOR B
- Layton et al. reported that the intralesional injection of a steroid is helpful but cryotherapy is more effective (85% improvement in terms of flattening) for recent acne keloids located on the back.[17] Treatment with intralesional triamcinolone was beneficial, but the response to cryosurgery was significantly better in early, vascular lesions.[17] SOR B
- If the keloid is older and/or firmer, it may not respond to injection therapy as well as softer and newer lesions. It may help to pretreat the keloid with cryotherapy. It is not necessary to freeze a margin of normal tissue. After liquid nitrogen or another freezing modality is applied to the keloid, it is allowed to thaw and develop edema. This generally takes 1 to 2 minutes, which allows an easier introduction of intralesional steroids into the lesions. SOR C
- In one double-blind, clinical trial, 40 patients were randomized to receive intralesional triamcinolone (TAC) or a combination of TAC and 5-fluorouracil (5-FU).[18] Both groups received injections at weekly intervals for 8 weeks and lesions were assessed for erythema, pruritus, pliability, height, length, and width. Both groups showed an acceptable

improvement in nearly all parameters, but these were more significant in the TAC plus 5-FU group ($P < 0.05$ for all except pruritus and percentage of itch reduction). Good-to-excellent improvement was reported by 20 percent of the patients receiving TAC alone and by 55 percent of the patients in the group receiving TAC plus 5-FU.[18] SOR B

- Earlobe keloids may be excised with a shave excision and injection of the base with steroid (**Figure 141-7**). It is hard to get much volume of steroid into the base of these keloids, so 40 mg/mL triamcinolone is preferred as the concentration for injection. SOR C Another option is to use radiofrequency electrosurgery technique with a pure cutting setting (and using steroid in the anesthetic).

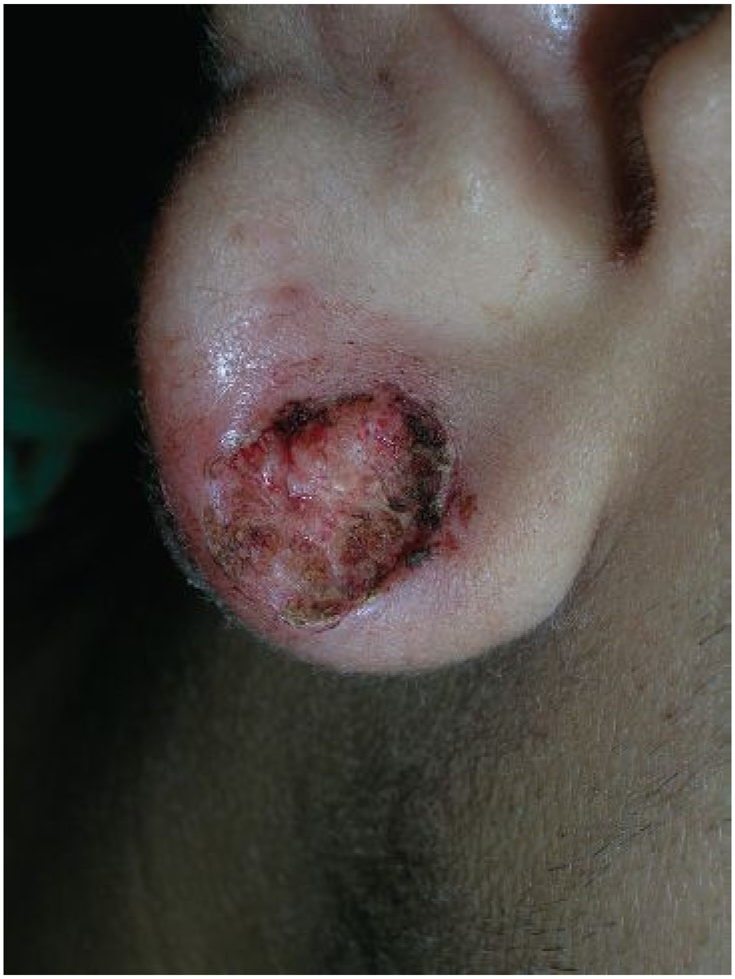

FIGURE 141-7 Ear lobe keloid was shaved off with a DermaBlade and the base was treated with electrosurgery to stop the bleeding. Then 0.1 mL of

40 mg/mL triamcinolone was injected into the base of the remaining keloid. (*Used with permission from Richard P. Usatine, MD.*)

- According to one article, simple excision of earlobe keloids can result in recurrence rates approaching 80 percent.[19] A randomized, prospective trial comparing steroid injections versus radiation therapy found that 2 of 16 keloids (12.5%) recurred after surgery and radiation therapy, whereas 4 of 12 (33%) recurred after surgery and steroid injections. These results did not produce a statistically significant difference. No alteration of skin pigmentation, wound dehiscence, or chronic dermatitis was observed in any patient in either group.[19] Although radiation therapy was considered easy to obtain in this study, it is reasonable to use steroid injections in office practice.

PREVENTION

- Avoiding trauma, including surgical trauma, whenever possible may decrease keloids in susceptible individuals.

PROGNOSIS

- A 2006 systematic review of 396 studies and an accompanying meta-analysis of 36 articles concluded that any treatment gave patients an overall 70 percent (95% confidence interval, 49% to 91%) chance of improvement.[5]

FOLLOW-UP

- Follow-up is based on the chosen treatment. Follow-up for intra-lesional steroid injections is usually in 1 month.

PATIENT EDUCATION

- Advise patients to avoid local skin trauma, for example, ear piercing, body piercing, and tattoos, and to control inflammatory acne.

142 PYOGENIC GRANULOMA

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A young girl is brought in by her mother to see their pediatrician for a red growth on the face that has been there for two months (**Figure 142-1**). The red growth bleeds easily if traumatized. The pediatrician recognizes the typical features of a pyogenic granuloma and presents various treatment options to the mother including excision with biopsy. It is clear that the child will not stay still for local anesthetic with the needle but is willing to allow the physician to use a Cryo Tweezer to freeze the pyogenic granuloma. The pediatrician places the Cryo Tweezer in liquid nitrogen and applies the device to the pyogenic granuloma. As the child is cooperative with the procedure a second freeze is performed in the same manner. On follow-up visit in 3 weeks, the pyogenic granuloma is gone. The mother is warned if there is regrowth to return for further evaluation and treatment.

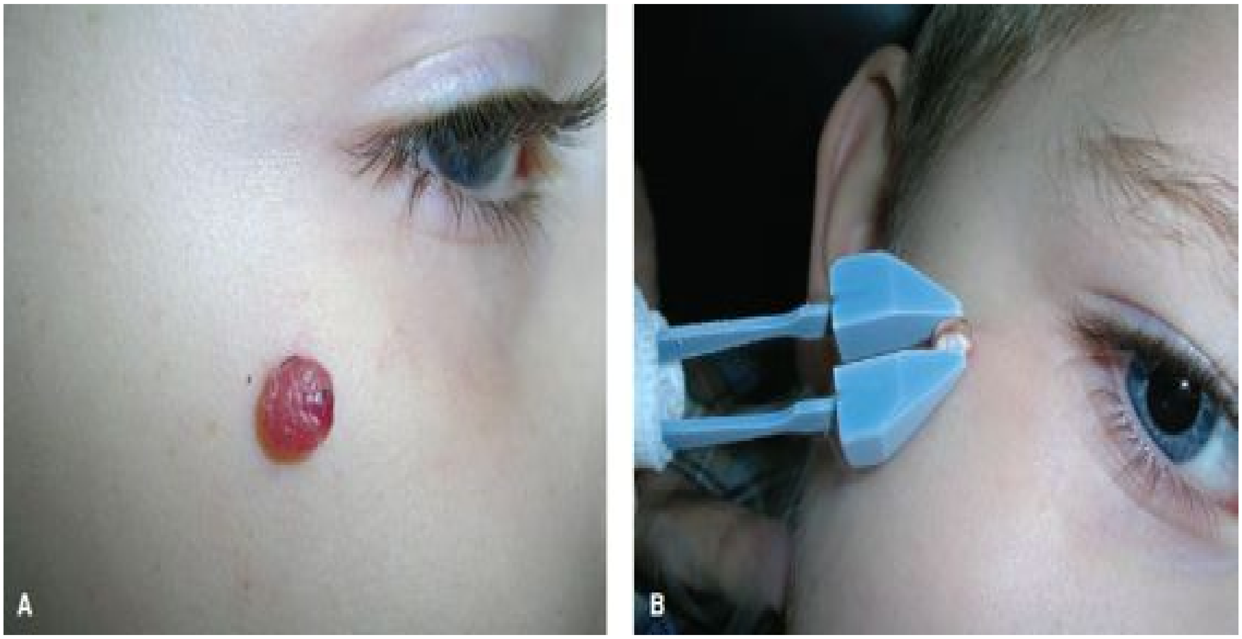

FIGURE 142-1 A. Pyogenic granuloma on the cheek of a young girl. B. Cryotherapy of the pyogenic granuloma using a cryo tweezer. This method was chosen because the girl was afraid of the needle needed for local anesthesia and surgical excision. She tolerated the cryotherapy well. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Pyogenic granuloma (PG) is the name for a common, benign, acquired, vascular neoplasm of the skin and mucous membranes.

SYNONYMS

- The term “lobular capillary hemangioma” is an accepted and preferred term because PG is neither pyogenic (purulent bacterial infection) nor a granuloma.[1] We continue to use “pyogenic granuloma” as this is still the most recognized term.

EPIDEMIOLOGY

- Most often seen in children and young adults (0.5% of children’s skin lesions); 42 percent of cases occur by 5 years of age and about 1 percent are present at birth.[1]
- Oral lesions occur most often in the second and third decade, more commonly in women (2:1).[1] In a case series from Israel of pediatric gingival lesions (N = 233), one-quarter were PGs.
- Also common during pregnancy.
- PG has also been reported in the gastrointestinal tract, the larynx, and on the nasal mucosa, conjunctiva, and cornea.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is unknown but may be the result of trauma, infection, or preceding dermatoses.
- Consists of dense proliferation of capillaries and fibroblastic stroma that is infiltrated with polymorphonuclear leukocytes.
- Multiple PGs have been reported at burn sites and following use of oral contraceptives, protease inhibitors, and topical application of tretinoin for acne.[2]
- PGs are known to regress following pregnancy. Vascular endothelial growth factor (VEGF) was found in one study to be high in the granulomas in pregnancy and was almost undetectable after parturition and associated with apoptosis of endothelial cells and regression of granuloma.[3]

RISK FACTORS

- Trauma (up to 50%), including nose piercing,[4] or chronic irritation (e.g., orthodontic appliance).[1,5]
- Multiple lesions can follow manipulation of a primary lesion.[6]
- Pregnancy or use of oral contraceptives for oral PGs; postulated due to imbalance between angiogenesis enhancers and inhibitors.[1]
- Infection with *Bartonella*.[1]

DIAGNOSIS

CLINICAL FEATURES

- Usually solitary, erythematous, dome-shaped papule or nodule that bleeds easily (**Figures 142-1** to **142-6**); rarely causes anemia. Satellite lesions may rarely occur.

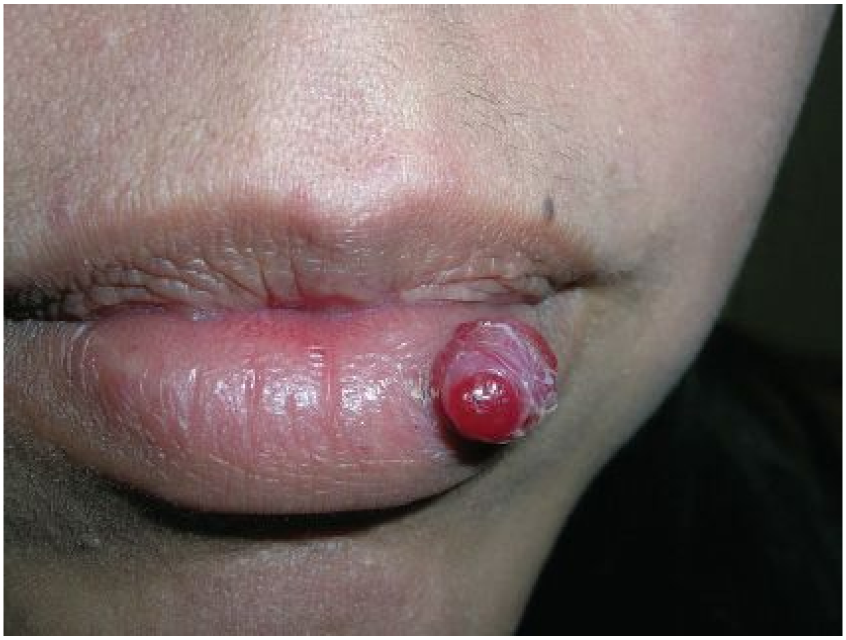

FIGURE 142-2 Pyogenic granuloma on the lip. This was surgically excised. (*Used with permission from Richard P. Usatine, MD.*

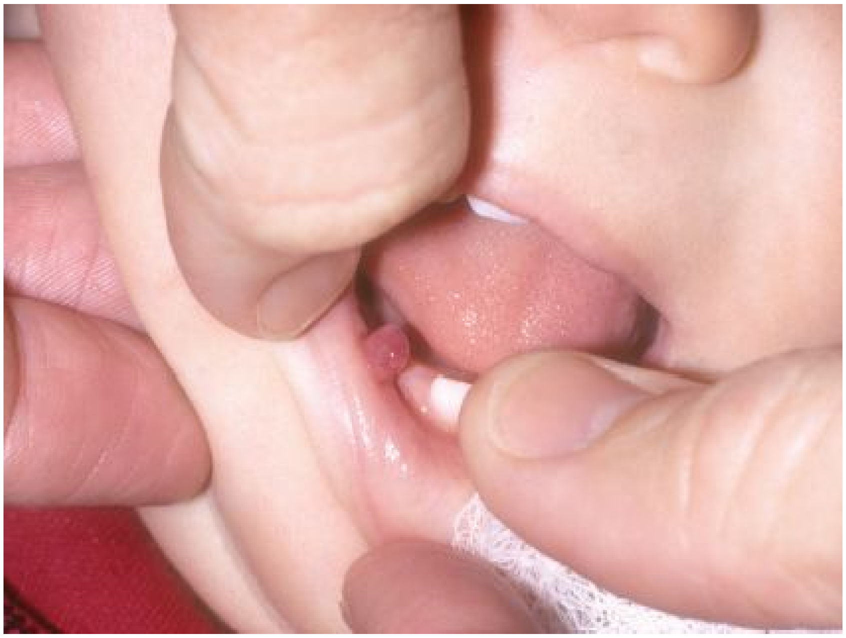

FIGURE 142-3 Pyogenic granuloma on the lip of an infant. (*Used with permission from Richard P. Usatine, MD*.)

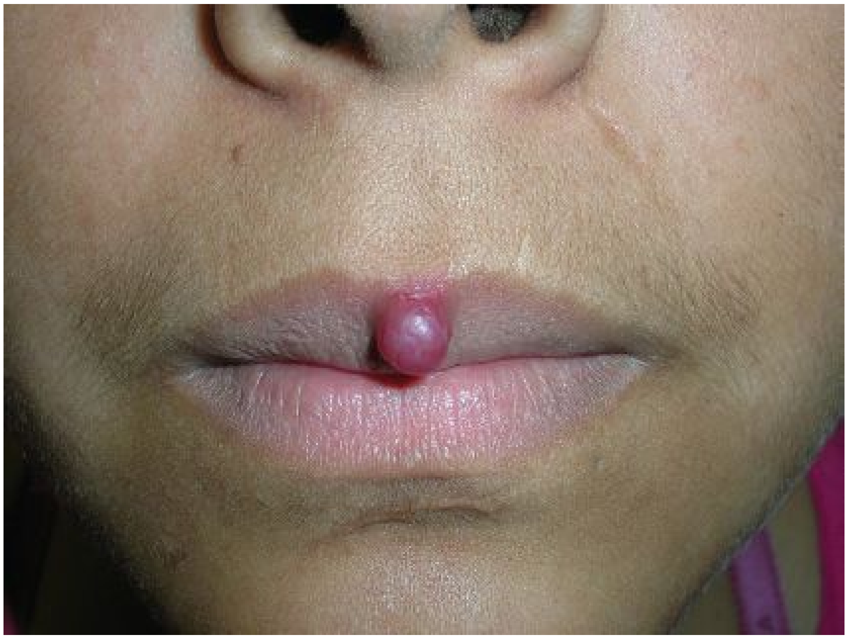

FIGURE 142-4 Pyogenic granuloma on the upper lip. (*Used with permission from Richard P. Usatine, MD*.)

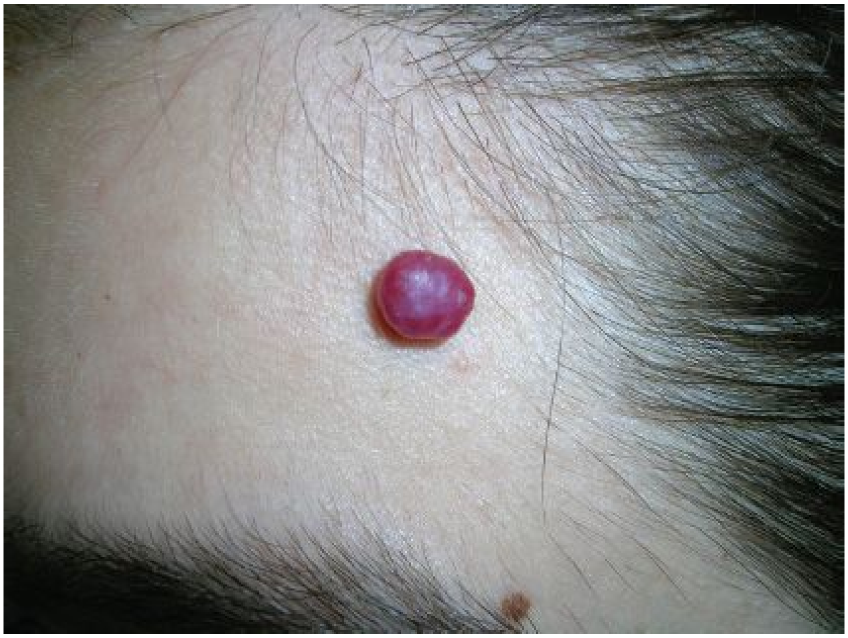

FIGURE 142-5 Pyogenic granuloma on the forehead and a 14-year-old girl. (*Used with permission from Richard P. Usatine, MD*.)

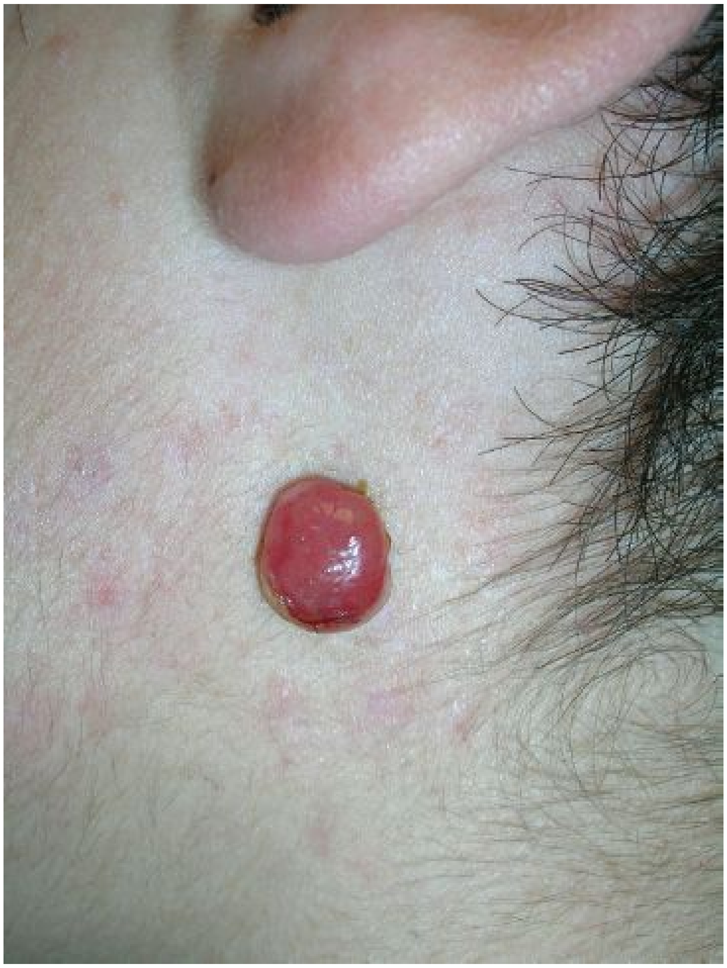

FIGURE 142-6 Pyogenic granuloma on the neck 12-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

- Prone to ulceration, erosion, and crusting.
- Size ranges from a few millimeters to several centimeters (average size is 6.5 mm).[1]
- Rapid growth over a period of weeks to maximum size.
- Variants include cutaneous, oral mucosal (granuloma gravidarum), satellite, subcutaneous, intravenous, and congenital types.[1]
- PG can also arrive within port-wine stains (PWS); in one case series (N = 31 with nodules arising within PWS), 14 biopsy specimens were PGs.[7] Most PGs and arteriovenous malformations (10 specimens) occurred in the area innervated by the second branch of the trigeminal nerve. In one

case series, PGs arising with PWS were seen as a complication of 595 nm tunable pulsed dye laser treatment of the original lesion.[8]

TYPICAL DISTRIBUTION

- Cutaneous PG most often found on the head and neck (62.5%) (specifically the gingiva, lips as in **Figure 142-2** to **142-4**), nose, face (**Figure 142-5**), neck (**Figure 142-6**), trunk (20%), and extremities (18%; **Figure 142-7**).[1] The fingers and hands are very commonly involved (**Figure 142-7**). PGs have also been reported on the glans penis in association with phimosis.[9]

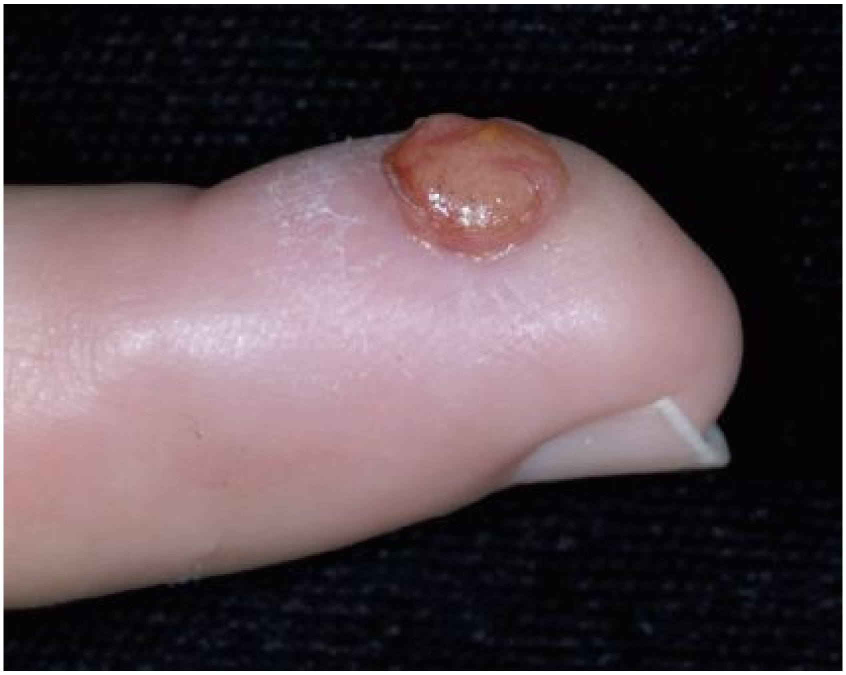

FIGURE 142-7 Small pyogenic granuloma on the finger of a 17-year-old boy for 2 months. It started with a small injury to the finger. (*Used with permission from Richard P. Usatine, MD.*)

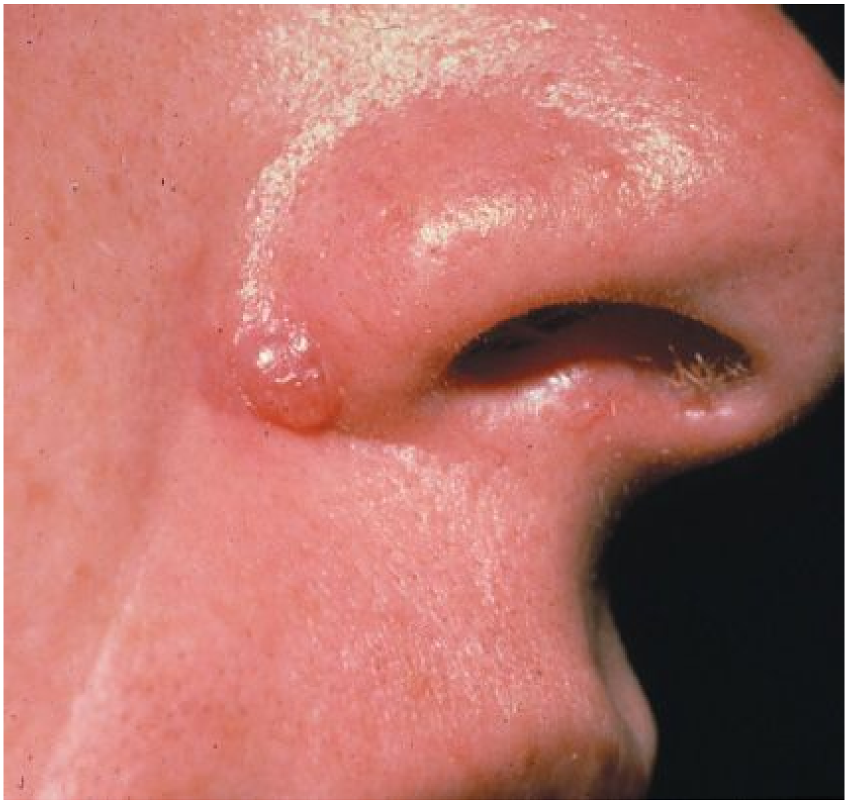

FIGURE 142-8 Amelanotic melanoma on the nose that could be confused with a pyogenic granuloma. Always send what you suspect to be a PG to the pathologist. (*Used with permission from UTHSCSA Division of Dermatology*.)

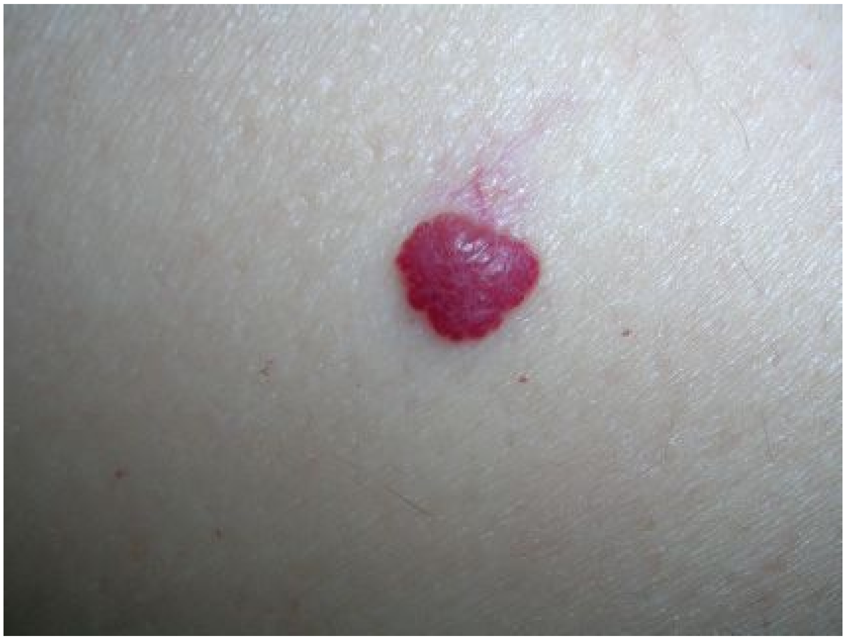

FIGURE 142-9 Cherry hemangioma on the arm. (*Used with permission from Richard P. Usatine, MD*.)

- Pregnancy PG occurs most commonly along the maxillary intraoral mucosal surface.
- In one retrospective study (N = 58 cases) and literature review, causes of PG included drugs, local trauma, and peripheral nerve injury.[10] The authors suggested that histological examination might be needed to rule out malignant melanoma.

IMAGING

- Reddish homogeneous area surrounded by a white collarette is the most frequent dermoscopic pattern in pyogenic granulomas (85%).[11] In more advanced lesions, white lines that intersect the central areas may be seen that are likely fibrous septa. Slight pressure can obscure vascular structures within a PG so care should be taken as the visualization of vascular structures within a red tumor requires assessment for melanoma.[12]
- In vivo reflectance confocal microscopy is under investigation for differentiation of acquired vascular lesions.[13]

BIOPSY

- If treatment involves excision, than the tissue should be sent to pathology to confirm the diagnosis and exclude malignancy.
- Early lesions resemble granulation tissue (numerous capillaries and venules with endothelial cells arrayed radially toward the skin surface; stroma is edematous).[1]
- The mature PG exhibits a fibromyxoid stroma separating the lesion into lobules. Proliferation of capillaries is present, with prominent endothelial cells. The epidermis exhibits inward growth at the lesion base.[1]

DIFFERENTIAL DIAGNOSIS

Although cutaneous malignancies are rare in children, PG may be confused with lesions including atypical fibroxanthoma, basal cell carcinoma, Kaposi carcoma, metastatic cutaneous lesions, squamous cell carcinoma, and amelanotic melanoma (**Figure 142-8**). It is especially important to send the excised lesion that appears to be a PG for pathology to make sure that a malignancy is not missed.

Benign tumors that may be confused with PG include:

- Cherry hemangioma—Small, bright-red, dome-shaped papules that represent benign proliferation of capillaries (**Figure 142-9**). These tend to be flatter and do not bleed as easily as a PG. Many cherry angiomas are acquired as part of normal aging so are seen more frequently in older adults.
- Fibrous papule of the nose is a benign tumor of the nose. Most are skin colored and not confused with PG. A benign clear cell variant of a fibrous papule can closely resemble a PG.

MANAGEMENT

Removal of the lesion is indicated to alleviate any bleeding or discomfort, for cosmetic reasons or when the diagnosis is uncertain.

NONPHARMACOLOGIC

- Untreated PGs eventually atrophy, become fibromatous, and slowly regress, especially if the causative agent is removed.

MEDICATIONS

- A case of successful treatment of a recurrent pyogenic granuloma was reported using a 14-week course of twice-weekly imiquimod 5 percent topical application.[14] SOR C
- Topical 98 percent phenol (3 applications, 1 minute each consecutively followed by silver sulfadine, and 10 percent povidone iodine) has also been successfully used without scarring for periungual PGs, but required weekly treatment over 2 to 14 weeks in one case series.[15]

PROCEDURES

A number of procedures have been used for elimination of PGs; data are limited to case series reports.[16]

- Cryotherapy is more likely to be tolerated by young children rather than an excision, which requires a needle injection with a local anesthetic. A Cryo Tweezer (**Figure 142-1**) or cryoprobe (**Figure 142-10**) is likely to be more effective as both devices can compress the vascular structures for more effective cryodestruction. Also, both devices may be less frightening and painful than a spray application (author experience).

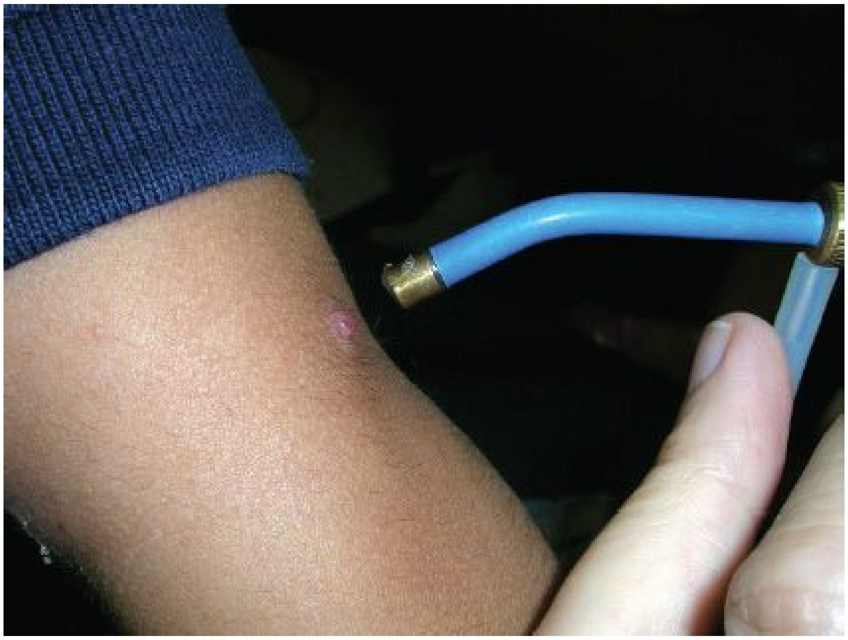

FIGURE 142-10 Pyogenic granuloma on the arm of a 7-year-old boy being treated with cryotherapy using a probe delivery device to allow for

compression of the lesion at the same time that the cold is being delivered to the site. (*Used with permission from Richard P. Usatine, MD.*)

- Simple surgical excision has a low recurrence rate (<4%) but is associated with scarring (55%).[16] SOR Ⓒ
- Removal can be accomplished with shave excision and electrodesiccation —The latter reduces recurrence (about 10%); scarring appears less than with simple excision (31%) or cauterization alone (43.5%).[1,16] PGs bleed extensively when manipulated or cut. It is important to use lidocaine with epinephrine, wait 10 minutes for the epinephrine to work and have an electrosurgery device to control bleeding. Cut the PG off with a blade and send to pathology. Curetting the base will also help stop the bleeding and prevent recurrence. The base is curetted and electrodesiccated until the bleeding can be stopped. A pressure dressing should be applied before the patient leaves the office. SOR Ⓒ
- Both cryosurgery and laser surgery often require more than one treatment and scarring may be high (12% to 42% and 44%, respectively).[1,16] SOR Ⓒ In one case series, 19 of 20 patients had recurrence-free healing after one to four treatments using a 1,064-nm neodymium-doped yttrium aluminum garnet (Nd:YAG) laser.[17]
- Sclerotherapy in one case series was reported to leave no scarring or recurrence.[16] SOR Ⓒ

PROGNOSIS

- PG develops over weeks, and growth typically stabilizes over several months.[1] Eventually, it shrinks to become a fibrotic angioma. Some nodules spontaneously infarct and involute. In one pediatric retrospective case series with telephone follow-up, four untreated patients had spontaneous resolution within 6 to 18 months with no recurrences.[18]
- Congenital PG is an uncommon disseminated variant that presents with multiple lesions, similar in appearance to the cutaneous form, present at

birth. The condition appears to follow a benign course, with spontaneous resolution over 6 to 12 months.[1]

FOLLOW-UP

- As needed.

PATIENT EDUCATION

- Explain to patients that lesions may resolve spontaneously and that multiple treatments are available.
- Once treated, if the lesion begins to recur, patients should follow-up quickly before the lesion gets larger and harder to treat.

SECTION 10 NEVI AND MELANOMA

143 BENIGN NEVI

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A teenager is brought to the office by her mother who has noted that the moles on her daughter's back are changing (**Figure 143-1**). A few have white halos around the brown pigmentation and some have lost their pigment completely, with a light area remaining. The teenager has no symptoms but wants to make sure these are not skin cancers. Halo nevi are an uncommon variation of common nevi. These appear benign and the patient and her mother are reassured.

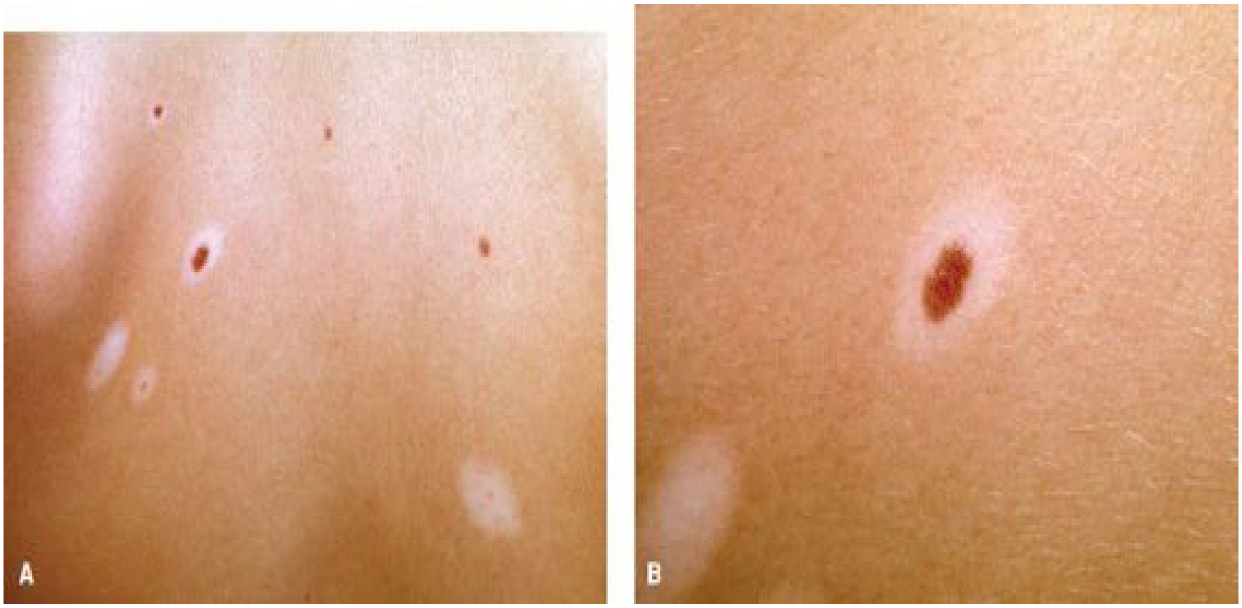

FIGURE 143-1 A. Multiple halo nevi on the back. B. Close-up of a halo nevus in transition. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Most nevi are benign tumors caused by the aggregation of melanocytic cells in the skin. However, nevi can occur on the conjunctiva, sclera and other structures of the eye. There are also nonmelanocytic nevi that are produced by other cells as seen in Becker nevi and comedonal nevi. Although most nevi are acquired, many nevi are present at birth.

SYNONYMS

Moles.

EPIDEMIOLOGY

- Acquired nevi are common lesions, forming during early childhood; few adults have none.
- Prevalence appears to be lower in dark-skinned individuals.
- Present in 1 percent of neonates, increasing through childhood, and peaking at puberty; new ones may continue to appear in adulthood. In a convenience sample of children in Colorado, non-Hispanic white children had the highest number of nevi compared to other racial/ethnic groups. Beginning at age 6 years, non-Hispanic white boys had significantly more nevi than non-Hispanic white girls (median, 21 versus 17), Hispanic white children (median 11), black children (median 7), and Asian/Pacific Islander children (median 6).[1] This number is similar to a study of children (N = 180, ages 1 to 15 years) in Barcelona where the mean number of nevi was 17.5.[2]
- In the Colorado study previously cited, non-Hispanic white children developed an average of 4 to 6 new nevi per year from 3 to 8 years of age.

Development of new nevi leveled off in chronically exposed body sites at 7 years of age and at a higher level for boys than girls.[1]

- Adults typically have 10 to 40 nevi scattered over the body.
- The peak incidence of melanocytic nevi (MN) is in the fourth to fifth decades of life; the incidence decreases with each successive decade.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Benign tumors composed of nevus cells derived from melanocytes, pigment-producing cells that colonize the epidermis.
- MN represent proliferations of melanocytes that are in contact with each other, forming small collections of cells known as nests. Genetic mutations present in common nevi as well as in melanomas include BRAF, NRAS, and *c*-kit.[4]
- Sun (UV) exposure, skin-blistering events (e.g., sunburn), and genetics play a role in the formation of new nevi.[3]
- Three broad categories of MN are based on location of nevus cells:[5]

Junctional nevi—Composed of nevus cells located in the dermoepidermal junction; may change into compound nevi after childhood (except when located on the palms, soles, or genitalia; **Figure 143-2**).

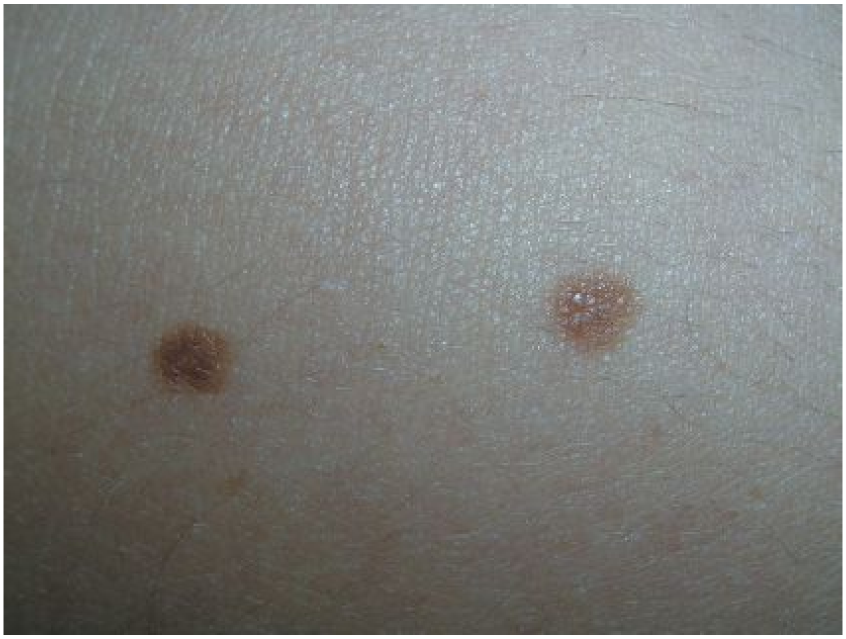

FIGURE 143-2 Two benign junctional nevi on the arm of a teenage girl. Note how these are flat macules. (*Used with permission from Richard P. Usatine, MD*.)

Compound nevi—A nevus in which a portion of nevus cells have migrated into the dermis (**Figure 143-3**).

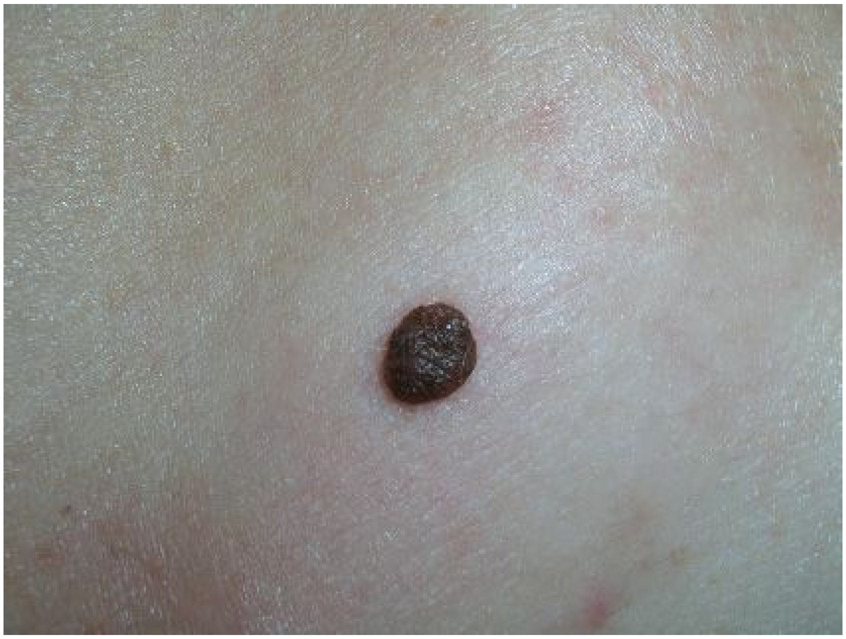

FIGURE 143-3 Benign compound nevus on the chest of a 14-year-old girl proven by biopsy. Note the brown pigmentation and the fact that the nevus is raised. (*Used with permission from Richard P. Usatine, MD*.

Dermal nevi—Composed of nevus cells located within the dermis (usually found only in adults). These are usually raised and have little to no visible hyperpigmentation (**Figures 143-4** and **143-5**).

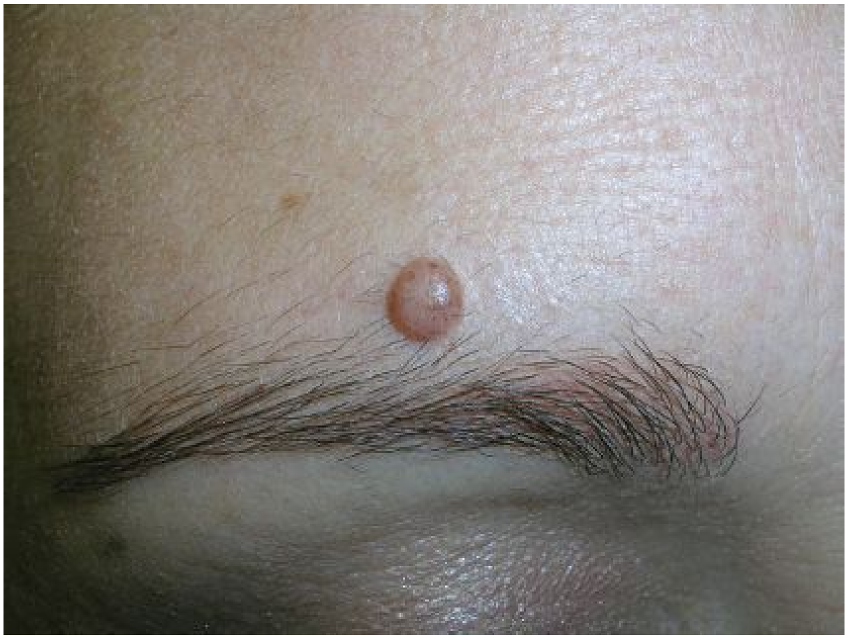

FIGURE 143-4 Dermal nevus (intradermal melanocytic nevus)–dome shaped with some scattered pigmentation. (*Used with permission from Richard P. Usatine, MD*.)

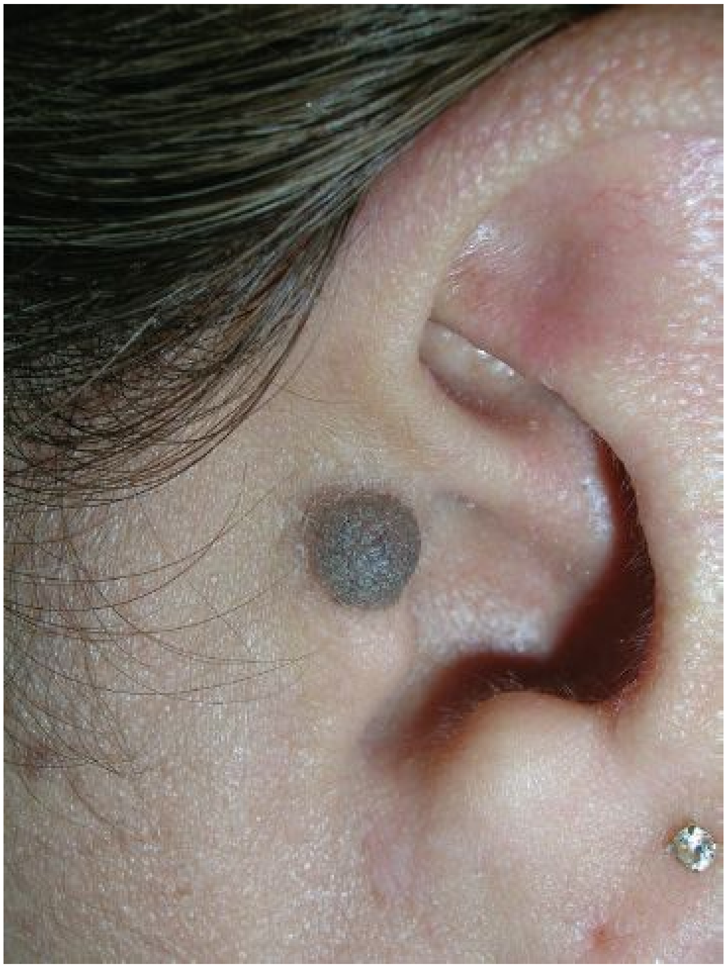

FIGURE 143-5 Dermal nevus over the tragus. This biopsy proven dermal nevus was uniformly pigmented. (*Used with permission from Richard P. Usatine, MD.*)

- Special categories of nevi:
    - Halo nevus—Compound or dermal nevus that develops a symmetric, sharply demarcated, depigmented border (**Figure 143-1**). Most commonly occurs on the trunk and develops during adolescence. Repigmentation may occur.
    - Blue nevus—A dermal nevus that contains large amounts of pigment so that the brown pigment absorbs the longer wavelengths of light and scatters blue light (Tyndall effect; **Figure 143-6**). Blue nevi are not always blue and color varies from tan to blue, black, and gray. The nodules are firm because of associated stromal sclerosis. Usually appears in childhood on the extremities, dorsum of the hands and face.

A rare variant, the cellular blue nevus is large (>1 cm), frequently located on the buttocks, and may undergo malignant degeneration.

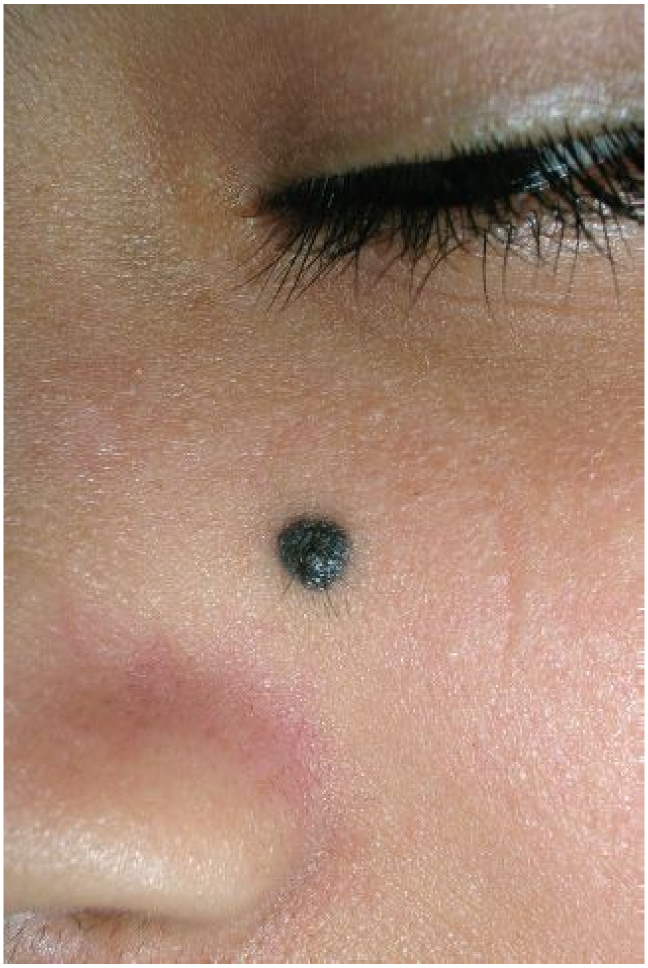

FIGURE 143-6 Blue nevus on the left cheek that could resemble a melanoma with its dark color. In this case it was fully excised with a 5-mm punch with a good cosmetic result. Blue nevi are benign and do not need to be excised unless there are suspicious changes. (*Used with permission from Richard P. Usatine, MD*.)

- Nevus spilus—Hairless, oval, or irregularly shaped brown lesion with darker brown to black dots containing nevus cells (**Figure 143-7**). May appear at any age or be present at birth; unrelated to sun exposure.

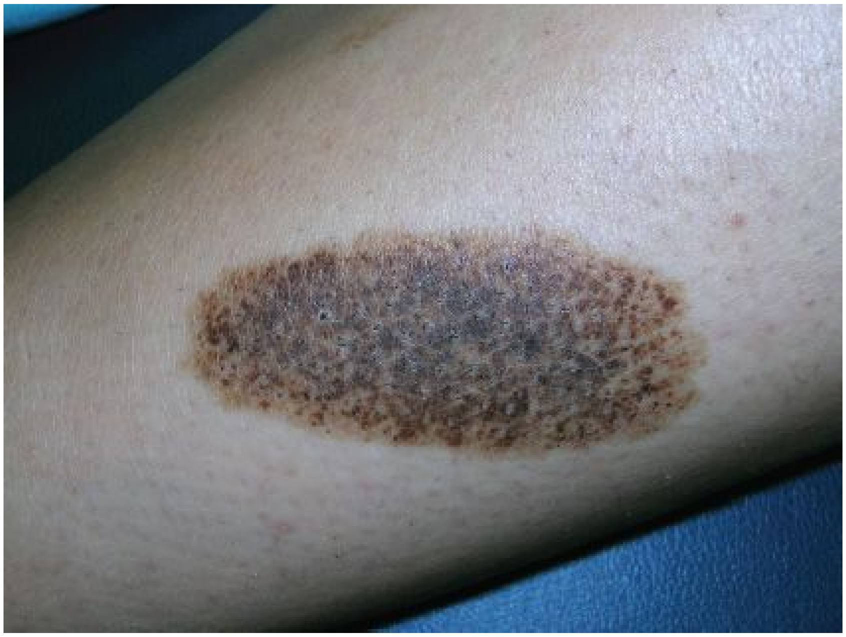

FIGURE 143-7 Nevus spilus on the leg of a young woman from birth. It appears benign and needs no intervention. (*Used with permission from Richard P. Usatine, MD*.)

- Spitz nevus (formerly called benign juvenile melanoma because of its clinical and histologic similarity to melanoma)—Hairless, red, or reddish brown dome-shaped papules generally appearing suddenly in children, sometimes following trauma (**Figures 143-8** and **143-9**). The pink color is caused by increased vascularity. Most importantly, these should be fully excised with clear margins.

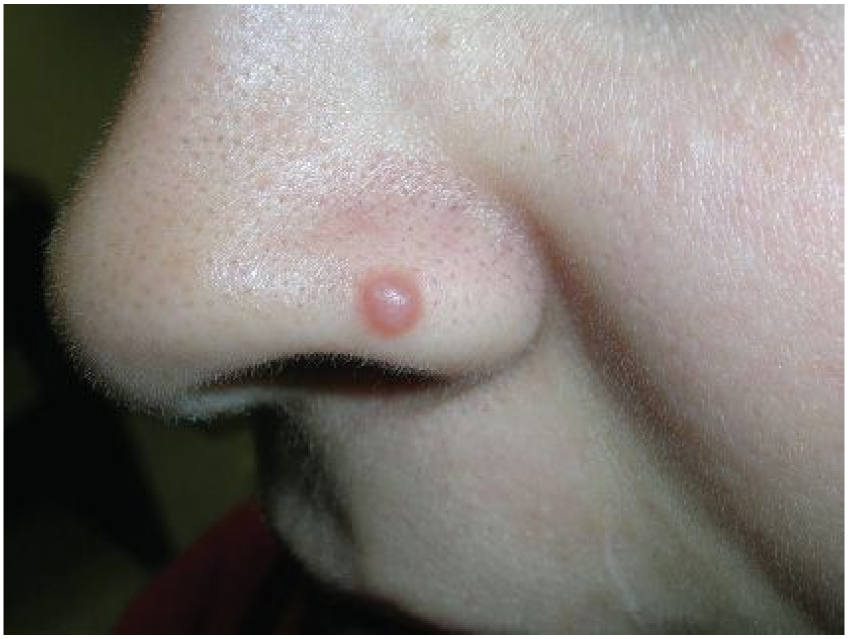

FIGURE 143-8 Spitz nevus that grew over the past year on the nose of this 18-year-old female. It was fully excised with no complications. (*Used with permission from Richard P. Usatine, MD*.)

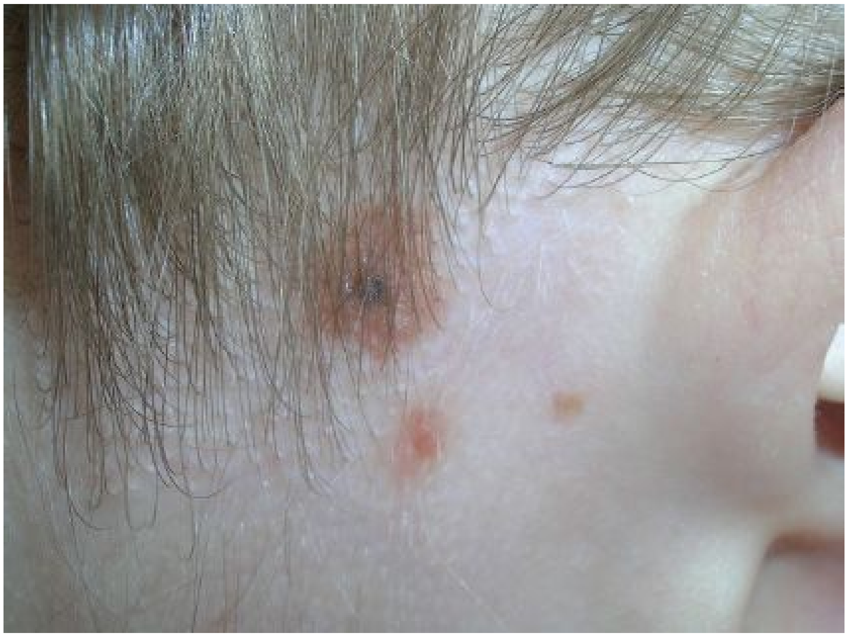

FIGURE 143-9 Spitz nevus on face of this 9-year-old boy. He very bravely allowed us to excise it with local anesthesia. (*Used with permission from Richard P. Usatine, MD*.)

  - Nevus of Ota—Dark brown nevus that occurs most commonly around the eye and can involve the sclera (**Figure 143-10**).

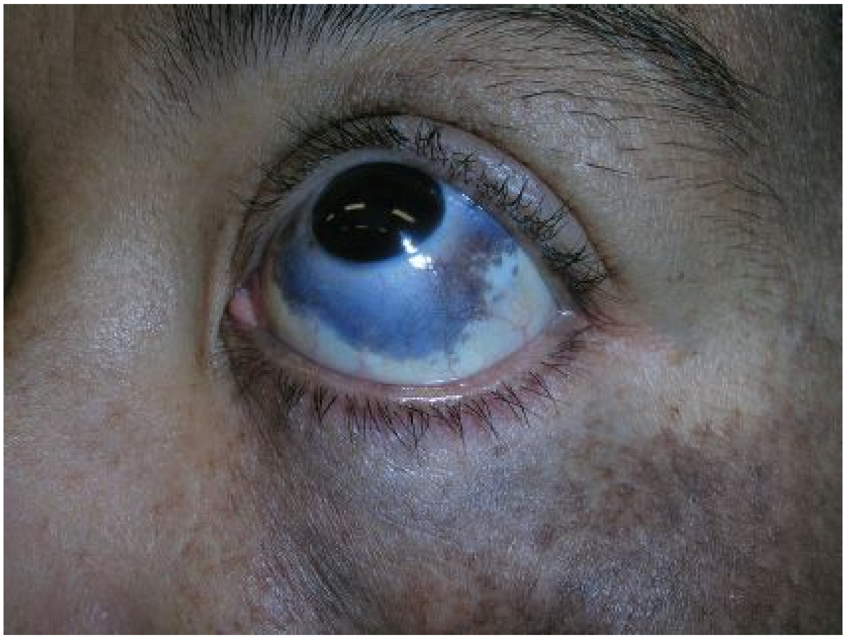

FIGURE 143-10 Nevus of Ota on the face of this young woman since early childhood. It involved both eyes and the skin around both eyes. The scleral pigmentation looks blue. (*Used with permission from Richard P. Usatine, MD*.)

- Both acquired and congenital MN hold some risk for the development of melanoma; the number of MN, especially more than 100, is an important independent risk factor for cutaneous melanoma.[6]

NONMELANOCYTIC NEVI

- Becker nevus—A brown patch often with hair located on the shoulder, back or submammary area, most often in adolescent boys (**Figures 143-11** and **143-12**). The lesion may enlarge to cover an entire shoulder or upper arm. Although it is called a nevus, it does not actually have nevus cells and has no malignant potential. It is a type of hamartoma, an abnormal mixture of cells and tissues normally found in the area of the body where the growth occurs.

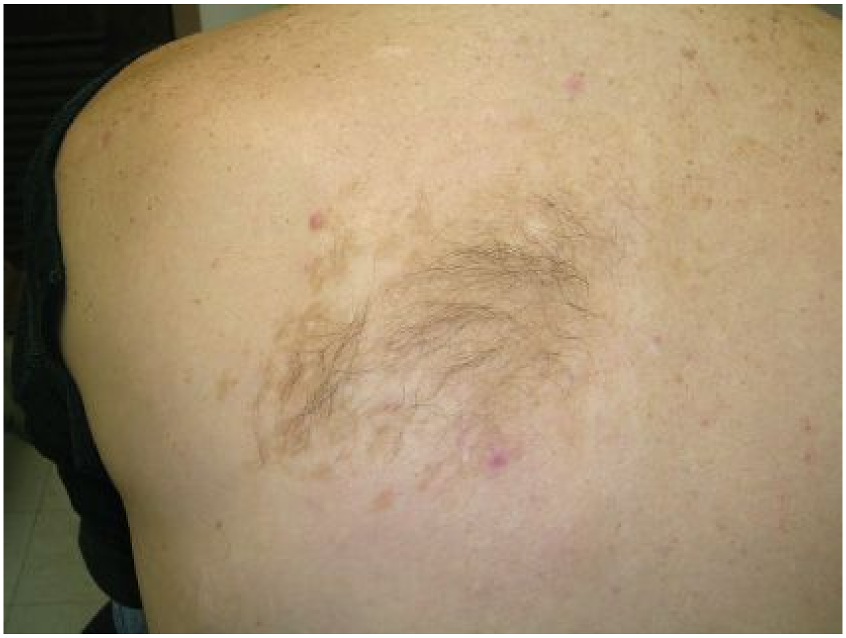

FIGURE 143-11 Becker nevus that developed during adolescence. Hair is frequently seen on this type of nonmelanocytic nevus. (*Used with permission from Richard P. Usatine, MD*.)

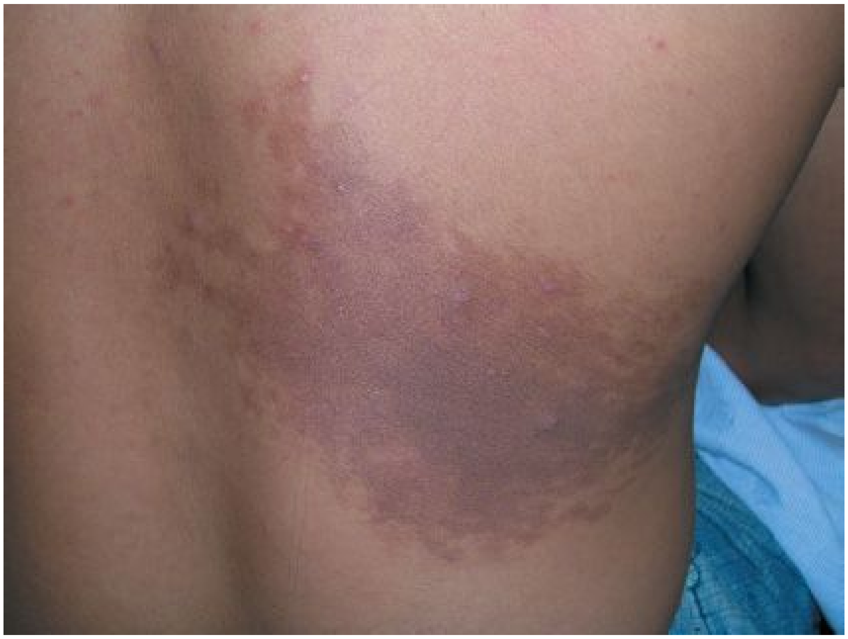

FIGURE 143-12 Becker nevus on the back of a 16-year-old Hispanic boy for 2 years. While this nevus did not have hair, it did have increased acne within the area–another feature of the Becker nevus. (*Used with permission from Richard P. Usatine, MD*.)

- Nevus depigmentosus is usually present at birth or starts in early childhood. There is a decrease number of melanosomes within a normal number of melanocytes. It typically has a serrated or jagged edge (**Figure 143-13**).

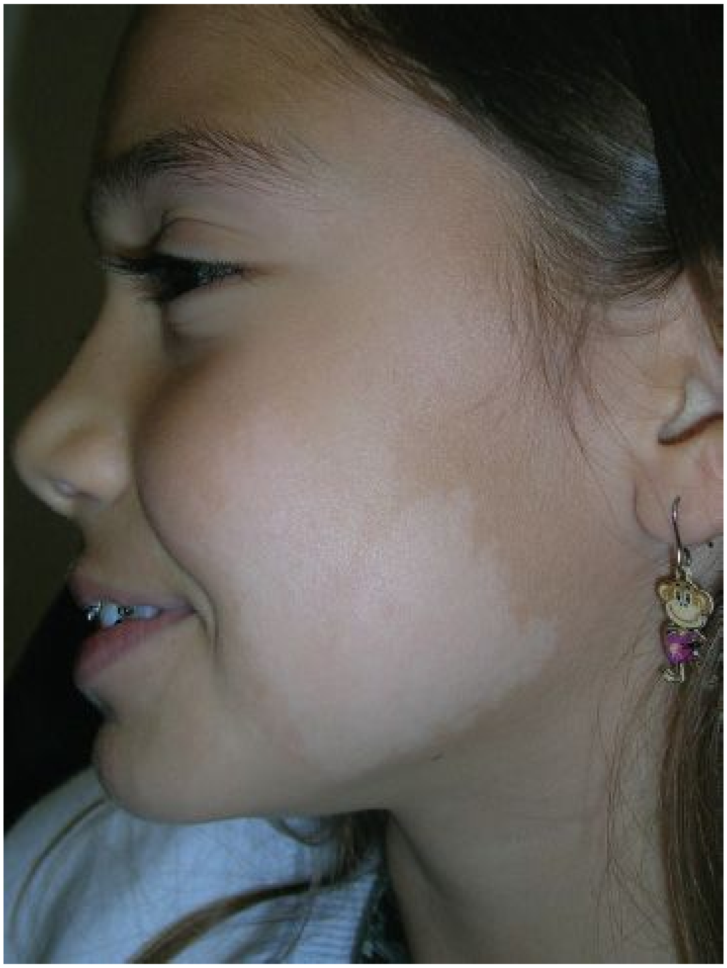

FIGURE 143-13 Nevus depigmentosus on the face of this young girl since birth. (*Used with permission from Richard P. Usatine, MD.*)

- Nevus anemicus—A congenital hypopigmented macule or patch that is stable in relative size and distribution. It occurs as a result of localized hypersensitivity to catecholamines and not a decrease in melanocytes. On diascopy (pressure with a glass slide) the skin is indistinguishable from the surrounding skin (**Figure 143-14**).

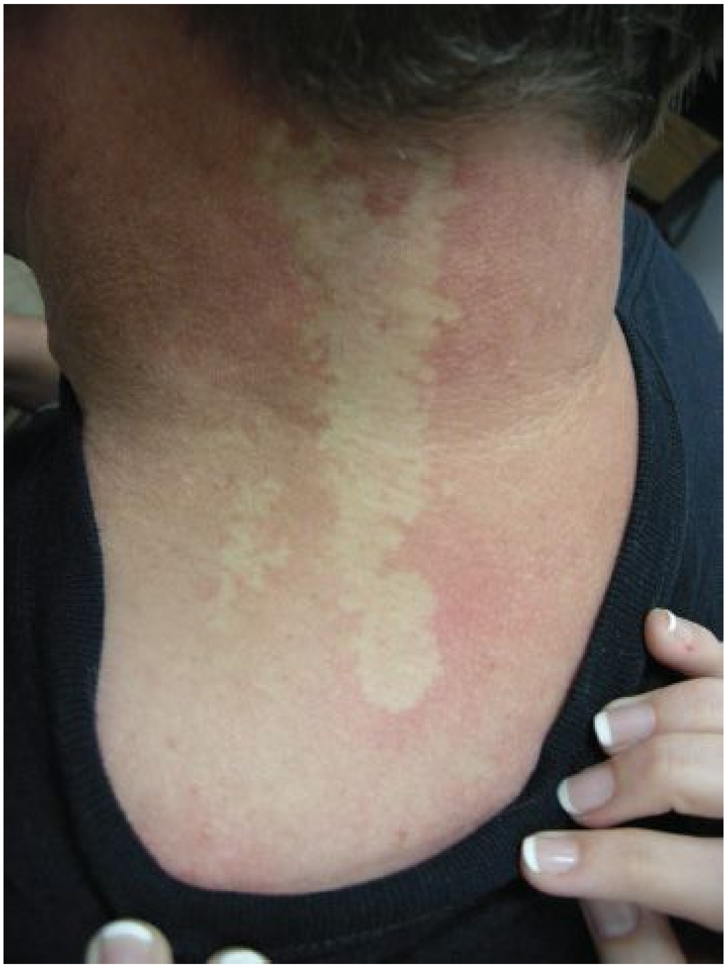

FIGURE 143-14 Nevus anemicus on the posterior neck. The localized hypersensitivity to catecholamines causes the area to stay lighter than the surrounding skin. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

- Nevus comedonicus (comedonal nevus) is a rare congenital hamartoma characterized by an aggregation of comedones in one region of the skin (**Figure 143-15**).

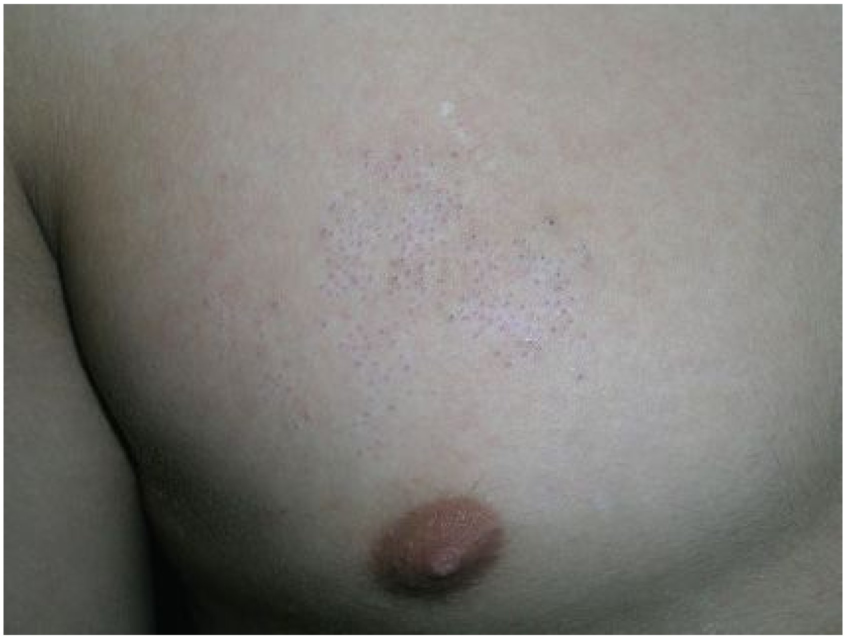

FIGURE 143-15 Nevus comedonicus on the chest of this 15-year-old boy since birth. This is a congenital hamartoma with open comedones. It is not acne. (*Used with permission from Richard P. Usatine, MD.*)

- Epidermal nevi are congenital hamartomas of ectodermal origin classified on the basis of their main component: sebaceous, apocrine, eccrine, follicular, or keratinocytic. See Chapter 144, Congenital Nevi for a full discussion of this type of nevus.
  - Note that nevus comedonicus and epidermal nevi tend to follow Blaschko lines, which come from embryologic development.

RISK FACTORS

- In the Barcelona study of children, male gender, past history of sunburns, facial freckling, and family history of breast cancer were independent risk factors for having a higher number of nevi.[2]
- In one study among very light-skinned (and not darker skinned) children without red hair, children who develop tans have greater numbers of nevi.[7]
- Engaging in outdoor sports increases the number of nevi.[8]

- Although neonatal blue-light phototherapy (NBLP) was not related to nevus count at age 9 years in one study,[9] investigators of a twin study (N = 59 sets) in which one of the pair received NBLP found a higher prevalence of both cutaneous and uveal melanocytic lesions in exposed twins.[10]

DIAGNOSIS

CLINICAL FEATURES

Most benign MN are tan to brown, usually less than 6 mm, with round shape and sharp borders.

- Junctional nevi—Macular or slightly elevated mole of uniform brown to black pigmentation, smooth surface, and a round or oval border (**Figure 143-2**). Most are hairless and vary from 1 to 6 mm.
- Compound nevi—Slightly elevated, symmetric, flesh colored or brown with a round or oval border, often becoming more elevated with age (**Figure 143-3**). Hair may be present and a white halo may form.
- Dermal nevi (same as intradermal nevi)—Skin color or brown color that may fade with age; dome shaped is most common, but shapes vary, including polypoid, warty, and pedunculated. Often found on the face (**Figures 143-4** and **143-5**) with the size ranging from 2 to 10 mm.

TYPICAL DISTRIBUTION

- Most often above the waist on sun-exposed areas but may appear anywhere on the cutaneous surface; less commonly found on the scalp, breasts, or buttocks.
- Among children in the Barcelona study, 61.1 percent had nevi on the face and neck, 17.2 percent on the buttocks, and 11.7 percent on the scalp; approximately 1/3 had congenital nevi (Chapter 144, Congenital Nevi).[2]

- In an Australian study of white children, MN of all sizes were highest on the outer forearms, followed by the outer upper arms, neck, and face.[11] Boys had higher densities of MN of all sizes on the neck than girls, and girls had higher densities of MN of 2 mm or greater on the lower legs and thighs than boys. Habitually sun-exposed body sites had higher densities of small MN and highest prevalence of larger MN.

IMAGING

- Dermoscopy can be a useful technique for diagnosing benign nevi. For MN, dermoscopic diagnosis relies on color; pattern (i.e., globular, reticular, starburst, and homogeneous blue pattern); pigment distribution (i.e., multifocal, central, eccentric, and uniform); and special sites (e.g., face, acral areas, nail, and mucosa), in conjunction with patient factors (e.g., history, pregnancy).[12]
- Authors of a review of dermoscopy in the pediatric population reported that acquired MNs in children show peripheral globules and nevo-melanocytic junctional nests at the perimeter.[13] Lesions tend to grow in a symmetric, centrifugal fashion with peripheral globules becoming sparser and eventually disappearing as the lesions mature; mature MNs manifest a reticular or homogeneous pattern. Investigators in one study found change in 16.2 percent of 2497 benign melanocytic lesions with minor suspicion of melanoma undergoing short term dermoscopy.[14] Change was more often seen in younger (0 to 18 years and 19 to 35 years) and older patients.
- In the Barcelona study, the most frequent dominant dermoscopic pattern in children was the globular type (**Figure 143-16**) with the homogeneous pattern predominating in the youngest children and the reticular pattern predominating in adolescents.[2]

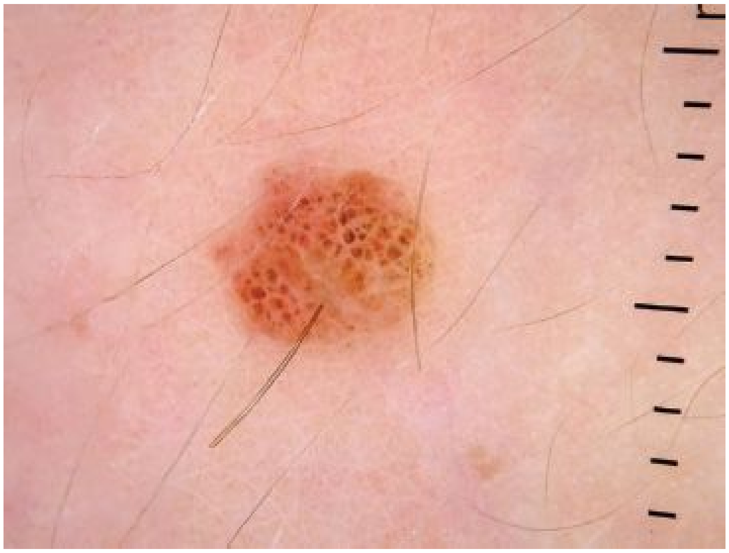

FIGURE 143-16 Dermoscopy of a benign melanocytic nevus in a teenage girl showing a globular pattern often seen in the nevi of children. (*Used with permission from Richard P. Usatine, MD*.)

BIOPSY

Biopsy is necessary if you suspect melanoma or a Spitz nevus (**Figure 143-9**). A biopsy that cuts below the pigmented area is preferred if there is a reasonable suspicion for melanoma. This can be done with a scoop shave, a punch that gets the whole lesion, or an elliptical excision. If the patient wants a raised benign appearing nevus excised for cosmetic reasons, a shave excision may be adequate. Send all lesions (except skin tags) to the pathologist for examination, even when they appear benign, to avoid missing a melanoma.

- Immunostaining is performed by the pathologist as a valuable adjunct to histopathologic evaluation in differentiating benign from malignant melanocytic tumors.[15]

DIFFERENTIAL DIAGNOSIS

Benign nevi may develop atypia or become melanoma. This should be suspected if a lesion has atypical features including asymmetry, border irregularity, color variability, diameter greater than 6 mm, and evolving (called the ABCDE approach [asymmetry, border irregularity, color irregularity, diameter >6 mm, evolution]). Any lesion that becomes symptomatic (e.g., itchy, painful, irritated, or bleeding), or develops a loss or increase in pigmentation, should be evaluated and biopsied if needed. Dermoscopy can be used to increase one's accuracy in distinguishing between benign and malignant lesions.

- Melanomas are skin cancers that can develop from a preexisting nevus. Distinguishing a benign nevus from a nevus that might be malignant melanoma is an important skill to develop. However, because clinical appearance can be misleading, a biopsy is necessary when there is a reasonable suspicion for cancer (Chapter 147, Melanoma).
- Dysplastic or atypical nevi are variants that are relatively flat, thinly papular, and relatively broad. Often, the lesions exhibit target-like or fried egg-like morphology, with a central papular zone and a macular surrounding area with differing pigmentation (Chapter 146, Dysplastic Nevus).
- Labial melanotic macules are benign dark macules on the lip that are not nevi and not melanomas (**Figure 143-17**). They can be removed for cosmetic purposes.

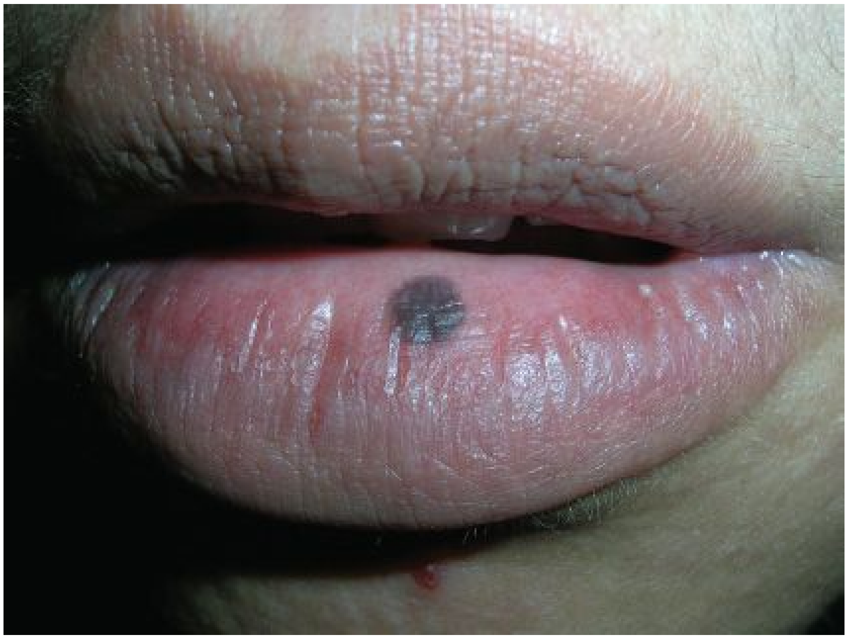

FIGURE 143-17 Labial melanotic macule. These are benign but are not nevi. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

Nevi are generally only removed for cosmetic reasons or because of concern over changes in the lesion suggestive of dysplasia or melanoma.

- A full excisional biopsy with a sutured closure is usually the best means to diagnose a lesion if concern exists regarding the possibility of melanoma. If the lesion is found to be benign, no further treatment is usually required.
- Punch excision can be used to excise smaller lesions.
- Scoop shave—Unfortunately, if a punch biopsy is used to sample a larger lesion it may miss a melanoma in another part of the lesion. A broad scoop shave is better than a punch biopsy when a full elliptical excision is not possible or desirable (e.g., a large flat pigmented lesion on the face).
- Nevi removed for cosmesis are often removed by shave excision.[3]

If a Spitz nevus is suspected, either biopsy it now or schedule the patient for a full excision. The histopathology is too close to a melanoma to just watch it.

- Becker nevi and comedonal nevi do not become melanoma because they lack melanocytes. Therefore, there is no reason to excise them. Generally, these are large and the risks of excision for cosmetic reasons outweigh the benefits.

PREVENTION

- Sun protection to limit sunburn may help reduce the appearance of nevi. In a trial of 209 white children, children randomized to the sunscreen group, especially those with freckles, had significantly fewer new nevi on the trunk than did children in the control group at 3-year follow-up.[16]
- In another study, a partially tailored mailed intervention on child sun protection behaviors was effective in increasing parental reported use of sunscreen, protective clothing and hats, shade-seeking, and midday sun avoidance, and resulted in fewer reported sunburns and fewer nevi ≥2 mm at 1 year.[17]

PROGNOSIS

- Degeneration of common nevi into melanoma is very rare.
- Patients with multiple or large MN appear to have an increased risk of melanoma.[3]
- Nevi may recur or persist following removal; in one study, dysplastic MN were the most likely to persist.[18] In another study, of 61 benign nevi biopsy sites reexamined, two (3.3%) recurred.[19]

FOLLOW-UP

- Patients with multiple or sizable MN should be followed by an experienced clinician because they appear to have an increased lifetime risk of melanoma, with the risk increasing in rough proportion to the size and/or number of lesions.[3]
- As noted in the section on imaging, MN in children often undergo change. Change may be more common for scalp nevi; in a follow-up study of 44 scalp nevi in children (30% of total population), most (77%) showed clinical signs of change during mean follow-up of 2.8 years; about half (53%) became more atypical and the other half (47%) became less atypical since the initial examination.[20] Scalp MN may require closer monitoring.

PATIENT EDUCATION

- Patients and their parents should be encouraged to use sunscreen to prevent skin cancer as well as to reduce the development of new nevi.
- Patients with multiple or sizable MN and their parents should be taught to look for and report asymmetry, border irregularity, new symptoms, and color and size changes.

PATIENT RESOURCES

144 CONGENITAL NEVI

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A small congenital nevus (**Figure 144-1**) was noted on this 6-month-old child by his new family physician during a routine exam. The parents acknowledged that it was present from birth and asked if it needed to be removed. They were reassured that nothing needs to be done about it and unless there were suspicious changes in the future it could remain there for the remainder of their child’s life.

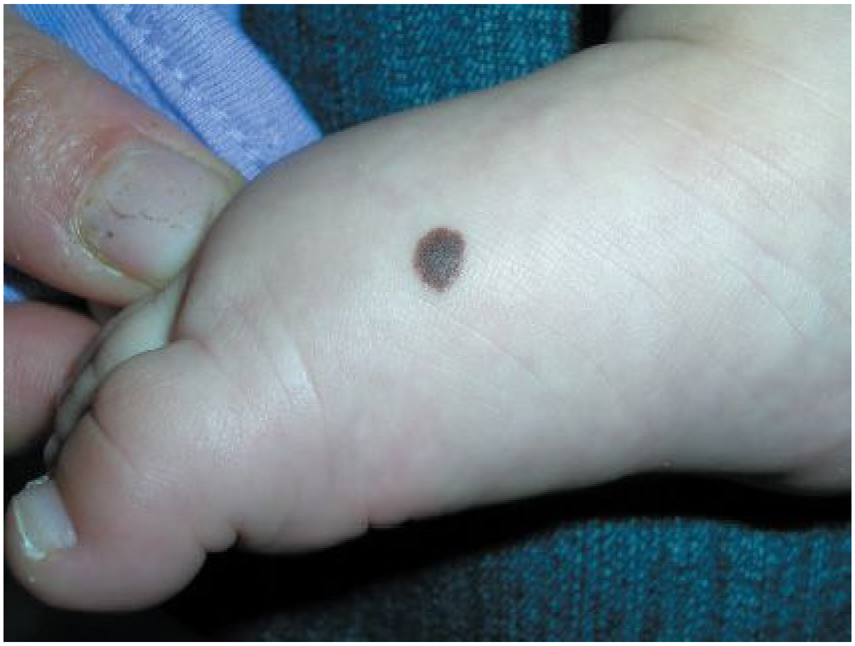

FIGURE 144-1 Small congenital nevus found on the foot of a 6-month-old child. The parents were counseled to not get it excised at this time. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Congenital melanocytic nevi (CMN) are benign pigmented lesions that have a wide variation in size and presentation and are composed of melanocytes, the pigment-forming cells in the skin.

SYNONYMS

- Garment nevus, bathing trunk nevus (**Figure 144-2**), giant hairy nevus, giant pigmented nevus, pigmented hairy nevus, nevus pigmentosus, nevus pigmentosus et pilosus (pigmented nevus with hair).[1]

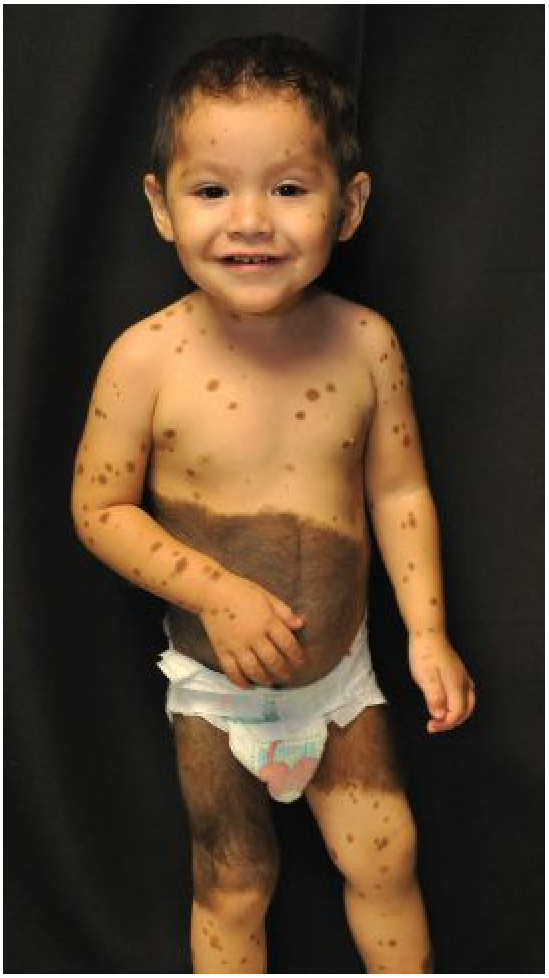

FIGURE 144-2 Large bathing trunk nevus with multiple satellite nevi on this happy 2-year old boy. The mother has opted for no surgical intervention. (*Used with permission from Richard P. Usatine, MD*.) velus hairs on the surface. In time, these hairs become terminal hairs and the lesion could then be termed congenital hairy nevus. It has a significant premalignant potential. Staged excisions are often performed to debulk the lesion even if it cannot all be removed. Careful clinical follow-up is required on at least an annual basis at the physician's office and monthly at home looking for any changes that would prompt biopsy to exclude malignant degeneration. (*Image used with permission from Robert Brodell, MD*.)

- Tardive congenital nevus refers to a nevus with similar features to congenital nevi, but appears at age 1 to 3 years.

EPIDEMIOLOGY

- CMN develop in 1 to 6 percent of newborns and are present at birth or occasionally develop during the first year of life.[1] In a recent case series in California (N = 594), 2.4 percent of the infants had CMN.[2]
- In an Italian prevalence study of over 3000 children aged 12–17 years, congenital melanocytic nevi or congenital nevus-like nevi were found in 17.5 percent; most (92%) were small (<1.5 cm).[3]
- Congenital nevi are also seen in neurocutaneous melanosis, a rare syndrome characterized by the presence of congenital melanocytic nevi and melanotic neoplasms of the central nervous system.
- The development of melanoma within CMN (**Figure 144-8**) is believed to occur at a higher rate than in normal skin. Estimates range from 4 to 10 percent with smaller lesions having lowest risk.[1]
    - In a systematic review, 46 of 651 patients with CMN (0.7%) followed for 3.4 to 23.7 years developed melanomas, representing a 465-fold increased relative risk of developing melanoma during childhood and

adolescence.[4] The mean age at diagnosis of melanoma was 15.5 years (median 7 years).

  - Patients with giant CMN (larger than 20 cm; **Figures 144-2** to **144-5**) appear to be at highest risk where subsequent melanoma has been reported in 5 to 7 percent by age 60 years.[5] In one study, 70 percent of patients who had a large CMN diagnosed with melanoma were diagnosed within the first 10 years of life.[6]

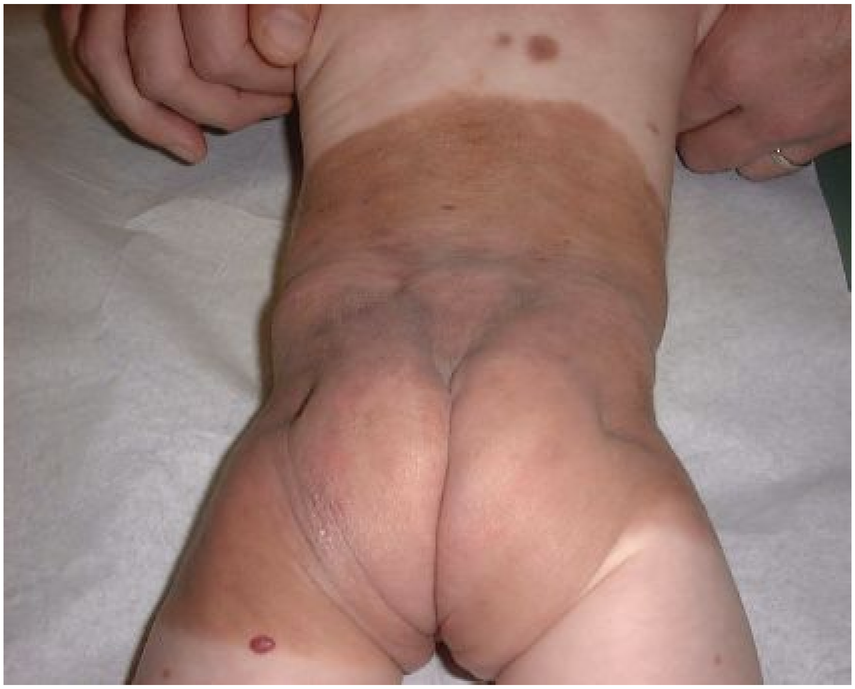

FIGURE 144-3 Bathing trunk congenital melanocytic nevus has fine velus hairs on the surface. In time, these hairs become terminal hairs and the lesion could then be termed congenital hairy nevus. It has a significant premalignant potential. Staged excisions are often performed to debulk the lesion even if it cannot all be removed. Careful clinical follow-up is required on at least an annual basis at the physician’s office and monthly at home looking for any changes that would prompt biopsy to exclude malignant degeneration. (*Image used with permission from Robert Brodell, MD.*)

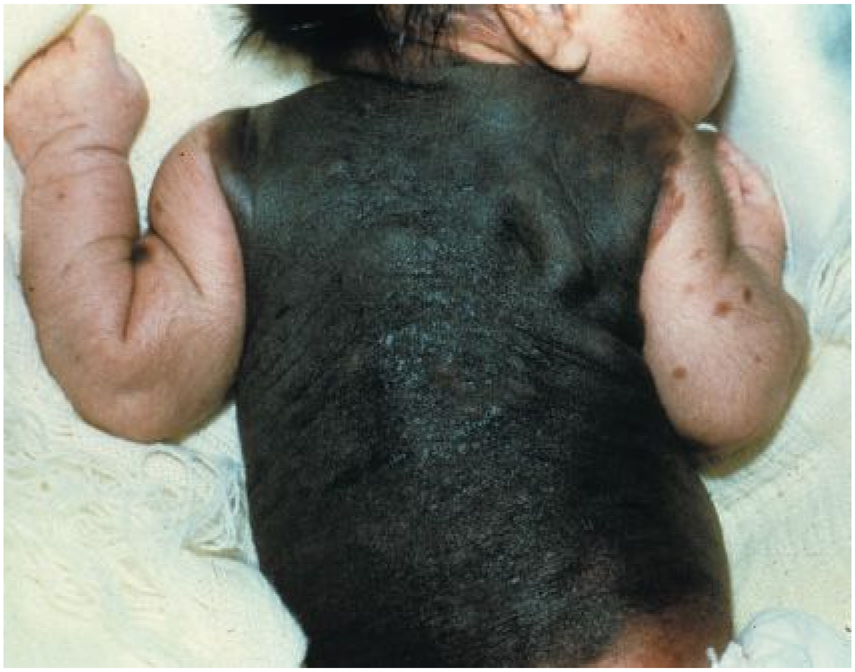

FIGURE 144-4 Infant born with large bathing trunk nevus covering most of the back and chest. (*Used with permission from UTHSCSA Division of Dermatology*.)

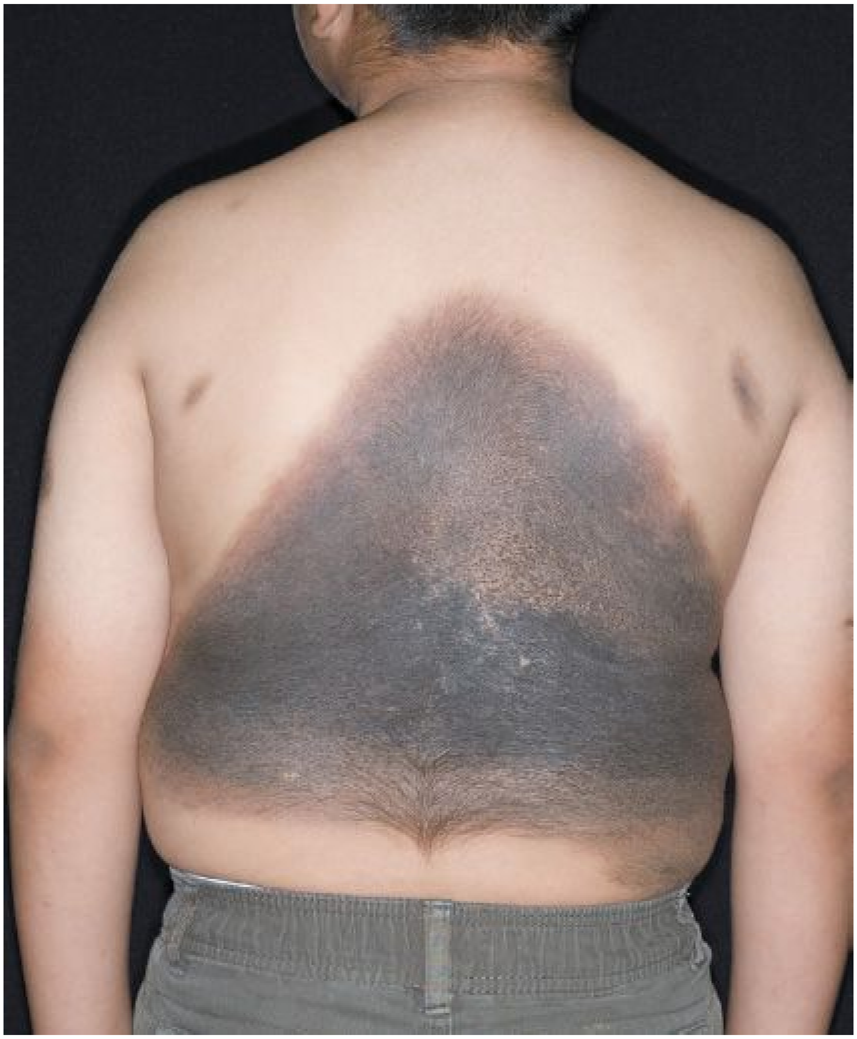

FIGURE 144-5 Giant congenital bathing trunk nevus surrounded by satellite nevi in a 7-year-old Hispanic boy. The patient was referred for consideration of staged removal of this potentially dangerous lesion. (*Used with permission from Richard P. Usatine, MD*.)

- However, in a prospective study of 230 medium-sized congenital nevi (1.5 to 19.9 cm; (**Figures 144-6** to **144-7**) in 227 patients from 1955 to 1996, no melanomas occurred. The average follow-up period was 6.7 years to an average age of 25.5 years.[7]

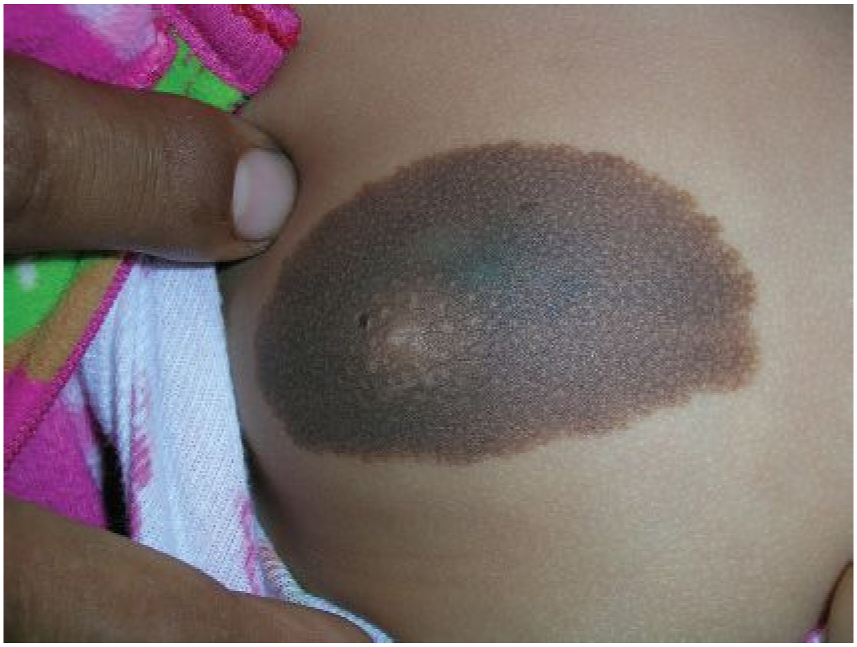

FIGURE 144-6 Congenital nevus on around the areola of a 4-monthold girl. It was recommended to not excise this nevus as it would likely cause damage to breast development in the future. As there are no malignant features this nevus will be followed with yearly clinical exams. (*Used with permission from Richard P. Usatine, MD.*)

  - Other risk factors for melanoma include personal or family history of melanoma or other skin cancer, presence of multiple nevi, red hair, blue eyes, freckling, and history of radiation (see Chapter 147, Melanoma).[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology of CMN is unknown.
- Congenital nevi result from a proliferation of benign melanocytes in the dermis, epidermis, or both. Melanocytes of the skin originate in the neuroectoderm and migrate vertically to the skin and other locations such as the central nervous system and eye.[1] Defects in migration or maturation are hypothesized as causal.

MAKING THE DIAGNOSIS

Diagnosis is usually made based on clinical features.

CLINICAL FEATURES[1]

- Variable mixtures of color including pink-red (primarily at birth), tan, brown, black, or multiple shades within a single lesion; color usual remains constant over time but the nevus will grow as the child grows.
- Shapes are also highly variable including oval, round, linear, and random; lesions have irregular but well demarcated borders. The pigment may fade off into surrounding skin.
- Nevi may become raised over time or a portion may become raised (**Figure 144-8**). The skin surface ranges from smooth to pebbly (**Figure 144-9**) to hyperkeratotic.

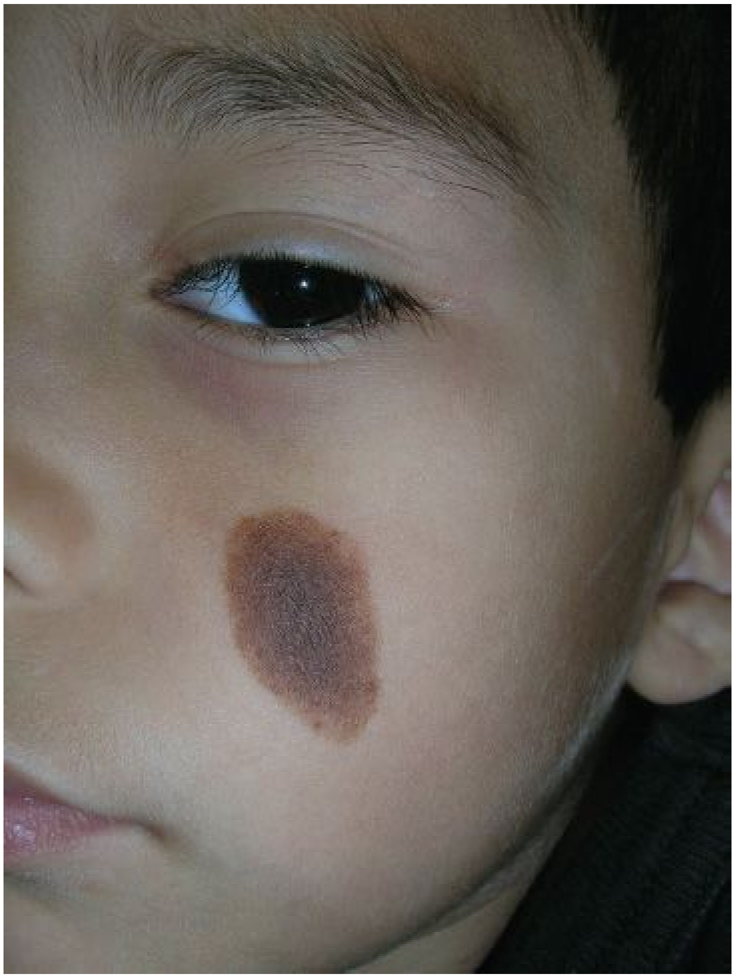

FIGURE 144-7 Medium-sized congenital nevus on the face of this 4-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

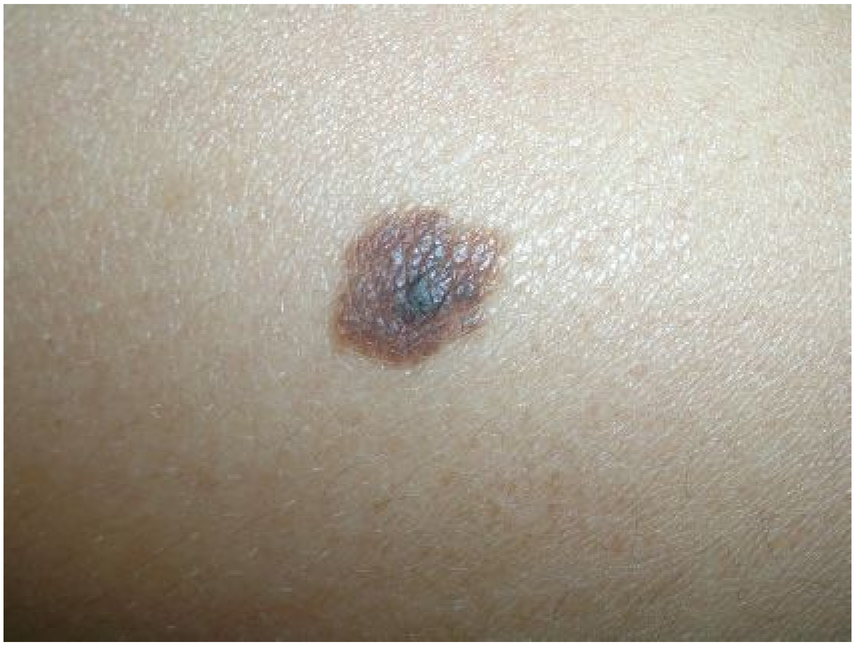

FIGURE 144-8 Congenital nevus on the shoulder of this 10-year-old girl that was biopsied to confirm that it was benign. Note the small area of raised pigmentation in the middle of the nevus that prompted the parent’s request for a biopsy. (*Used with permission from Richard P. Usatine, MD*.)

- Macular portion usually found at edges.
- Frequently exhibit hypertrichosis (**Figures 144-10** and **144-11**).

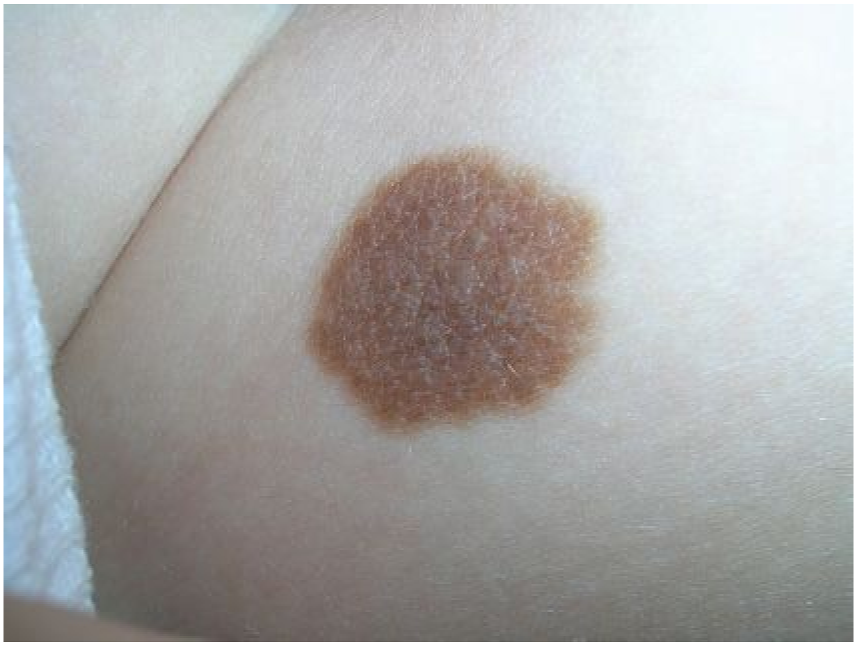

FIGURE 144-9 Congenital nevus on a 7-year-old boy with a pebbly surface. (*Used with permission from Richard P. Usatine, MD.*)

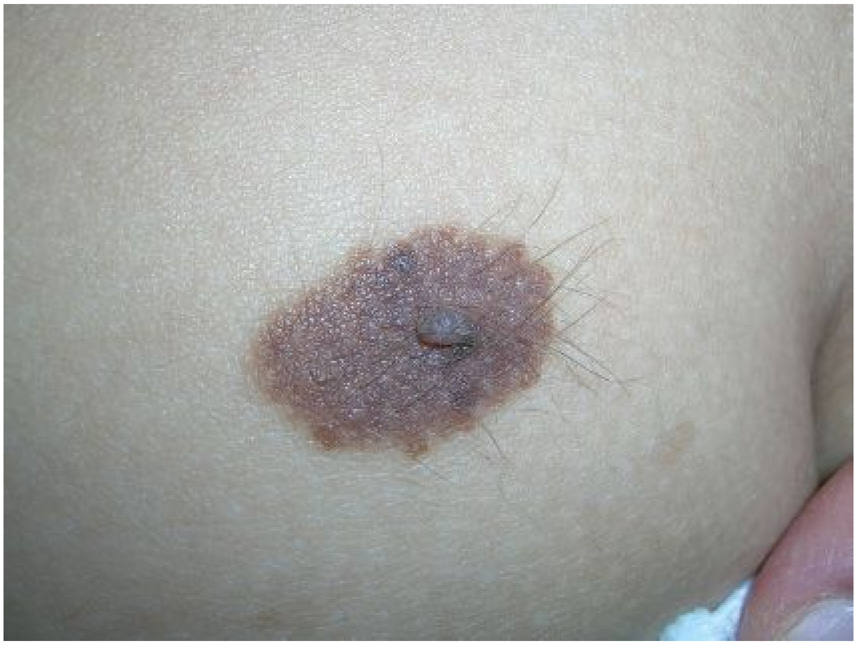

FIGURE 144-10 A benign hairy congenital nevus on the upper buttocks of a 7-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

- Heavily pigmented large congenital melanocytic nevi over a limb may be associated with underdevelopment of the limb.[1]
- Lesions are classified by size in adulthood as:[1]
  - Small (<1.5 cm; **Figure 144-1**).
  - Medium (1.5 cm-19.9 cm; **Figures 144-6** and **144-10**).
  - Large (>20 cm; **Figures 144-2** through **144-5**). Giant nevi are often surrounded by several smaller satellite nevi (**Figures 144-2** through **144-5** and **144-11**).

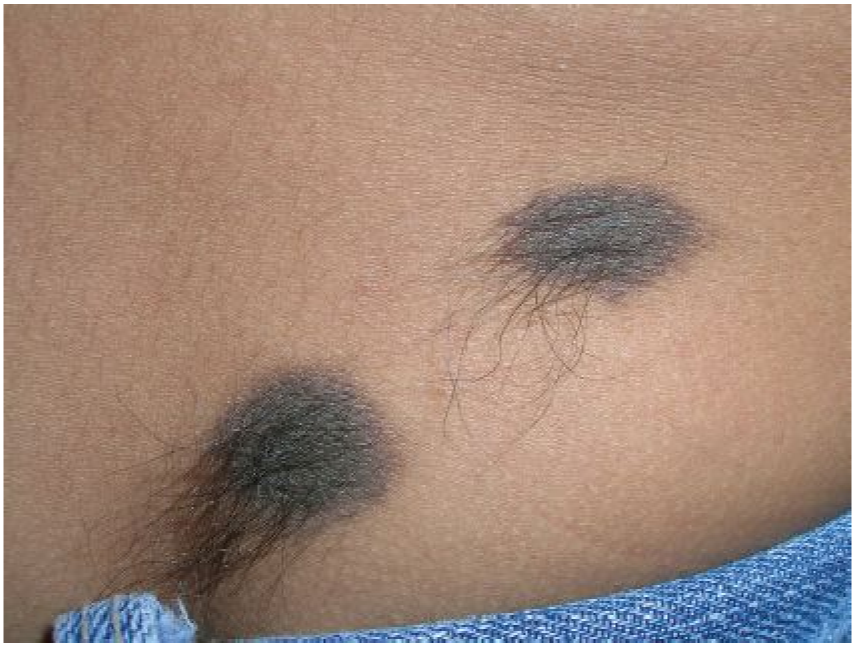

FIGURE 144-11 Two satellite nevi with hypertrichosis in a child with one larger congenital nevus not shown in this photograph. (*Used with permission from Richard P. Usatine, MD.*)

  - Lesions on a child's head of >9 cm are considered large based on likely eventual growth.[1]

IMAGING

- Dermoscopy findings depend on the age and location. In one study, the globular pattern (**Figure 144-12**) was most common in children under age 11 years and on the trunk.[8] The majority of reticular lesions were located on the limbs and the variegated pattern was the most specific for congenital nevi. In one Japanese follow-up study of children with acral CMN (N=24 lesions), changes in dermoscopic features were observed in 4 lesions on patients younger than age 14 years.[9]
- Magnetic resonance imaging (MRI) of the central nervous system can be a useful diagnostic tool in patients suspected of having neurocutaneous melanosis; one author recommended a screening MRI for patients with giant congenital melanocytic nevi.[10]

TYPICAL DISTRIBUTION

- Congenital nevi may be found anywhere on the body.

BIOPSY

- Although there are many histological subtypes, distinguishing histologic features of CMN include:[1]
  - Involvement by nevus cells of deep dermal appendages and neurovascular structures (e.g., hair follicles, sebaceous glands, arrector pili muscles, and within walls of blood vessels).
  - Infiltration of nevus cells between collagen bundles.

DIFFERENTIAL DIAGNOSIS

- Acral nevi—Congenital nevi that appear on the palms and soles are one type of acral nevus (**Figure 144-13**). Other acral nevi may be acquired. If acral nevi appear benign we do not need to be biopsied. The most benign easily recognizable benign pattern of an acral nevus shows pigment running in the valleys of the Hill in Valley pattern seen on the skin in these areas.

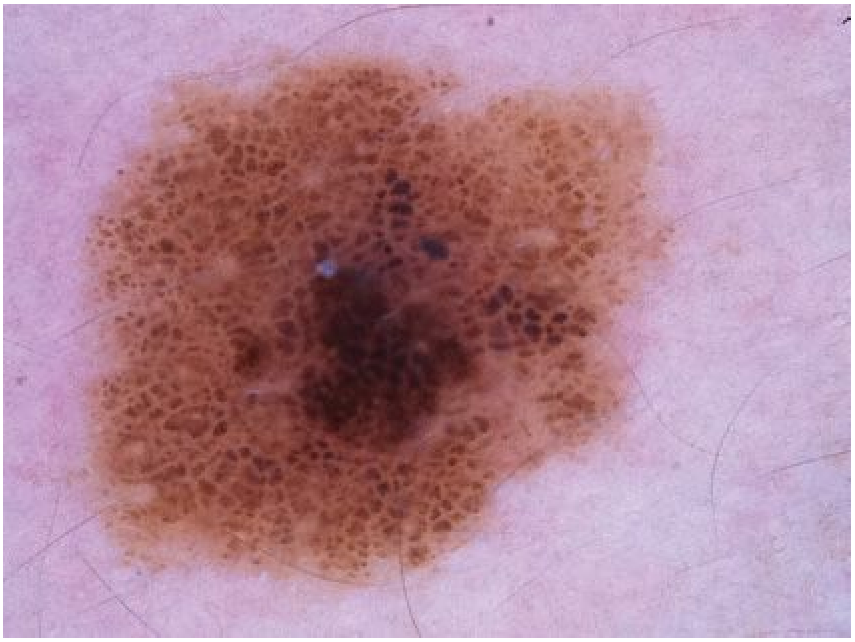

FIGURE 144-12 Dermoscopy of a congenital nevus in a child showing a globular pattern. This is the congenital nevus on the 10-year-old girl in Figure 144-8. (*Used with permission from Richard P. Usatine, MD*.)

- Becker nevus—A brown macule, patch of hair, or both on the shoulder, back, or submammary area that most often develops in adolescence. The border is irregular and the lesion may enlarge to cover an entire shoulder or upper arm. It is a type of hamartoma and is not a melanocytic nevus (see Chapter 143, Nevus). A Becker's nevus can appear at birth and enlarge during adolescence (**Figure 144-14**).

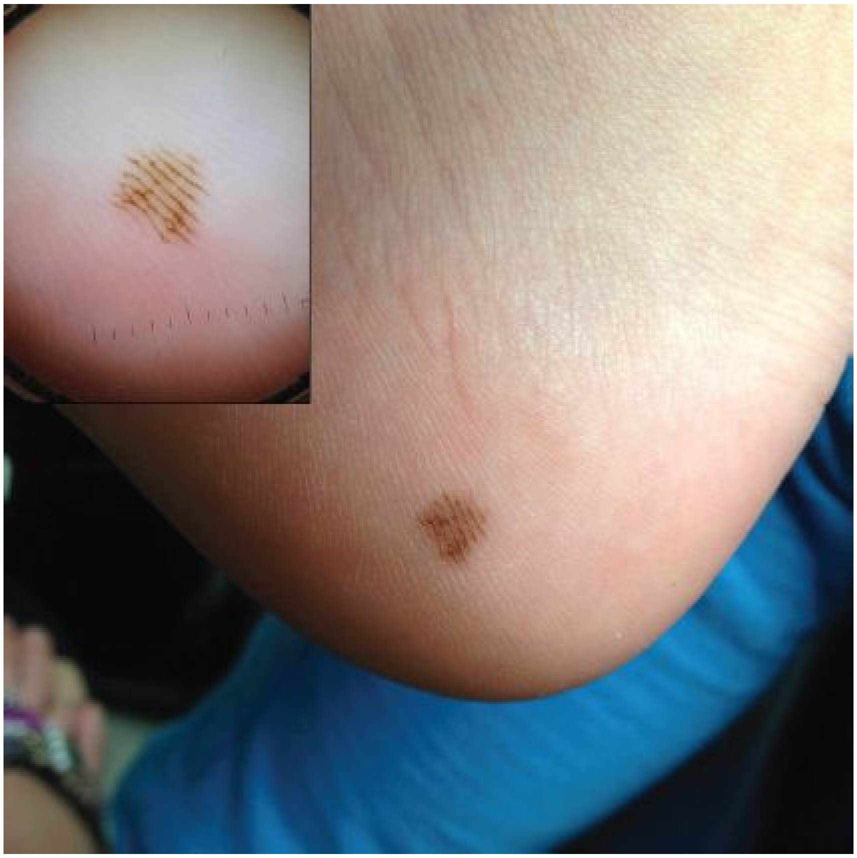

FIGURE 144-13 Acral congenital nevus close to the sole of the foot of an 8-year-old girl. The dermascopic image in the upper left corner shows parallel pigmented lines running in the valleys of the acral skin reassuring the physician that this is a benign nevus. (*Used with permission from Richard P. Usatine, MD*.)

- Café-au-lait spots—Coffee-and-milk-colored patch that can be present at birth or develop during early childhood. Although a number of large café-au-lait spots are associated with neurofibromatosis, a few of them can occur in completely unaffected children. These light-brown patches have increased melanin but are not nevi (see Chapter 206, Neurofibromatosis).
- Dermal Melanocytosis (Mongolian Spot)—Blue-gray hyperpigmented patch present at birth with less well-defined borders than a congenital nevus. They are seen most often on the buttocks and back and can be quite large (see Chapter 168, Hyperpigmentation).
- Nevus depigmentosus—A benign nonmelanocytic nevus with hypopigmentation that may have jagged edges resembling a continent.

These are often congenital but can also be acquired (**Figure 144-15**).

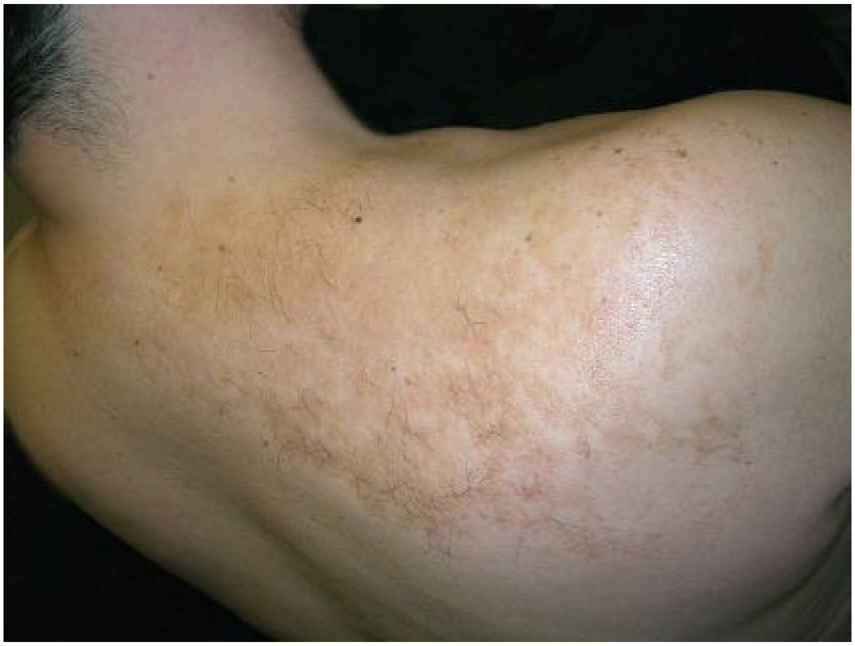

FIGURE 144-14 A congenital Becker's nevus presenting with hyperpigmentation and hair growth on the right shoulder of this teenage boy. (*Used with permission from Richard P. Usatine, MD*.

- Nevus spilus (speckled nevus)—Hairless, oval or irregularly shaped brown lesion with darker brown to black dots containing nevus cells. These may appear at birth or any age (**Figure 144-16**; see Chapter 143, Benign Nevus).

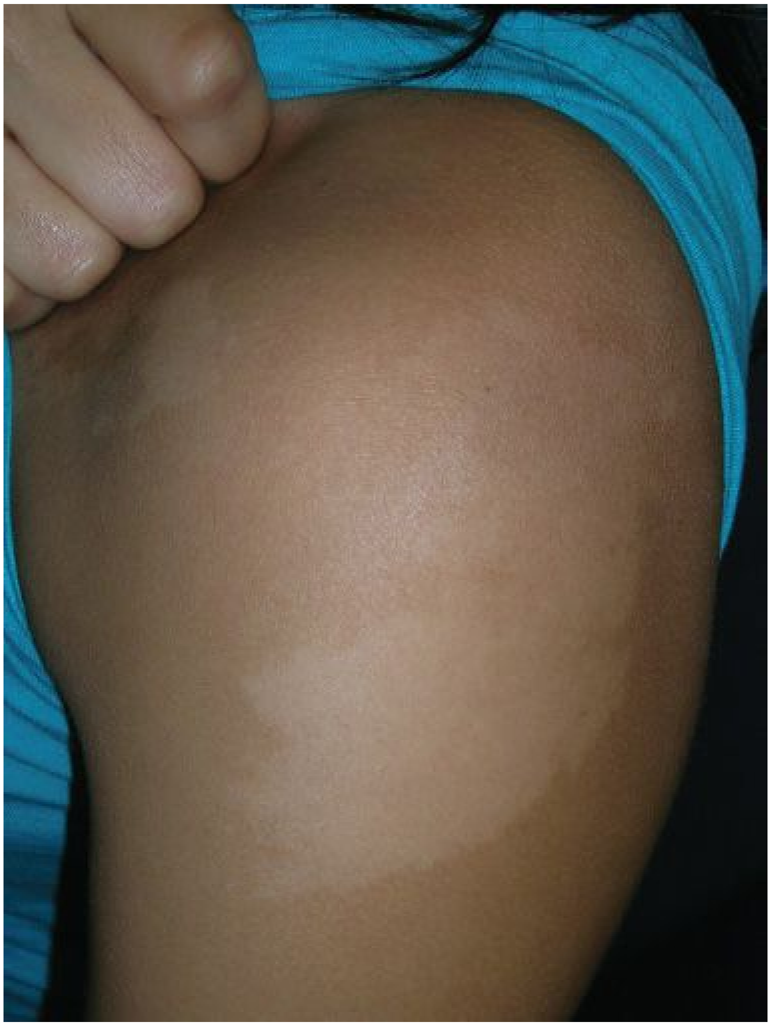

FIGURE 144-15 Congenital nevus depigmentosus on the shoulder of a 17-year-old girl since birth. (*Used with permission from Richard P. Usatine, MD*.)

- Changes that can occur to a congenital nevus may include the development of a halo (**Figure 144-17**) or pigment incontinence (**Figure 144-18**). It is best to biopsy any suspicious changes.

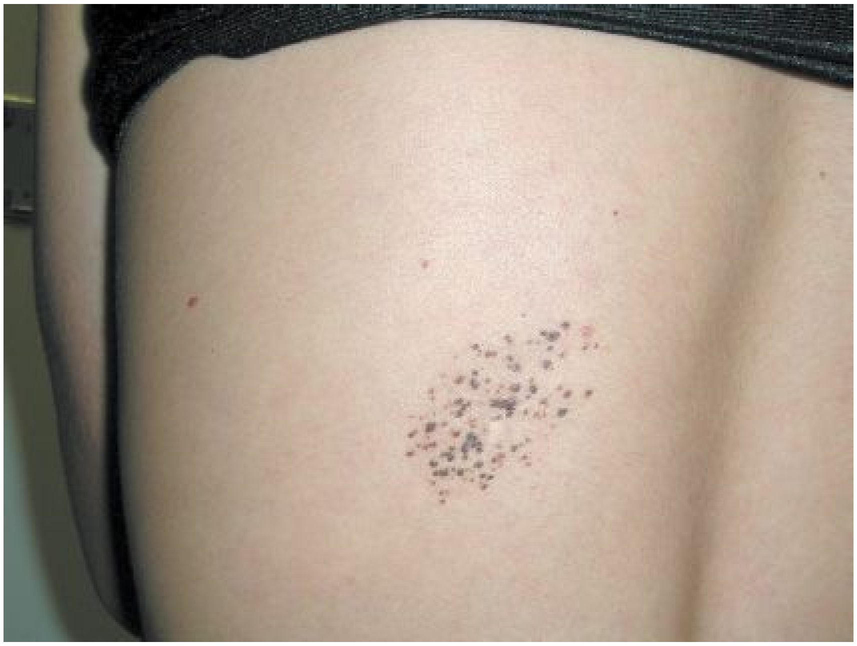

FIGURE 144-16 A speckled congenital nevus (nevus spilus) on the back. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

The management of CMN depends on size and location of the lesion (difficulty in monitoring), associated symptoms, the age of patient, the effect on cosmesis, and the potential for malignant transformation.

- For small and medium-sized CMN, the risk of malignant transformation is small and prophylactic removal is not recommended. For cosmesis, treatments include dermabrasion, curettage, laser therapy, and surgical excision.
- Larger CMN can be surgically removed but may require tissue expanders, tissue grafts, and tissue flaps to close large defects. Because the melanocytes may extend deep into underlying tissues (including muscle, bone, and central nervous system), removing the cutaneous component may not eliminate the risk of malignancy.
    - There is also concern that surgical intervention may adversely affect CMN cells.[11]

- Laser treatment of the lesions has been performed with a number of different types of lasers.[12] Because of the lack of penetrance to deeper tissue levels, long-term recurrence or malignant transformation is also an issue with these techniques.
    - In a case series of patients with CMN (N-52) at a mean of 8 years follow-up, most (87%) were satisfied with their treatment and about three quarters had minimal visible pigmentation after treatment completion.[13] Treatment failure occurred in 5 patients and recurrence developed in 5; a few patients had hypertrophic scarring or hyperpigmentation and 1 patient developed an intracranial melanoma.
- Careful life-long follow-up with photographs is an acceptable approach, especially with the affordability of digital cameras.
- Garment or bathing trunk nevi (**Figures 144-2** through **144-5**).
    - About half of the melanomas that develop in bathing trunk nevi do so before age 5 years.[14] These melanomas can be missed by observation because they can have non-epidermal origins.
- Surgical excision is recommended by some experts to prevent melanoma.[14] SOR Ⓒ
- Changes to watch for that call for a biopsy include:
    - Partial regression (depressed white areas).
    - Inflammation.
    - Rapid growth or color change.
    - Development of a firm nodule (**Figure 144-19**).

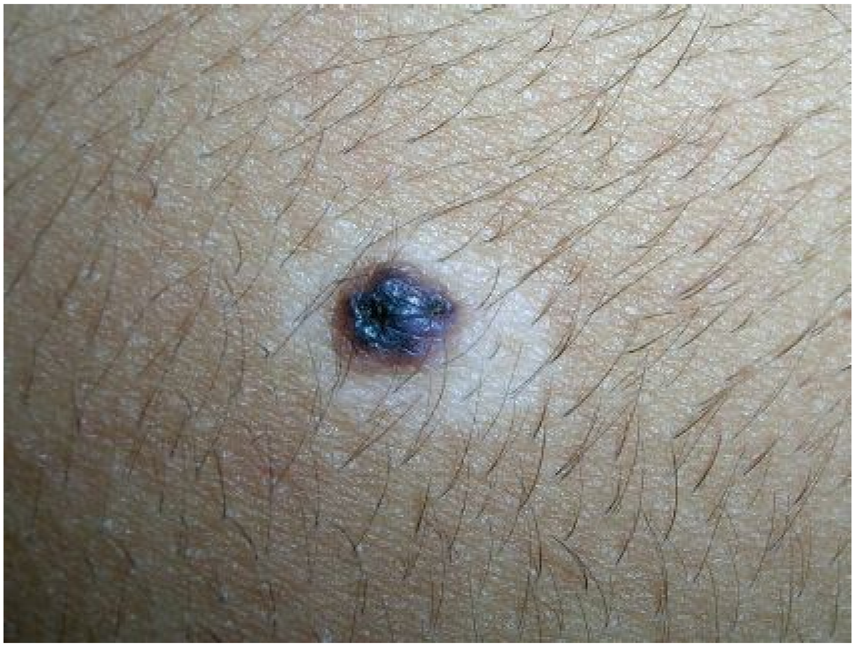

FIGURE 144-17 This congenital nevus on a 12-year-old girl became darker and developed a halo around it. Upon excision it was determined that it was an inflamed congenital intradermal nevus with no malignant features. (*Used with permission from Richard P. Usatine, MD*.)

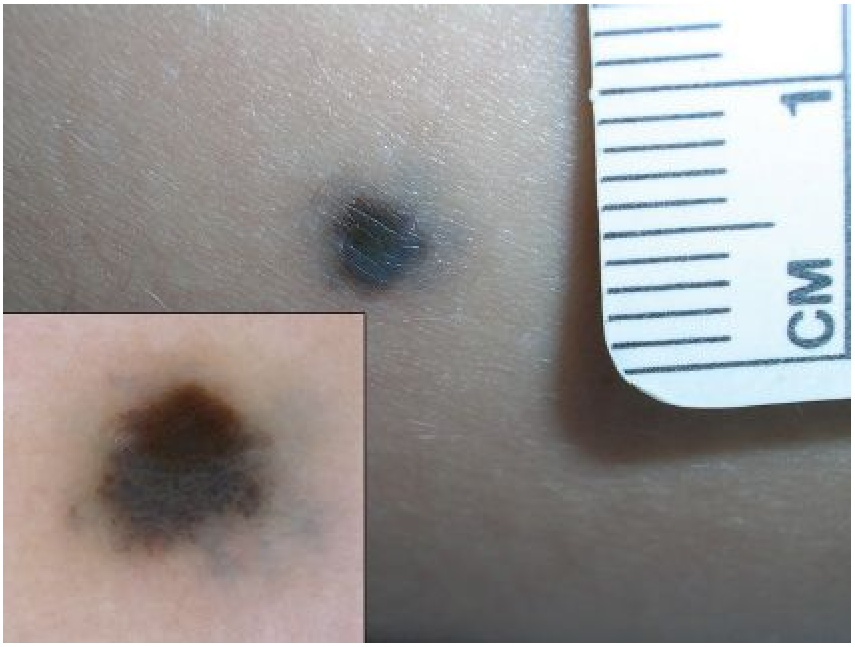

FIGURE 144-18 Color changes appearing in a congenital nevus. The dermoscopic image in the bottom left corner was not reassuring and a

biopsy revealed pigment incontinence but no signs of malignancy. (*Used with permission from Richard P. Usatine, MD*.)

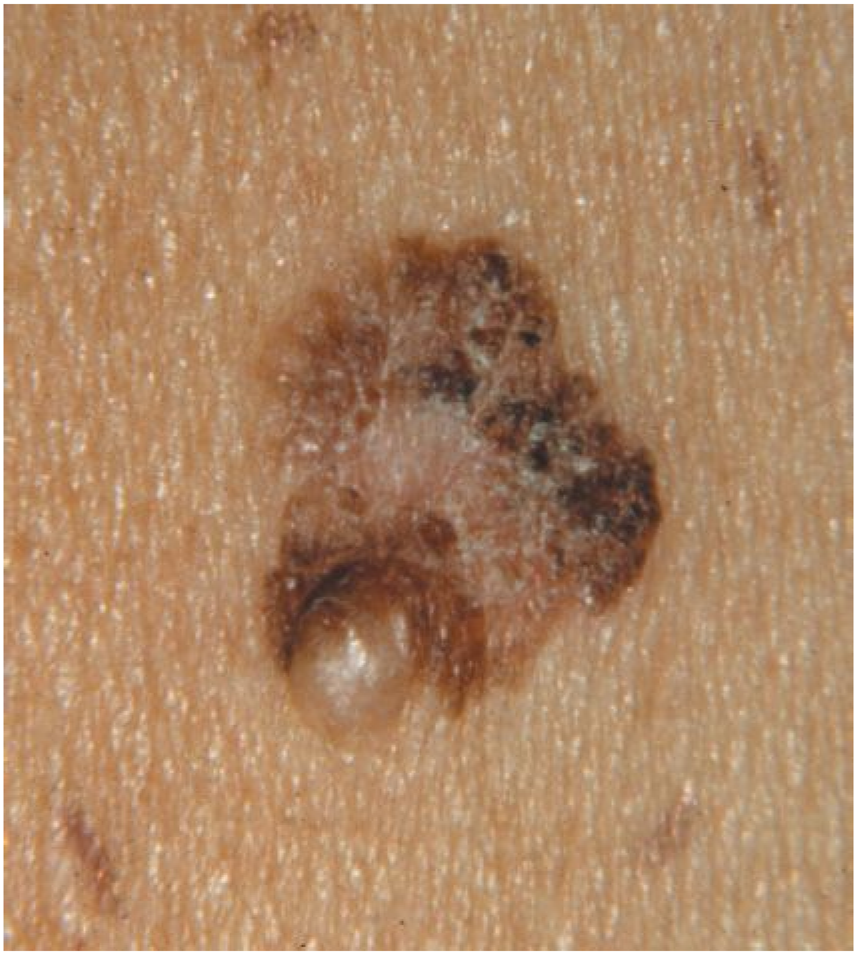

FIGURE 144-19 Melanoma arising in an acquired nevus showing features of central regression and a new elevated nodule. These are the same features that would make a congenital nevus suspicious for melanoma. (*Used with permission from UTHSCSA Division of Dermatology*.)

FOLLOW-UP

- Patients with giant CMN or multiple CMN may benefit from consultation with a neurologist, pediatrician, or both because of the risk of neurocutaneous melanosis and its neurologic manifestations or obstructive hydrocephalus.

- Bathing trunk nevi can also be associated with spina bifida, meningocele, and neurofibromatosis.[14]
- Because patients with all forms of CMN, especially giant CMN, have an increased risk of developing melanoma, physicians should consider baseline photography and regular follow-up with an experienced clinician for these patients.

PATIENT EDUCATION

- All patients should be told about the importance of protection from ultraviolet light exposure. This is especially important in people with giant CMN, because they at a significantly increased risk of melanoma.
- Patients (or their parents) should be taught to look for signs of melanoma (ABCDE: asymmetry, border irregularity, color irregularity, diameter >5 mm, evolution).

145 EPIDERMAL NEVI AND NEVUS SEBACEOUS

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A 15-year-old boy is brought in by his mother with a concern about growth of his birthmark. It has become somewhat more raised and bumpy in the past year (**Figure 145-1**). The adolescent reports no symptoms and is not worried about the appearance. He is otherwise healthy with no neurologic symptoms. The joint decision of the family and the doctor was to not excise the epidermal nevus at this time. He may choose to have this removed by a plastic surgeon in the future.

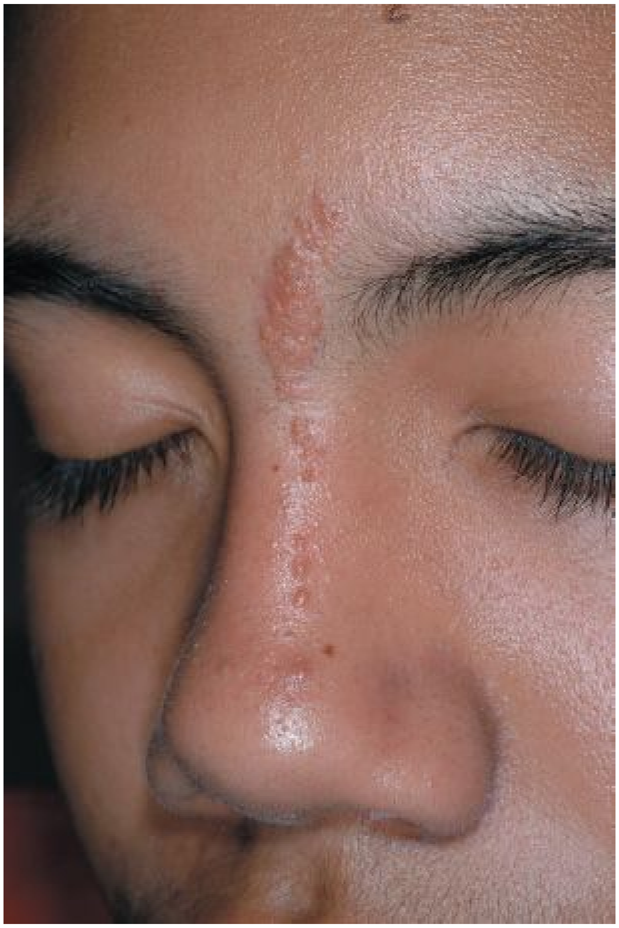

FIGURE 145-1 Epidermal nevus on the face of a teenager. This nevus has been present since birth, and the patient is otherwise healthy. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

- Epidermal nevi (EN) are congenital hamartomas of ectodermal origin classified on the basis of their main component: sebaceous, apocrine, eccrine, follicular, or keratinocytic.
- Nevus sebaceous (NS) is a hamartoma of the epidermis, hair follicles, and sebaceous and apocrine glands. A hamartoma is the disordered overgrowth of benign tissue in its area of origin.

SYNONYMS

- EN syndrome is also called Solomon syndrome and is a neurocutaneous disorder characterized by EN and an assortment of neurologic and visceral manifestations.
- NS is also called sebaceous nevus and nevus sebaceous of Jadassohn (**Figure 145-2**).

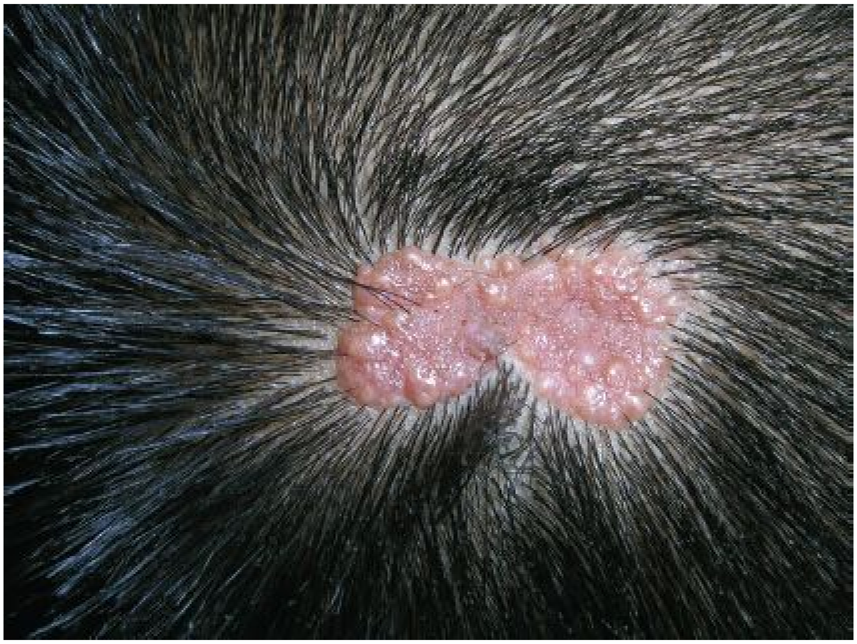

FIGURE 145-2 Nevus sebaceous on the scalp of a 14-year-old boy. (*Used with permission from Richard P. Usatine, MD.*)

- An inflammatory linear verrucous epidermal nevus (ILVEN; **Figure 145-3**) can be part of an epidermal nevus syndrome but some affected persons only have the cutaneous EN.

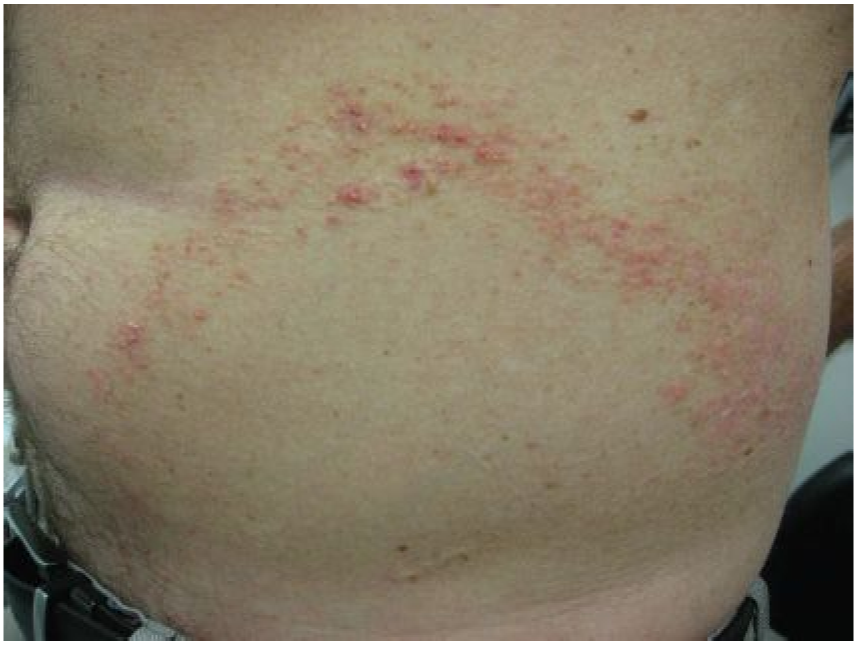

FIGURE 145-3 Inflammatory linear verrucous epidermal nevus (ILVEN) on the trunk. Topical steroids were not helpful in diminishing his pruritus. (*Used with permission from Robert T. Gilson, MD.*)

EPIDEMIOLOGY

- EN are uncommon (approximately 1 to 3 percent of newborns and children), sporadic, and usually present at birth, although they can appear in early childhood.
- EN are associated with disorders of the eye, nervous, and musculoskeletal systems in 10 to 30 percent of patients; in one study, 7.9 percent of patients with EN had one of the nine syndromes—an estimated one per 11,928 pediatric patients.[1]
- In another review of 131 cases of EN, most (60%) had noninflammatory EN, 1/3 had NS, and 6 percent had inflammatory linear verrucous EN.[2]
- NS are usually present at birth or noted in early childhood.[3] Most cases are sporadic but familial cases have been reported.
- Linear NS is estimated to occur in 1 per 1000 live births.[4]

- Linear NS syndrome includes a range of abnormalities including in the central nervous system (CNS). Patients with CNS involvement typically have cognitive impairment and seizures.[4] The cardiovascular, skeletal, ophthalmologic, and urogenital systems may also be involved.

ETIOLOGY AND PATHOPHYSIOLOGY

- EN histologically displays hyperkeratosis and papillomatosis, similar microscopically to seborrheic keratosis.[3] Also similar to seborrheic keratosis, some ENs of keratinocyte differentiation (about one third) have been found to have a mutation in the fibroblast growth factor receptor 3 (FGFR3) gene.[3]
- Nine EN syndromes have been reported and are described in the referenced article.[5]
- ENs frequently have a linear pattern that follows Blaschko lines (**Figures 145-1**, **145-3**, and **145-4**), which are believed to represent epidermal migration during embryogenesis.

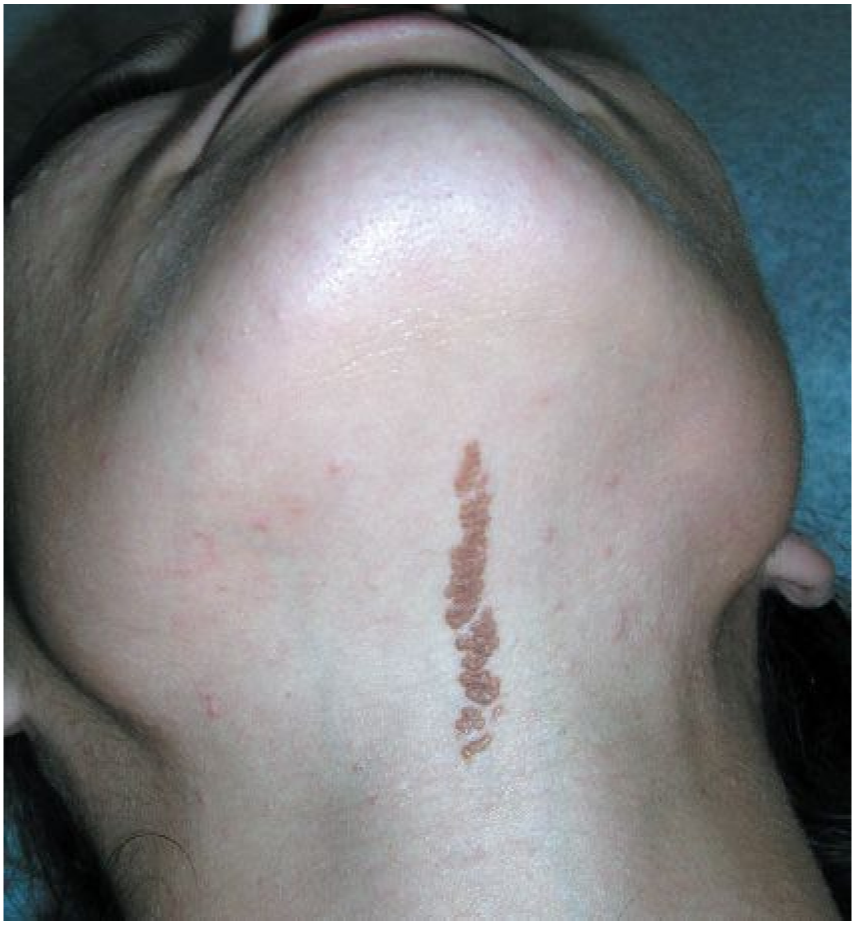

FIGURE 145-4 Linear epidermal nevus on the neck that appeared in early childhood. The patient had no neurologic, musculoskeletal, or vision problems. (*Used with permission from Richard P. Usatine, MD*.)

- EN tend to become thicker, verrucous (**Figure 145-4**), and hyperpigmented at puberty.[3]
- Similarly, NS demonstrate stages of evolution paralleling the histologic differentiation of normal sebaceous glands:[6]
  - Infancy and young children—Smooth to slightly papillated, waxy, hairless thickening (**Figure 145-5**).

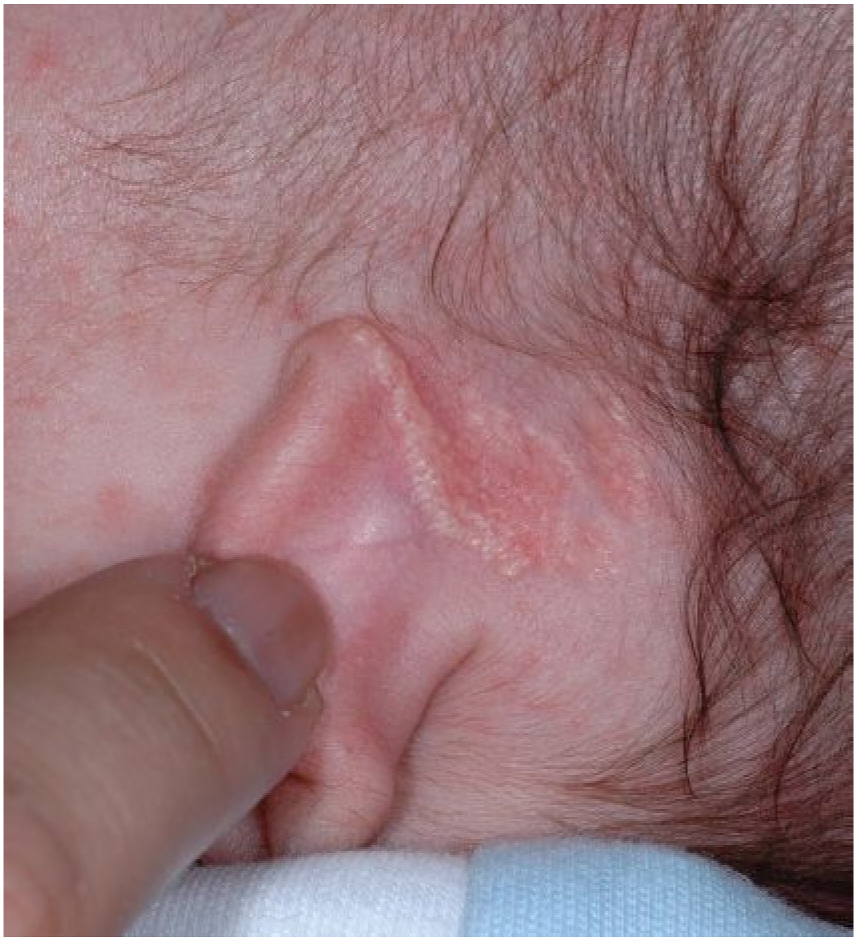

FIGURE 145-5 Nevus sebaceous behind the ear of an infant. Note the light color and the subtle presentation. (*Used with permission from Richard P. Usatine, MD*.)

  - Puberty—Epidermal hyperplasia resulting in verrucous irregularity of the surface covered with numerous closely aggregated yellow-to-brown papules (**Figure 145-6**).

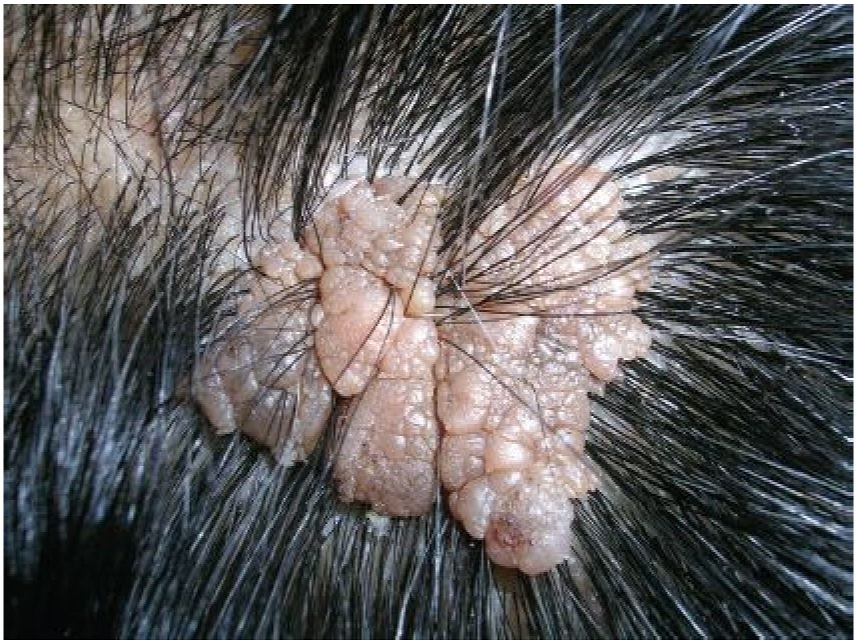

FIGURE 145-6 Nevus sebaceous on the scalp of a teenage female that is verrucous and brown. (*Used with permission from Richard P. Usatine, MD*.)

- Development of secondary appendageal tumors (**Figures 145-7**) occurs in 20 to 30 percent of patients, most are benign (most commonly basal cell epithelioma or trichoblastoma), but single (most commonly basal cell carcinoma) or multiple malignant tumors of both epidermal and adnexal origins may be seen and metastases have been reported. Rarely, these malignancies are seen in childhood.

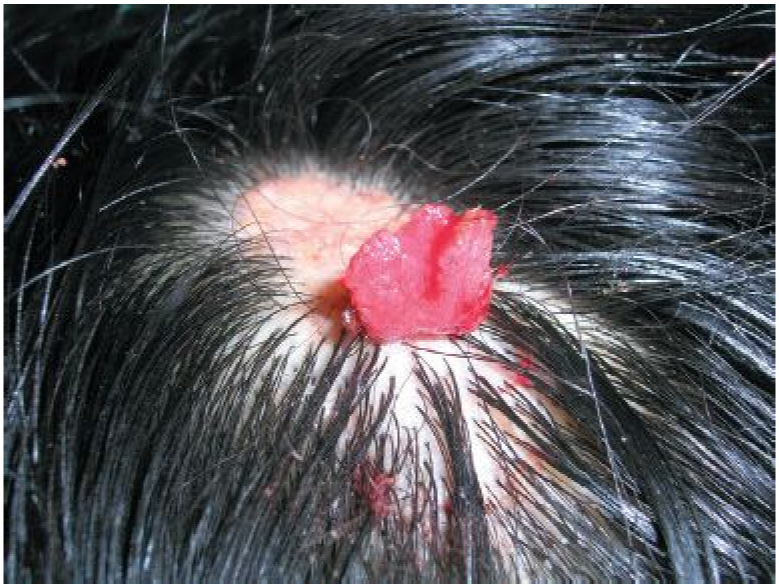

FIGURE 145-7 Nevus sebaceous with a benign tumor identified as a syringocystadenoma papilliferum by shave biopsy. Patient was referred for full removal of the nevus sebaceous. (*Used with permission from Richard P. Usatine, MD.*)

- NS were shown to have a high prevalence of human papillomavirus DNA and authors postulate that HPV infection of fetal epidermal stem cells could play a role in the pathogenesis.[7]

MAKING THE DIAGNOSIS

CLINICAL FEATURES OF EPIDERMAL NEVI

- EN are linear, round or oblong, well circumscribed, elevated, and flat-topped (**Figures 145-8** and **145-9**).

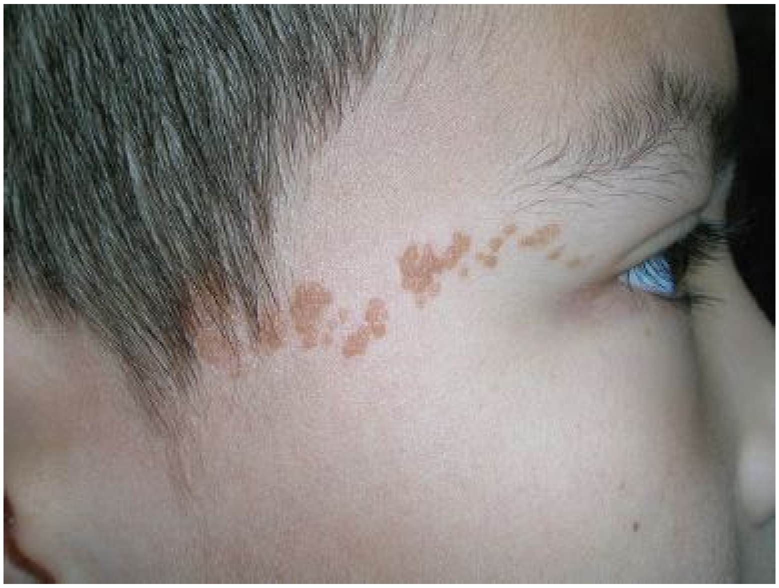

FIGURE 145-8 Epidermal nevus that is linear on the side of this young boy’s face. (*Used with permission from Richard P. Usatine, MD.*)

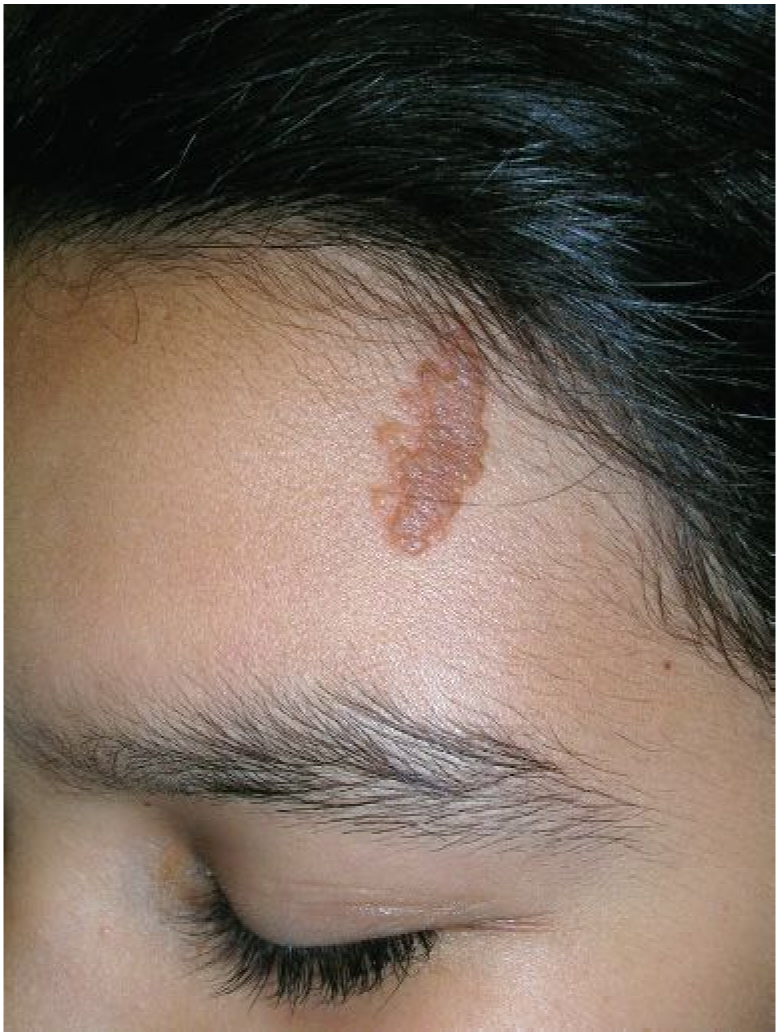

FIGURE 145-9 Epidermal nevus with some hyperpigmentation on the forehead of this young girl. (*Used with permission from Richard P. Usatine, MD*.

- Color is yellow-tan to dark brown.
- Surface is uniform velvety or warty (**Figures 145-8** and **145-9**).
- ILVEN, a less common type of EN, is pruritic and erythematous (**Figure 145-3**).

CLINICAL FEATURES OF NEVUS SEBACEOUS

- NS has an oval to linear shape ranging from 0.5 × 1 cm to 7 × 9 cm.
- NS is usually solitary, smooth, waxy, hairless thickening noted on the scalp at birth or in early childhood (**Figures 145-6**, **145-6**, and **145-10**).

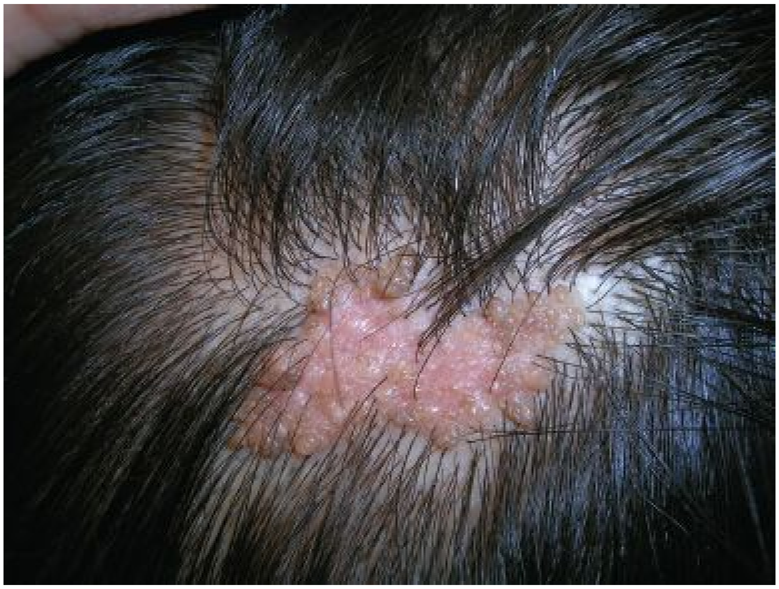

FIGURE 145-10 Nevus sebaceous on the scalp appearing verrucous with pink and brown coloration. (*Used with permission from Richard P. Usatine, MD*.)

- Early NS may be pink, orange, yellow or tan; later lesions can appear verrucous and nodular (**Figure 145-10**).

TYPICAL DISTRIBUTION

- EN occur most commonly on the head and neck followed by the trunk and proximal extremities; only 13 percent have wide spread lesions (**Figure 145-11**). Lesions may spread beyond their original distribution with age. Inflammatory verrucous EN is found on the limbs.

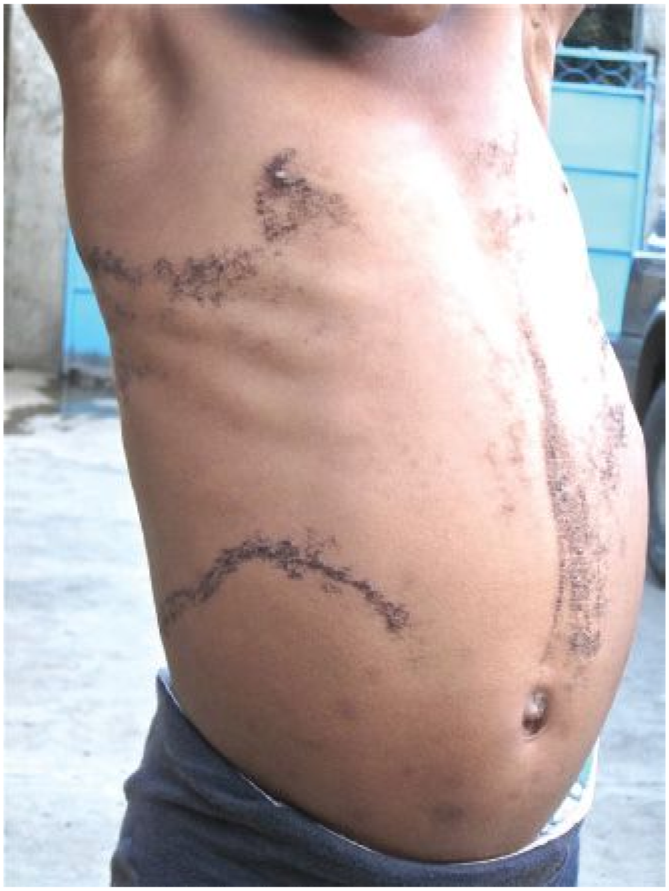

FIGURE 145-11 Extensive epidermal nevus following Blaschko lines on the trunk of this boy. Note how the lines are similar to the patient with inflammatory linear verrucous epidermal nevus (ILVEN) in Figure 145-2. (*Used with permission from Rick Hodes, MD.*)

- NS are commonly found on the scalp followed by forehead and retroauricular region (**Figures 145-10** and **145-5**) and rarely involves the neck, trunk, or other areas.

BIOPSY

- Biopsy is the most definitive method for diagnosing these nevi. A biopsy is not needed if the clinical picture is clear and no operative intervention is planned. A shave biopsy should provide adequate tissue for diagnosis because the pathology is epidermal and in the upper dermis.

    - Histologic features of epidermolytic hyperkeratosis within an EN are associated with mutations in the keratin gene that may be transmitted to offspring; widespread cutaneous involvement may be seen.[3]

DIFFERENTIAL DIAGNOSIS

- Lichen striatus—Discrete pink, tan, or skin-colored asymptomatic papules in a linear band that suddenly appear. The papules may be smooth, scaly, or flat topped. It is mostly seen in children. While it is most commonly seen on an extremity, it can appear on the trunk (**Figure 145-12**). It can resemble a linear EN but lichen striatus will spontaneously regress within one year.

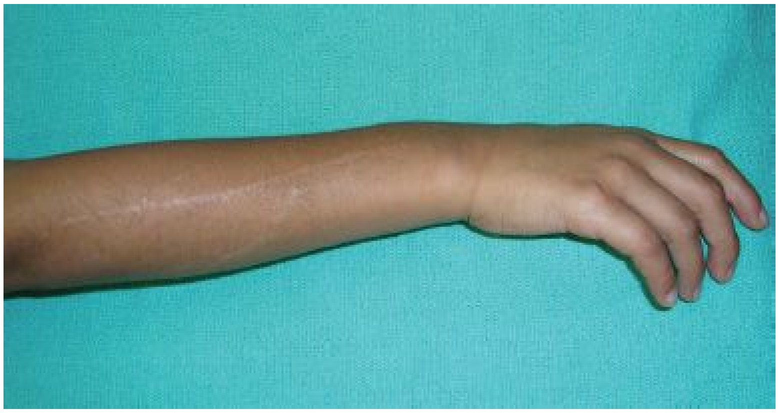

FIGURE 145-12 Lichen striatus that appeared suddenly on the arm of a young boy. (*Used with permission from Richard P. Usatine, MD.*)

- Syringoma (**Figure 145-13**)—Benign adnexal tumor derived from sweat gland ducts. Autosomal dominant transmission, soft, small, skin-colored to brown papules develop during childhood and adolescence, especially around the eyes but may be found on the face, neck, and trunk.

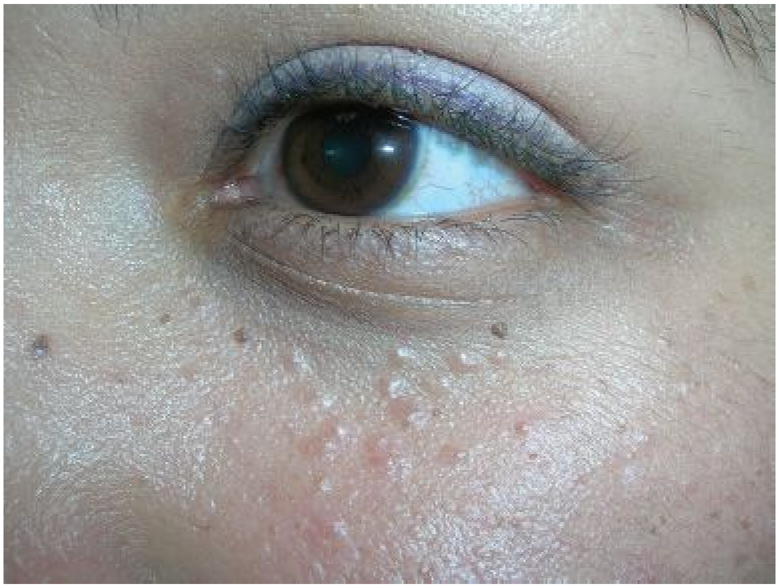

FIGURE 145-13 Syringoma on the lower eyelid of a teenage girl. (*Used with permission from Richard P. Usatine, MD*.)

MANAGEMENT

MEDICATIONS

- There are no proven topical methods for treatment of these lesions. Topical retinoids may improve lesion appearance but recurrence is common.[3]

PROCEDURES

- Destructive modalities for EN such as electrodessication or cryotherapy may temporally improve the appearance of the lesion, but recurrence is frequent.[3]
- Carbon dioxide laser is an alternative option for EN; however, scarring and pigment changes are potential permanent complications, especially in

patients with darker skin types.[8] This treatment does not completely remove NS and there is recurrence risk.

- Surgical excision is an option, but may be complicated by scarring.
- Because of the potential for malignant transformation particularly following puberty, many authors recommend early complete plastic surgical excision for NS (**Figure 145-14**); reconstructive surgery may be needed. SOR Ⓒ

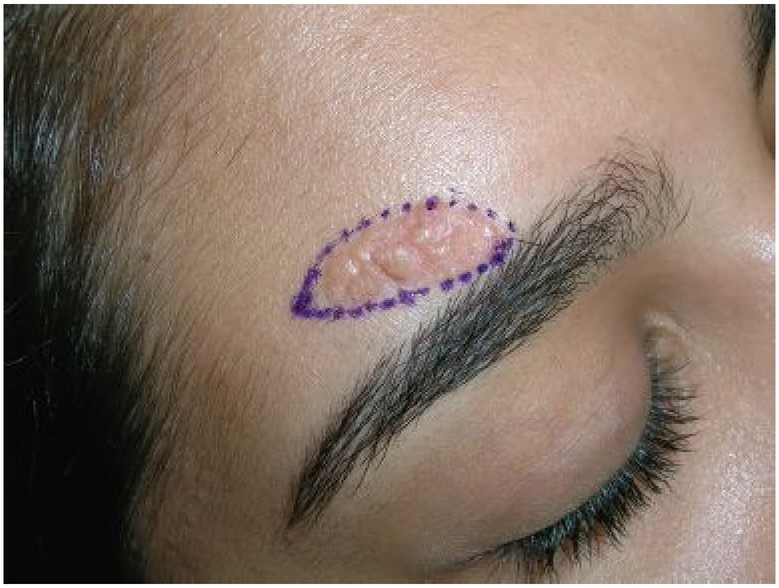

FIGURE 145-14 Nevus sebaceous about to be elliptically excised from the forehead of a 15-year-old girl. Careful surgery by an experienced surgeon produced an excellent cosmetic result. The girl and her parents requested the surgery for cosmetic and psychologic reasons as there were no signs of malignant degeneration. The girl and her parents were delighted with the results. (*Used with permission from Richard P. Usatine, MD.*)

- Excision of large lesions may require reconstructive surgery with a rotation flap to close.[9]

PROGNOSIS

- There are reports of spontaneous improvement in patients with widespread involvement of EN.
- Malignant potential is low in EN.[3]
- Malignant potential in NS is uncertain. Reports range from 0 to 2.7 percent.[3]
    - Early reports suggested a high rate of developing basal cell carcinomas while more recent studies identified trichoblastoma and syringocystadenoma papilliferum in NS, usually in adulthood.
    - In a retrospective analysis of 757 cases of NS from 1996 to 2002 in children ≤ age 16 years, investigators found no malignancies and question the need for prophylactic surgical removal.[10] In a study using data pooled from six large retrospective studies of giant NS (N = 2520), the cumulative incidence of malignant tumors was 0.5 percent.[11]
    - Squamous cell carcinoma has also been described in a NS.[12]

FOLLOW-UP

- Patients with NS should be examined for other associated findings. Consider a consultation with a neurologist and/or ophthalmologist.
    - In a study of 196 subjects with NS examined for clinical neurologic abnormalities, only 7 percent had abnormalities.[13] Abnormal exams were more frequent in individuals with extensive nevi (21% versus 5%) and a centrofacial location (21% versus 2%). The patients in **Figures 145-1** through **145-3** had no neurological abnormalities.

146 DYSPLASTIC NEVUS

Mindy A. Smith, MD, MS
Richard P. Usatine, MD

PATIENT STORY

A teenage boy presents with concern over a mole on his back that his mother says is growing larger and more variable in color. His mother, who is present with him, reports that his father had a melanoma that was caught early and successfully treated. The edges are irregular and the color almost appears to be “leaking” into the surrounding skin. He reports no symptoms related to this lesion. On physical exam, the nevus is 9 mm in diameter with asymmetry, variations in color and an irregular border (**Figure 146-1**). A full-body skin exam did not demonstrate any other suspicious lesions. Dermoscopy showed an irregular network with multiple asymmetrically placed dots off the network (**Figure 146-2**). A scoop saucerization was performed with a DermaBlade taking 2-mm margins of clinically normal skin (**Figure 146-3**). The pathology showed a completely excised compound dysplastic nevus with no signs of malignancy. No further treatment was needed except yearly skin exams to monitor for melanoma.

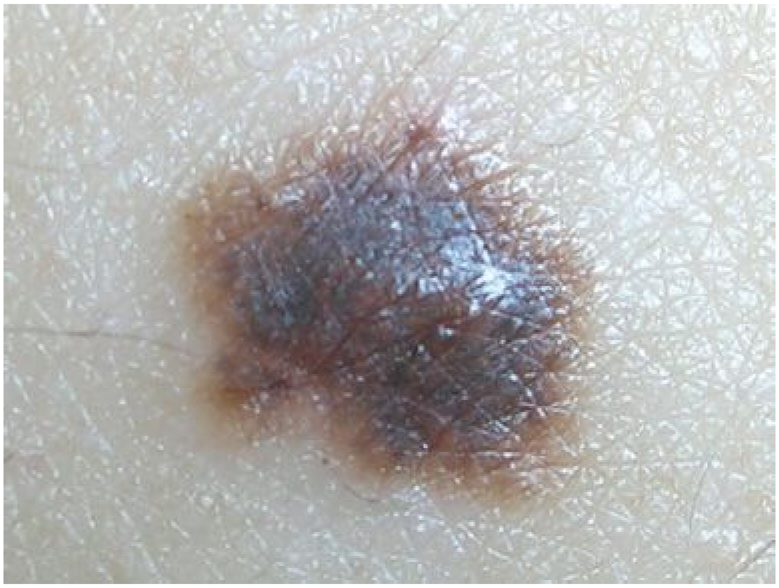

FIGURE 146-1 Growing 9-mm pigmented lesion on the back with asymmetry, variations in color and an irregular border. Pathology after excision revealed this to be a compound dysplastic nevus. (*Used with permission from Richard P. Usatine, MD*.)

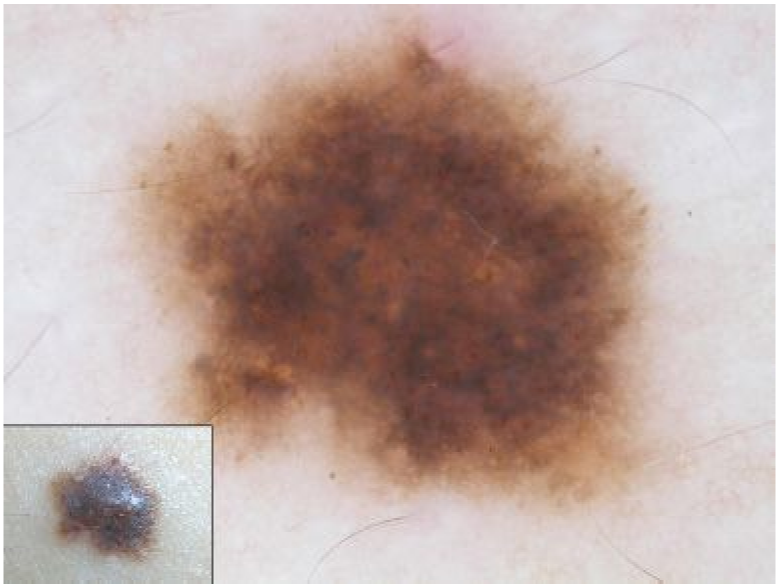

FIGURE 146-2 Dermoscopy of this compound dysplastic nevus shows an irregular network with multiple asymmetrically placed dots off the network. (*Used with permission from Richard P. Usatine, MD*.)

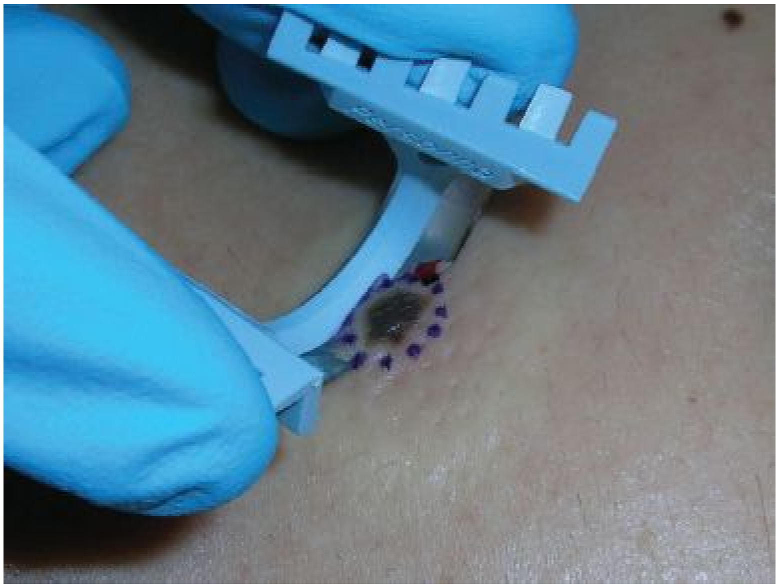

FIGURE 146-3 A scoop saucerization was performed with a DermaBlade taking 2-mm margins of clinically normal skin. Although this could have been an early thin melanoma, the pathology showed a completely excised compound dysplastic nevus with no signs of malignancy. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Dysplastic nevi (DN)/atypical moles are acquired melanocytic lesions of the skin whose clinical and histologic definitions are controversial and still evolving. These lesions have some small potential for malignant transformation and patients with multiple DN have an increased risk for melanoma.[1]

The presence of multiple DN is a marker for increased melanoma risk, similar to red hair, and, analogously, cutting off the red hair or cutting out all the DN does not change melanoma risk. The problem with DN is that any one lesion suspicious for melanoma must be biopsied to avoid missing melanoma, not to prevent melanoma from occurring in that nevus in the future.

SYNONYMS

Atypical nevus, atypical mole, Clark nevus, nevus with architectural disorder, and melanocytic atypia.[1]

EPIDEMIOLOGY

- DN are uncommon in children; in a study of Swedish children (N = 524), none had DN.[2] In another study of pathology reports from nevi removed from patients younger than 18 years, 3 of 199 nevi submitted for histologic analysis met the histologic criteria for DN.[3]
- Two percent to 9 percent of the population has atypical moles (AMs).[4,5] Among patients with melanoma, the rate of DN ranges from 34 to 59 percent.[4]
- Individuals with fair skin types are at higher risk of DN.[4]
- The sudden eruption of benign and atypical melanocytic nevi has been reported and is associated with blistering skin conditions and a number of disease states, including immunosuppression. Subsets of patients with immunosuppression have increased numbers of nevi on the palms and soles.[6]
- The National Institute of Health Consensus Conference on the diagnosis and treatment of early melanoma defined a syndrome of familial atypical mole and melanoma (FAMM). The criteria of FAMM syndrome are[7]:
    - The occurrence of malignant melanoma in one or more first- or second-degree relatives.
    - The presence of numerous (often >50) melanocytic nevi, some of which are clinically atypical.
    - Many of the associated nevi show certain histologic features (see the following section “Biopsy”).

ETIOLOGY AND PATHOPHYSIOLOGY

- Most DN are compound nevi (**Figure 146-1**) possessing a junctional and intradermal component (see Chapter 143, Benign Nevi).[1] The junctional component is highly cellular and consists of an irregular distribution of melanocytes arranged in nests and lentiginous patterns along the dermoepidermal junction. The dermal component, located at the center, consists of nests and strands of melanocytes with distinct sclerotic changes.[1]
- DN exhibit a host response consisting of irregular rete ridge elongation, subepidermal sclerosis, proliferation of dermal capillaries, and a perivascular, lymphohistiocytic inflammatory infiltrate.[1]
- Individuals with DN may have deficient DNA repair, and DN lesions are associated with overexpression of pheomelanin (pigment produced by melanocytes), which may lead to increased oxidative DNA damage and tumor progression.[8]

DIAGNOSIS

CLINICAL FEATURES

- Variable mixtures of color including tan, brown, black, and red within a single lesion (**Figures 146-4** and **146-5**).

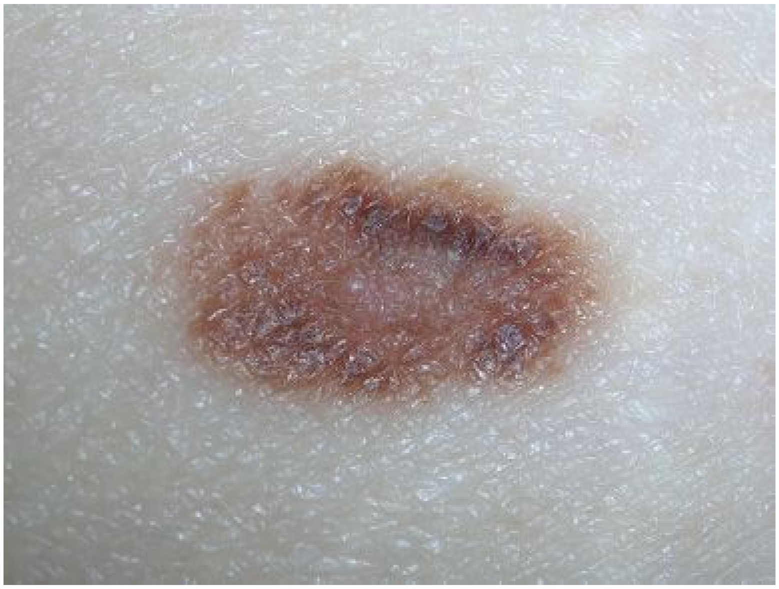

FIGURE 146-4 Dysplastic nevus in a young woman with malignant melanoma in a different region of her body. The size was greater than 6 mm and there was variation in color. This was fully excised to make sure there was no melanoma present. (*Used with permission from Richard P. Usatine, MD*.)

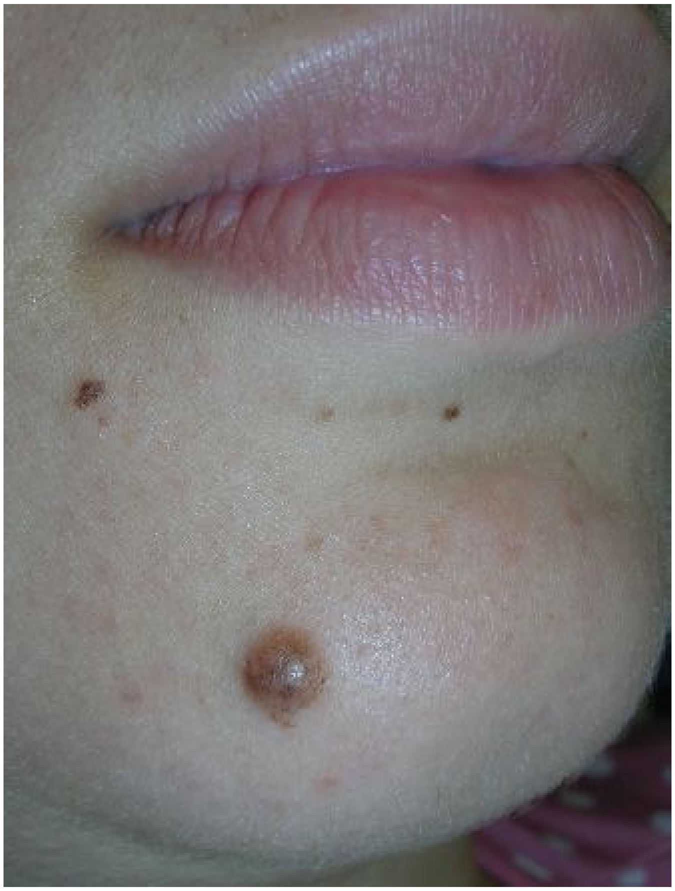

FIGURE 146-5 Dysplastic nevus on the chin of a teenage girl. A punch biopsy successfully removed the whole lesion and confirmed that it was not melanoma. (*Used with permission from Richard P. Usatine*, *MD*.)

- Irregular, notched borders; pigment may fade off into surrounding skin.
- Flat or slightly raised (**Figures 146-4** to **146-6**) with the macular portion at edge. Not verrucous or pendulous.

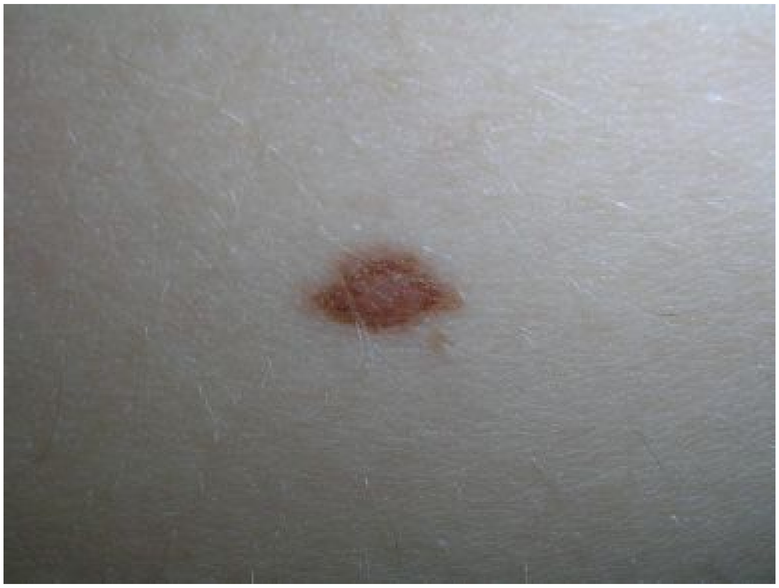

FIGURE 146-6 Dysplastic nevus on the back proven by biopsy. Note the fried egg appearance of this atypical mole. (*Used with permission from Richard P. Usatine, MD.*)

- Lesions frequently surrounded by a reddish hue from reactive hyperemia making them appear target-like.
- Usually larger than 6 mm; may be larger than 10 mm (**Figures 146-1** and **146-4**).
- Patients with FAMM syndrome may have more than 100 lesions, far greater than the average number of common moles (<50) in most individuals.

TYPICAL DISTRIBUTION

- Usually on sun-exposed areas, especially the back (**Figures 146-1** and **146-6**); may be found on sites where nevi are usually absent or rare such as the scalp, breasts, genital skin, buttocks, palm, and dorsa of feet.

IMAGING

- Although eccentric peripheral hyperpigmented and multifocal hyper- or hypopigmented types are more commonly seen in melanoma, no digital dermatoscopic criteria have been identified that can clearly distinguish DN from in situ melanomas.[9] However, dermoscopy increases diagnostic sensitivity and specificity of cutaneous melanoma from 60 to greater than 90 percent, especially using pattern recognition.[4]
- Investigators in one study found change in 16.2 percent of 2497 benign melanocytic lesions with minor suspicion of melanoma undergoing short-term dermoscopy.[10] Change was more often seen in younger (0 to 18 years and 19 to 35 years) and older patients.

BIOPSY

- The importance of histology is to distinguish DN from melanoma. Although not universally accepted, the World Health Organization Melanoma Program proposed a list of characteristics/criteria with individual lesions requiring two major and two minor criteria to be classified as a DN:[4]
    - Major criteria are basilar proliferation of atypical nevomelanocytes and organization of this proliferation in a lentiginous or epithelioid cell pattern.
    - Minor criteria are: (a) the presence of lamellar fibrosis or concentric eosinophilic fibrosis, (b) neovascularization, (c) inflammatory response, and (d) fusion of rete ridges. These established criteria yielded 92 percent mean concordance overall by panel members.

DIFFERENTIAL DIAGNOSIS

- Melanocytic nevi—Most common moles are tan to brown, smaller than 6 mm, round in shape, and with sharp borders (see Chapter 143, Benign Nevi).

- Melanoma—Skin cancer is often asymmetric, with irregular border and varied colors. It is usually larger than 6 mm in diameter (see Chapter 147, Melanoma).

MANAGEMENT

NONPHARMACOLOGIC

- Obtain a family history of DN and melanoma for patients presenting with DN.
- Because of the low risk of any one DN developing malignant transformation, the prophylactic removal of all DN is not recommended. SOR Ⓒ

MEDICATIONS

- Of the medications tested, including topical 5-fluorouracil, systemic isotretinoin, topical tretinoin with or without hydrocortisone, and topical imiquimod, none completely destroy DN.[4]

PROCEDURES

- Removal of at least one lesion is reasonable to histologically confirm the diagnosis and rule out melanoma. This should be accomplished with excisional biopsy and histologic confirmation of DN versus melanoma. DN is usually removed with conservative surgical margins (about 2 mm) to provide adequate tissue for the pathologist.[3] SOR Ⓒ
- Scoop saucerizations (deep shave biopsy with a DermaBlade or razor blade) including at least a 2-mm margin of clinically normal skin surrounding the pigmented lesion is a rapid and acceptable method of excision for pathology (**Figure 146-7**).

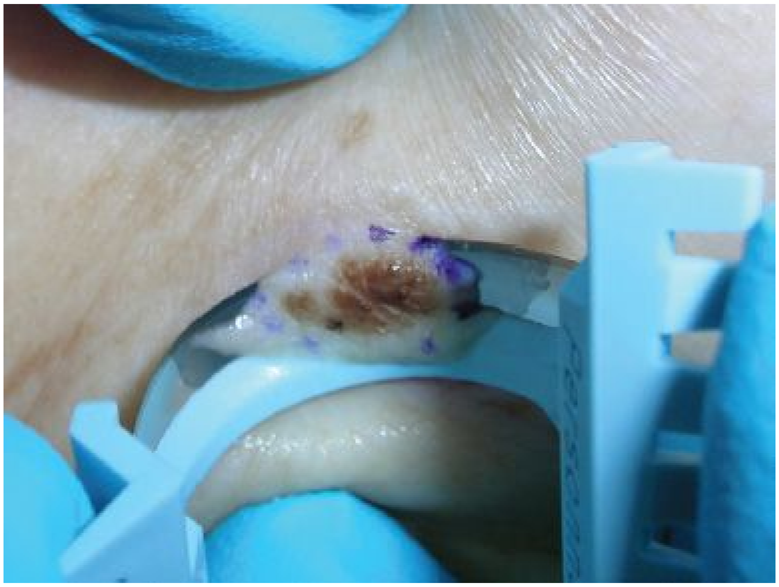

FIGURE 146-7 Scoop saucerization of a suspicious pigmented lesion that turned out to be a dysplastic junctional nevus with moderate atypia. The whole lesion was successfully excised with this deep shave. (*Used with permission from Richard P. Usatine, MD.*)

PREVENTION

- Avoid direct sunlight.
- Sun protection to limit sunburn may also help reduce the appearance of nevi. In one trial (N = 209 white children), children randomized to the sunscreen group, especially those with freckles, had significantly fewer new nevi on the trunk than did children in the control group at 3-year follow-up.[11]

PROGNOSIS

- The risk of a melanoma arising within a DN is estimated at 1:3000 per year.[1] However, there is also an increased risk of melanoma arising elsewhere on the skin in patients with DN; the actual incidence rate is uncertain and ranges from 0.5 to 46 percent.[4] There is also a substantially increased risk of melanoma associated with the number of atypical nevi (relative risk [RR] = 6.36; 95% confidence interval [CI]: 3.80, 10.33; for 5 versus 0).[12]

- In one case-control study, the estimated 10-year cumulative risk for developing melanoma in patients with AM syndrome was 10.7 percent (versus 0.62% in a control population).[13]
- DNs appear to be dynamic throughout adulthood. In a study of the natural history of DN, investigators found that 51 percent of all evaluated nevi (297 of 593) showed clinical signs of change during an average follow-up of 89 months.[14] New nevi were common in adulthood, continuing to form in more than 20 percent of patients older than age 50 years, and some nevi disappeared. Less is known about DN in children but change is common in other nevi (see Chapter 143, Benign Nevi).

FOLLOW-UP

- Patents with DN should have regular skin examinations with biopsy performed of any suspicious lesions (**Figure 146-7**).[4]
- Consider total-body photographs for monitoring (**Figures 146-8** and **146-9**).[4] In a study of 50 patients with 5 or more DN, the use of baseline digital photographs improved the diagnostic accuracy of skin self-examination on the back, chest, and abdomen, and improved detection of changing and new moles.[15] Individual DN can be monitored more precisely with digital dermoscopic photos added to the skin photographs (**Figure 146-9**).

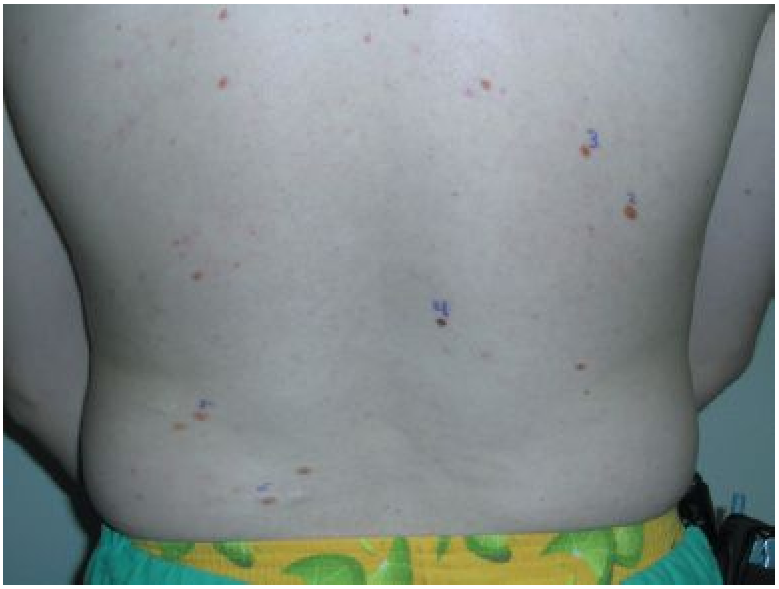

FIGURE 146-8 Multiple dysplastic nevi on the back of a young man. Multiple biopsies have all been negative, so patient is being followed by serial digital photography with numbering of the dysplastic nevi. (*Used with permission from Richard P. Usatine, MD*.)

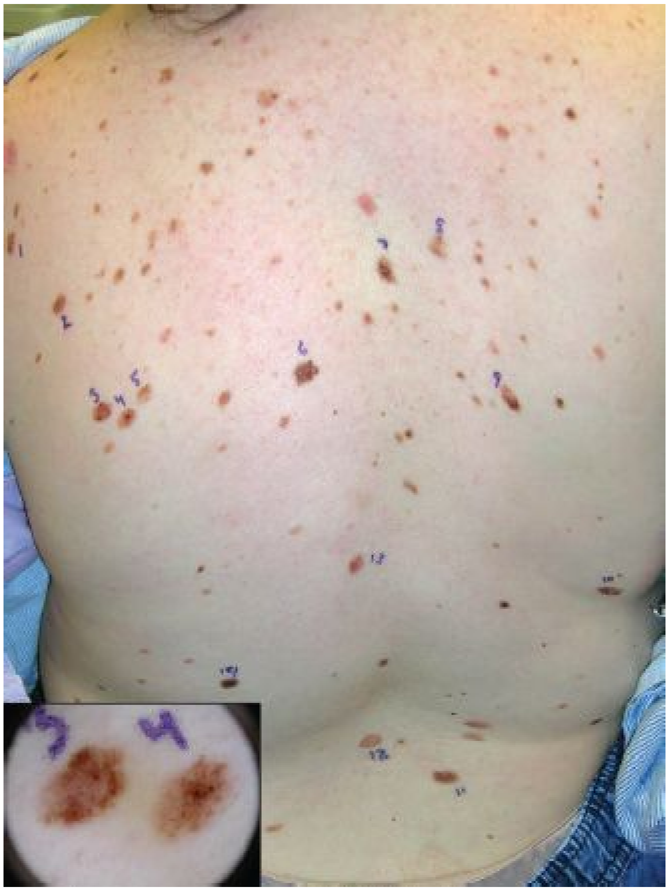

FIGURE 146-9 More than 14 dysplastic nevi are seen on the back of this young woman. She has never had a melanoma and has no family history of melanoma. Multiple biopsies so far have only shown dysplastic nevi, so she is being followed with serial digital photography of her nevi along with corresponding dermoscopic photographs. Note the dermoscopic images of nevi 3 and 4 in the bottom left corner. (*Used with permission from Richard P. Usatine, MD.*)

- Patients with numerous DN and who have a family history of melanoma are at a higher risk of developing melanoma and should be encouraged to have regular follow-up with a provider skilled in detecting melanoma.
- Patients with FAMM should also consider a baseline ophthalmologic examination because of a possible association between uveal melanoma and FAMM syndrome.[4]
- First-degree relatives of patients diagnosed with FAMM syndrome should be encouraged to be examined for DN and melanoma.

In a cohort study of 115 patients with dysplastic nevi an average follow-up of 17.4 years (range: 0.0 to 29.9) was achieved.[16] During these long-term follow-up periods, no patient developed melanoma at the site of an incompletely or narrowly removed histological dysplastic nevus. The authors concluded that this provides evidence that routine re-excision of mildly or moderately dysplastic nevi may not be necessary.[16]

PATIENT EDUCATION

- Patients with DN should avoid excessive exposure to natural or artificial UV light and routinely use a broad-spectrum sunscreen with a sun protective factor of 30 or greater and/or sun-protective clothing.
- Patients and their parents should be taught self-examination to detect changes in existing moles and to recognize clinical features of melanomas. Patients should be taught to look for and report asymmetry, border irregularity, new symptoms (e.g., pain, pruritus, bleeding, or ulceration), and color and size changes.

147 PEDIATRIC MELANOMA

Jonathan B. Karnes, MD
Richard P. Usatine, MD

PATIENT STORY

A 13-year-old red-haired female with a family history of melanoma in her father and multiple moles presents for a routine physical and is found to have a thin 8 mm pink papule on the right neck that has appeared in the last 6 months and occasionally bleeds when it rubs on a shirt (**Figure 147-1**). A narrow margin excisional biopsy was performed which revealed invasive melanoma 0.7 mm in depth with 2 mitoses per high power field. She was referred to pediatric surgery where she underwent wide local excision and sentinel lymph node biopsy of the neck, which revealed micrometastasis in one node. After PET scan showed no distant metastasis, she underwent lymph node dissection and was enrolled in a clinical trial through a major referral hospital in the region. Her prognosis is guarded, but similar to adults with the same cancer stage.

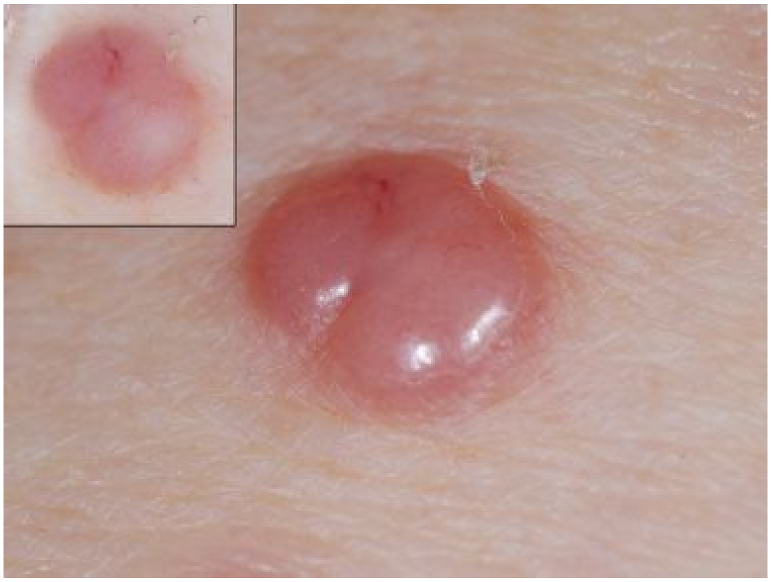

FIGURE 147-1 Amelanotic nodular melanoma with atypical vascular structures seen on dermoscopy (see inset in upper left corner). (*Used with permission from Ashfaq A. Marghoob, MD.*)

EPIDEMIOLOGY

- Although extremely rare, malignant melanoma is the most common skin cancer in children and represents 1 percent of all new cases of melanoma.[1]
- Between 1973 and 2009, 1230 children in the US were diagnosed with melanoma at a rate of 6 per million overall. Children aged 0 to 9 had the lowest rate at 1.1 per million while children aged 15 to 19 were diagnosed at the highest rate of 18 cases per million.[1]
- Melanoma incidence is on the rise in adults and children with the incidence increasing in children by 2 percent per year and 4 to 8 percent per year in adults.[1]
- In the US, the death rate is decreasing among persons younger than 65.[2]
- The lifetime risk of developing melanoma is 1 in 55 for men and 1 in 36 for women.[3]

RISK FACTORS

Risk factors can be broadly thought of as genetic risks, environmental risks, and phenotypic risks—arising from a combination of genetic and environmental risks. For example, a fair skinned child (genetic risk) who gets a sunburn (environmental) is much more likely to develop freckles (phenotypic) and melanoma. Childhood sun exposure is a significant risk factor for developing melanoma as an adult.[4]

ENVIRONMENTAL RISKS

- Exposure to sunlight.
- History of sunburn doubles the risk of melanoma and is worse at a young age.
- Artificial tanning.
- History of immunosuppression.
- Higher socioeconomic status (likely associated with more frequent opportunity for sunburns).

GENETIC RISKS

- Fair skin, blue or green eyes, red or blonde hair.
- In children, female sex is higher risk, in adulthood, male sex is higher risk.
- Melanoma in a first-degree relative.
- History of xeroderma pigmentosa or familial atypical mole melanoma syndrome.
- Personal history of a BRCA2 mutation confers a high risk of uveal melanoma.[5]

PHENOTYPIC RISKS

- Many nevi.
- Congenital nevi (**Figure 147-2**).

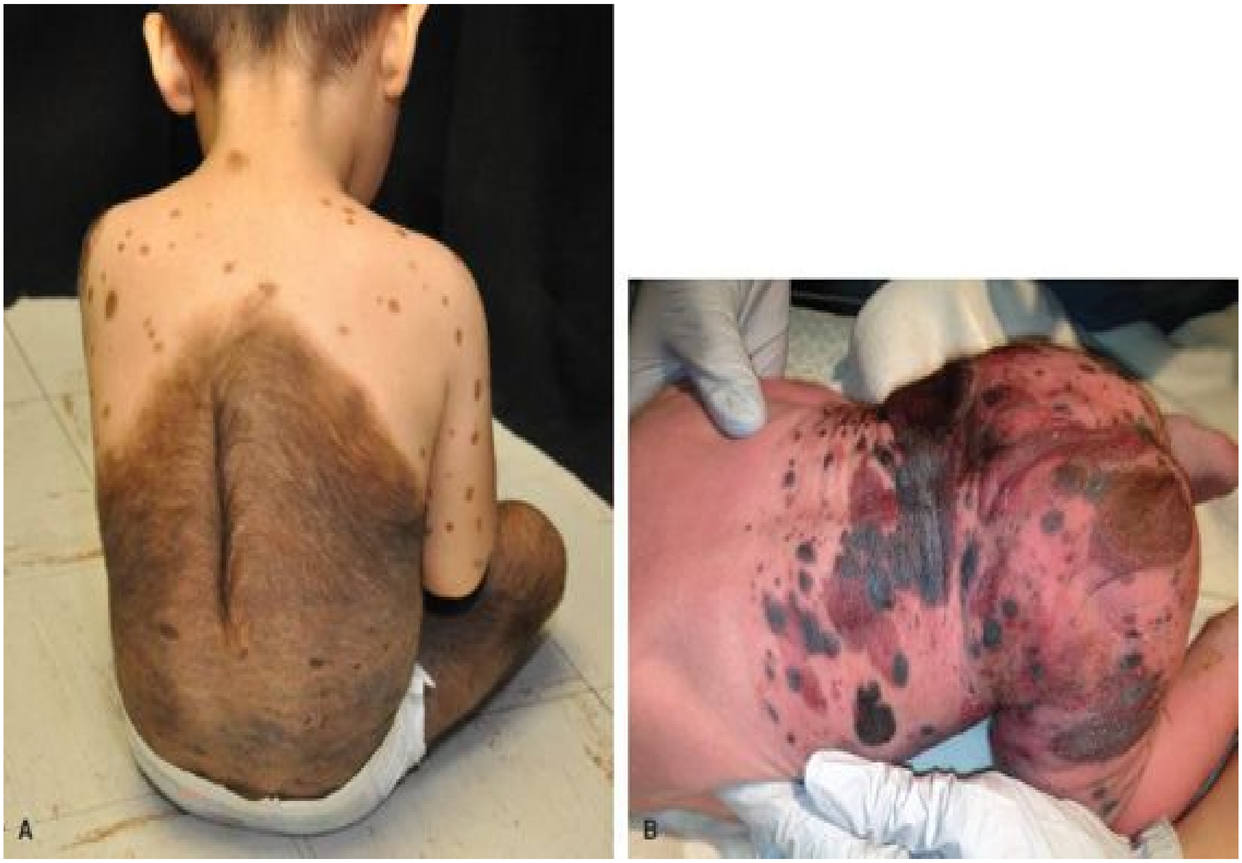

FIGURE 147-2 A. A 2-year-old boy with a bathing trunk nevus and numerous satellite congenital nevi. He benefits from regular skin screening and mole monitoring. (*Used with permission from Richard P. Usatine, MD.*) B. A giant bathing trunk nevus noted at birth. The dark black colors and variations in color make this a very concerning congenital nevus. Again, regular skin screening and mole monitoring will be a regular part of his care. (*Used with permission from Carrie Griffin, MD.*)

- Multiple dysplastic nevi.
- Increased age.
- Personal history of skin cancer.

DIAGNOSIS

CLINICAL FEATURES

Melanoma in children may deviate significantly from the traditional ABCDE criteria used to assess risk of melanoma.[6] The traditional ABCDE guidelines are listed below followed by newly proposed guidelines to increase the sensitivity of detecting melanoma in children.

TRADITIONAL ABCDE GUIDELINES

ABCDE guidelines for diagnosing melanoma (**Figure 147-3**).[7]

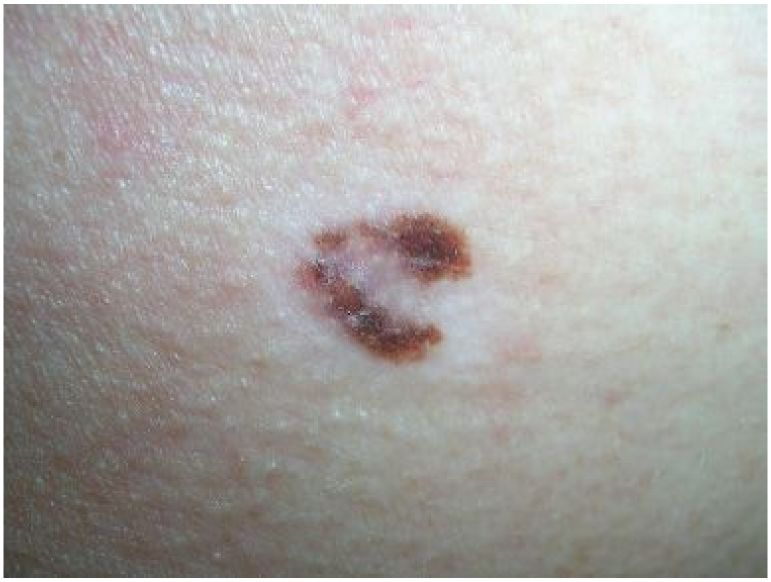

FIGURE 147-3 Superficial spreading melanoma on the neck demonstrates many traditional ABCDE features of melanoma. (*Used with permission from Richard P. Usatine, MD*.)

A = *Asymmetry*. Most early melanomas are asymmetrical—A line through the middle will not create matching halves. Benign nevi are usually round and symmetrical (**Figure 147-4**).

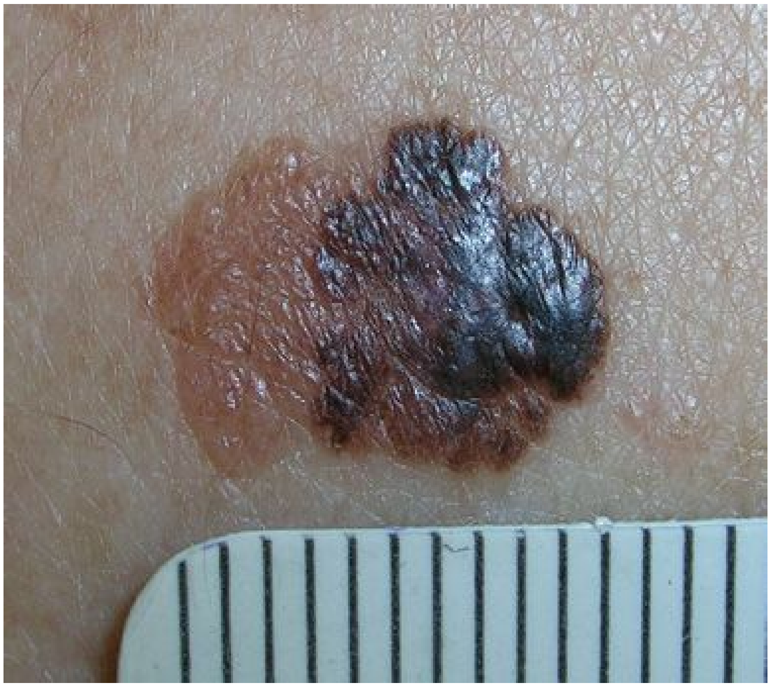

FIGURE 147-4 Marked asymmetry, border irregularity, color variation, and increased diameter characterize this thin melanoma. (*Used with permission from Richard P. Usatine, MD.*

B = *Border*. The borders of early melanomas are often uneven and may have scalloped or notched edges. Benign nevi have smoother, more even borders (**Figure 147-4**).

C = *Color* variation. Benign nevi are usually a single shade of brown. Melanomas are often in varied shades of brown, tan, or black, but may also exhibit red, white, or blue (**Figures 147-4** and **147-5**).

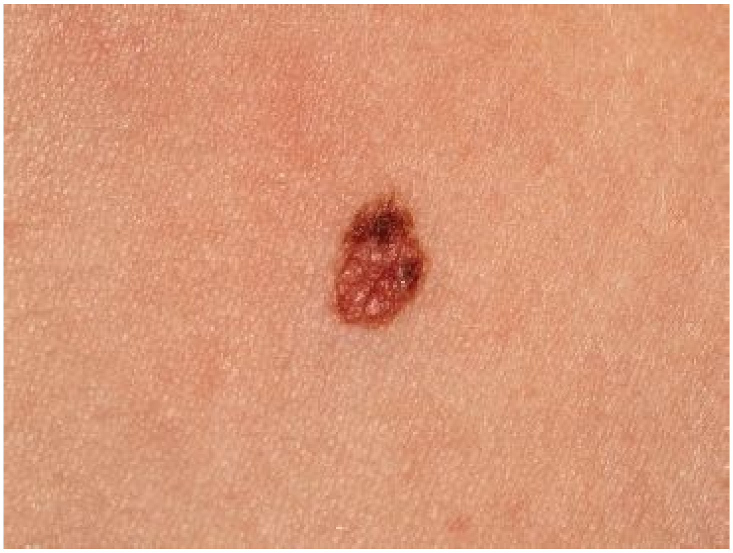

FIGURE 147-5 Small 4 × 5 mm melanoma that developed on the back of an 11-year-old boy. This melanoma demonstrated asymmetry and variation in color only. (*Used with permission from Kelly M. Cordoro, MD.*)

D = *Diameter* greater than or equal to 6 mm. Melanomas tend to grow larger than most nevi. Note that melanomas in children or adults can present less than 6 mm in diameter (**Figure 147-5**).

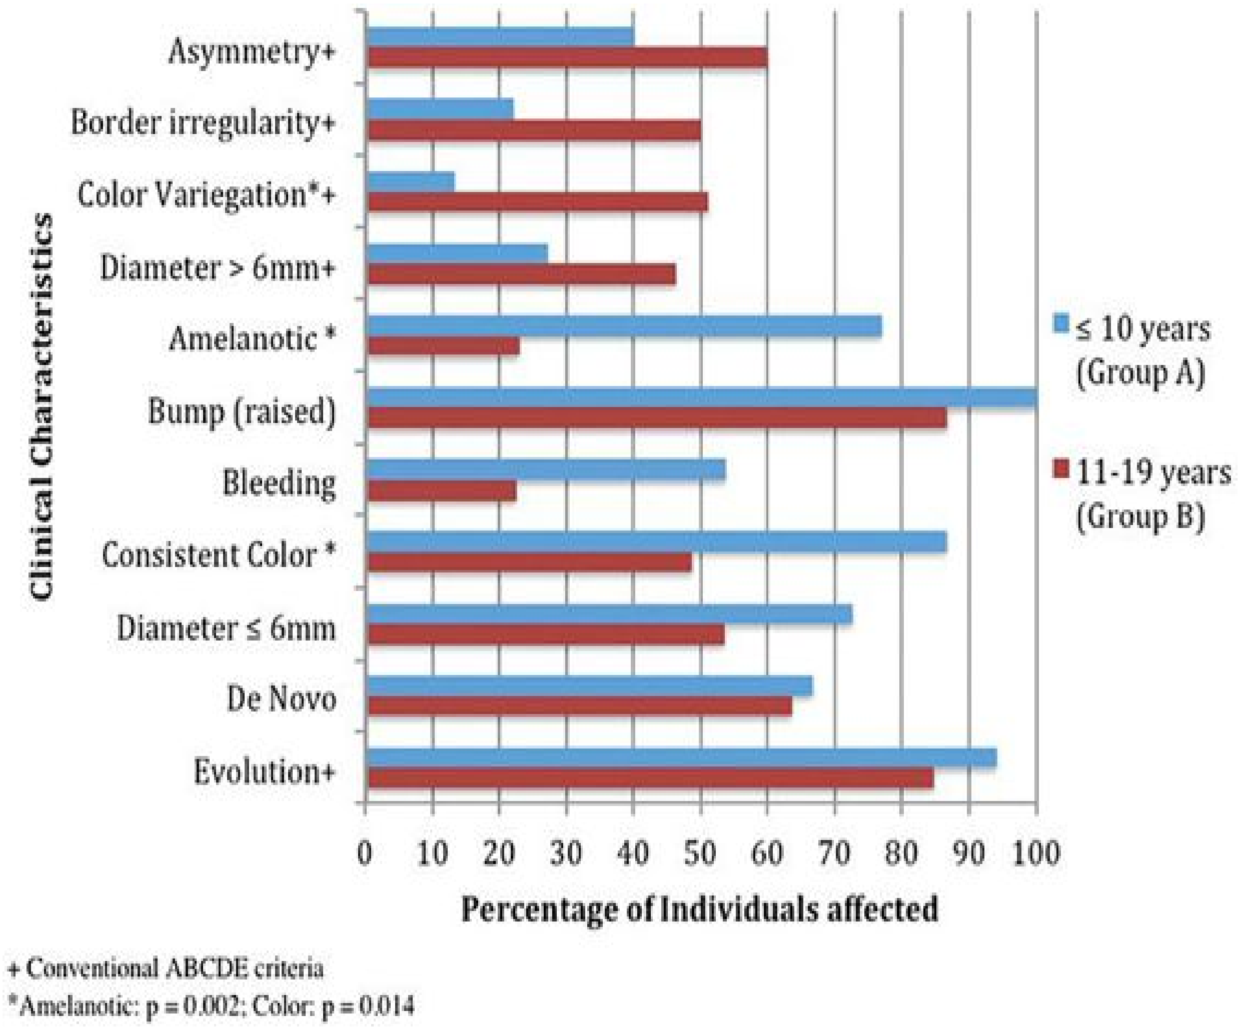

FIGURE 147-6 Comparison of conventional ABCDE criteria with other presenting features of melanoma in children. (*Used with permission from and copyright Cordoro KM, et al. Pediatric melanoma:Results of a large cohort study and proposal for modified ABCD detection criteria for children. J Am Acad Dermatol. 2013*.)

E = *Evolving* could be in size, shape, symptoms (itching, tenderness), surface (especially bleeding), and shades of color.

Modified ABCD criteria in children were developed and proposed by Cordoro, et al. in a recent large cohort study.[6] The criteria were developed from the data presented in **Figure 147-6** that compared conventional ABCDE criteria with other presenting features of melanoma in children.

In children, particularly those younger than 13, new ABCD detection criteria are needed as many childhood melanomas present as pink or skin colored uniform bumps. The modified ABCD detection criteria are listed below:

A = *Amelanotic* lesions are more common in children than adults (**Figures 147-1**, **147-6**, and **147-7**).

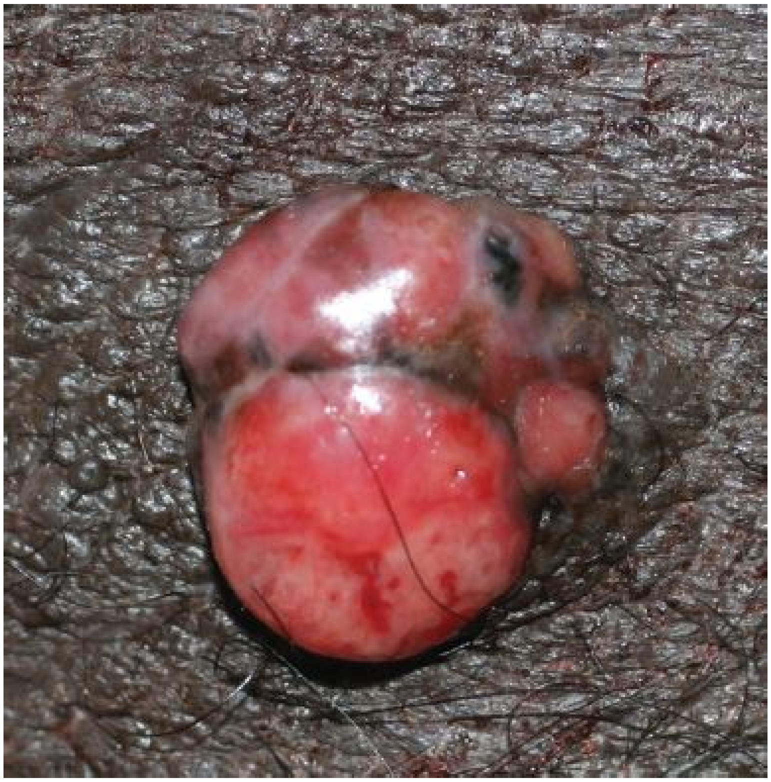

FIGURE 147-7 Amelanotic melanoma that developed in a large congenital melanocytic nevus. The boy was only 16-years old. (*Used with permission from Kelly M. Cordoro, MD*.)

B = *Bleeding*, *Bump*. Suspect any new bleeding papule or macule.

C = *Color uniformity* may be present in childhood melanoma rather than the color variation that is traditionally associated with melanoma (**Figure 147-8**).

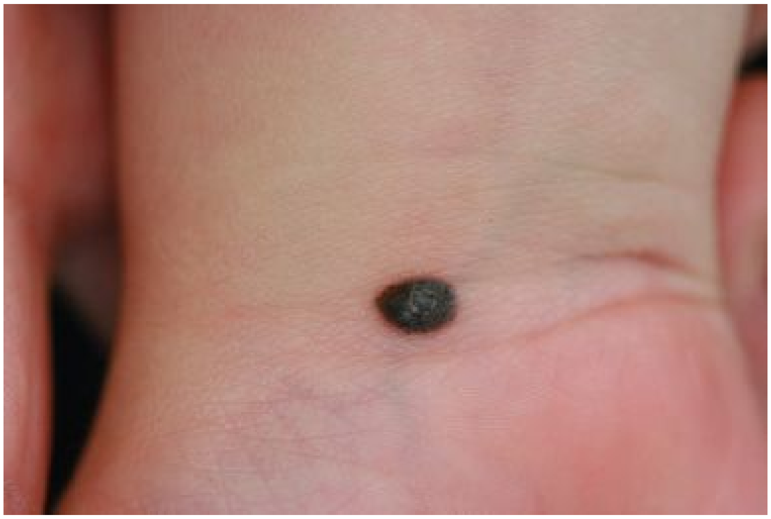

FIGURE 147-8 Spitzoid melanoma on the wrist of a 4-year-old girl. (*Used with permission from John L. Pfenninger, MD.*)

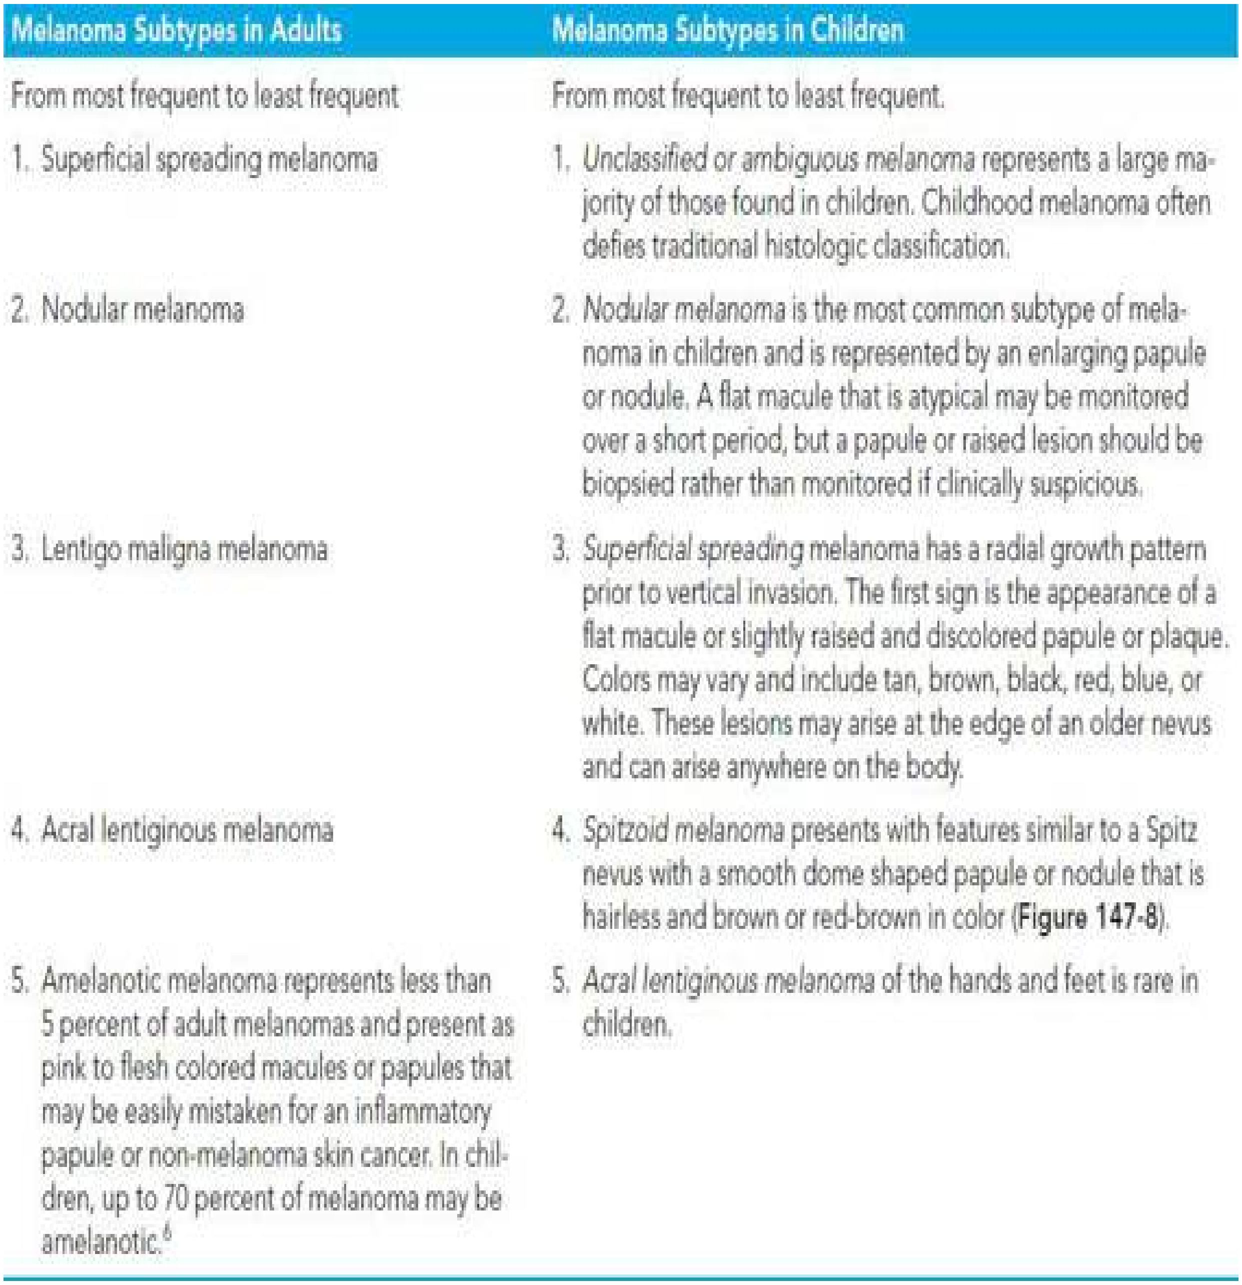
D = De Novo, any diameter. Any lesion arising out of the blue is suspicious in children.

Conventional subtypes of adult melanomas—superficial spreading, nodular, lentigo maligna melanoma, and acral lentiginous melanoma—are not as relevant in diagnosing childhood melanoma. In contrast, most childhood melanoma—especially in children under 10—is more clinically and histologically ambiguous and defies these classifications.[6] Any subtype may be classified as amelanotic when pigment is absent to a degree that the lesion is pink in color. In adults, this is rare, representing less than 5 percent of all melanoma. In children, however, up to 70 percent of melanoma may be amelanotic (**Table 147-1**).[6]

TABLE 147-1 Melanoma Subtypes Versus Melanoma Subtypes in Children



Melanoma Subtypes in Adults	Melanoma Subtypes in Children
From most frequent to least frequent	From most frequent to least frequent.
1. Superficial spreading melanoma	1. *Unclassified or ambiguous melanoma* represents a large majority of those found in children. Childhood melanoma often defies traditional histologic classification.
2. Nodular melanoma	2. *Nodular melanoma* is the most common subtype of melanoma in children and is represented by an enlarging papule or nodule. A flat macule that is atypical may be monitored over a short period, but a papule or raised lesion should be biopsied rather than monitored if clinically suspicious.
3. Lentigo maligna melanoma	3. *Superficial spreading* melanoma has a radial growth pattern prior to vertical invasion. The first sign is the appearance of a flat macule or slightly raised and discolored papule or plaque. Colors may vary and include tan, brown, black, red, blue, or white. These lesions may arise at the edge of an older nevus and can arise anywhere on the body.
4. Acral lentiginous melanoma	4. *Spitzoid melanoma* presents with features similar to a Spitz nevus with a smooth dome shaped papule or nodule that is hairless and brown or red-brown in color (**Figure 147-8**).
5. Amelanotic melanoma represents less than 5 percent of adult melanomas and present as pink to flesh colored macules or papules that may be easily mistaken for an inflammatory papule or non-melanoma skin cancer. In children, up to 70 percent of melanoma may be amelanotic.[6]	5. *Acral lentiginous melanoma* of the hands and feet is rare in children.

- Other rare melanoma variants include (**1**) nevoid melanomas, (**2**) malignant blue nevus, (**3**) Desmoplastic/Spindled/Neurotropic Melanoma, (**4**) Clear Cell Sarcoma (in fact a melanoma), (**5**) Animal-Type Melanoma, (**6**) Ocular Melanoma (**7**) and mucosal (lentiginous) melanoma.[8]

TYPICAL DISTRIBUTION

In children, the most common sites of melanoma are the trunk and lower limbs in females and the head and neck in males.[1]

DERMOSCOPY

Dermoscopy is a useful tool in pigmented lesions in adults and in children, though it is less well characterized in children. Dermoscopy is painless, adds information, and can assist in the decision to biopsy.[9] In a prospective study of 401 lesions evaluated for melanoma by experts in dermoscopy, the sensitivity of 66.6 percent with ABCDE criteria improved to 80 percent, and specificity rose from 79.3 to 89.1 percent (**Figure 147-9**).[9]

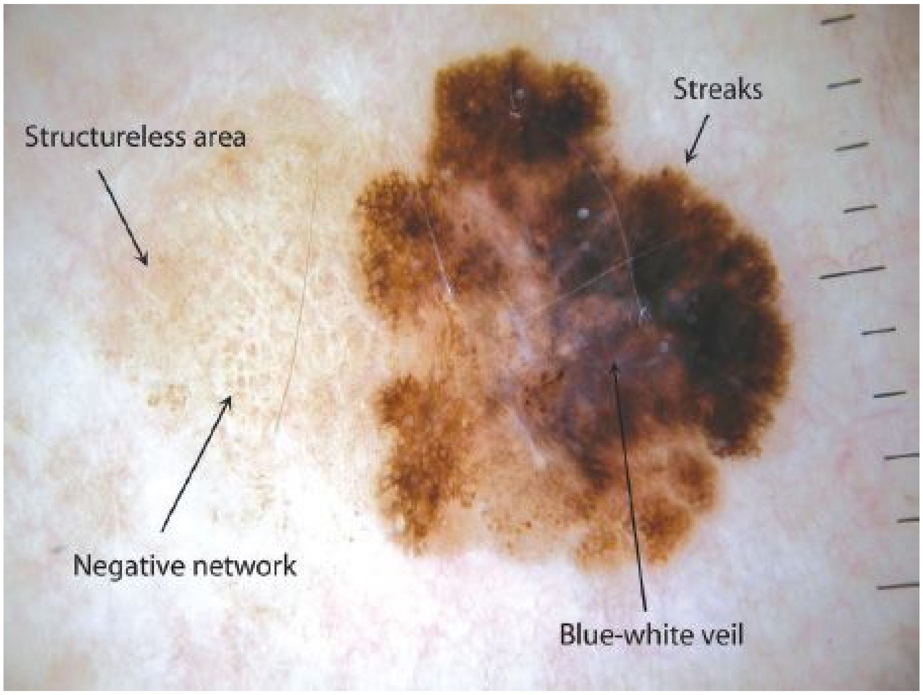


FIGURE 147-9 Observe many dermoscopic features of melanoma in this superficial spreading melanoma. This is the dermoscopic view of the melanoma in Figure 147-4. (*Used with permission from Richard P. Usatine, MD*.)

In a study of dermoscopy done by 60 physicians (35 general practitioners, 10 dermatologists, and 16 dermatology trainees) on unaided photos of 40 lesions using the ABCD rule, the Menzies method, a 7-point checklist, and pattern analysis, the sensitivity rose over the unaided eye.[10] In children, melanoma will deviate from the benign dermoscopic patterns and have at least one melanoma specific criteria, most commonly atypical vascular structure and crystalline structure (**Figure 147-1**).[11]

Accepted dermoscopic local features of melanoma include:

- Atypical network (includes branched-streaks).
- Streaks—Pseudopods and radial streaming.
- Atypical dots and globules.
- Negative pigment network.
- Blotch (off center).
- Blue-white veil/peppering over macular areas (regression).
- Blue-white veil over raised areas.
- Vascular structures.
- Peripheral tan/brown structureless areas.
- Crystalline structures

Figure 147-8 demonstrates a number of these features.

BIOPSY

In children, melanoma diagnosis is often delayed because of the rarity of the diagnosis and a natural tendency to avoid biopsy. Still, a full thickness skin biopsy remains the gold standard for diagnosing melanoma. Complete excisional biopsy with close margins (2 mm) is ideal for histologic diagnosis and tumor staging. Although there is evidence that an incisional biopsy of a portion of a melanoma does not worsen the prognosis, this should only be the rare case when a lesion is too large to excise in the office. When the clinical impression differs markedly from the pathology report, discuss the case with the reading pathologist and share clinical photos if you haven’t done so already. You may need to have the pathologist prepare “deeper sections” or “step sections”—meaning more slices from the same “loaf of bread.” Additionally, if the diagnosis of melanoma was expected and the result of an incisional biopsy does not meet the expectation, go forward with a complete excision or refer to a surgeon who can.

The National Comprehensive Cancer Network (NCCN) Melanoma Guidelines on the Principles of Biopsy state:[12]

- Excisional biopsy (elliptical, punch [when whole lesion is small], or saucerization) with 1- to 3-mm margins is preferred. Avoid wider margins to permit accurate subsequent lymphatic mapping.
- The orientation of the biopsy should be planned with definitive wide excision in mind.
- Full-thickness incisional or punch biopsy of clinically thickest portion of the lesion is acceptable in certain anatomic areas (e.g., palm/sole, digit, face, and ear) or for very large lesions.
- Shave biopsy (not saucerization or deep shave) may compromise pathologic diagnosis and complete assessment of Breslow thickness, but is acceptable when the index of suspicion is low.[13]

Despite strong opinions about biopsy technique, there is evidence that a scoop shave biopsy leads to an accurate diagnosis and staging 97 percent of the time.[13] Still, a shallow shave biopsy may miss important staging information and may cause “upstaging” and unnecessary lymph node biopsy.

DIFFERENTIAL DIAGNOSIS

Nevi of all types may mimic melanoma. In children, because of the high percentage of melanomas that are melanocytic, broaden the differential to include many inflammatory and vascular papules. Nevi of all types can mimic melanoma. Congenital nevi can be especially large and asymmetrical. Therefore, it is important to ask the patient if the pigmented area has been there from birth and consider how it has changed over time.

- Atypical nevi, also called dysplastic nevi, often mimic melanoma (**Figure 147-10**). When an atypical nevus is suspicious for melanoma, perform a full thickness biopsy or a broad scoop shave for histology. Only the less suspicious dysplastic nevi should be followed with photography or serial exams.

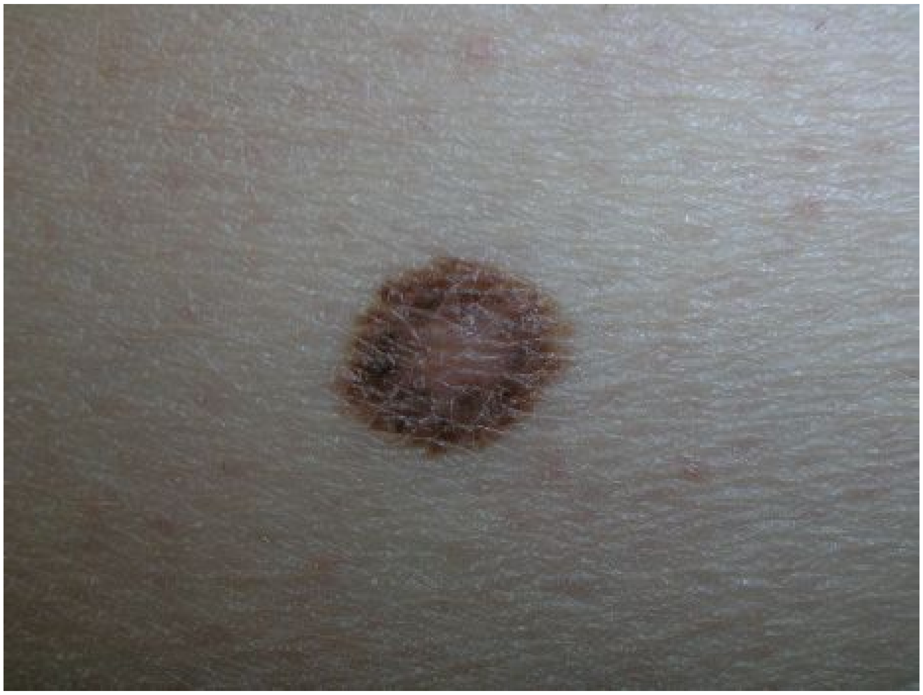

FIGURE 147-10 This benign compound dysplastic nevus has several features of melanoma including color variation and size greater than 6 mm. (*Used with permission from Richard P. Usatine, MD*.)

- Epidermal nevi are warty in appearance and may fall along embryonic cleavage lines. These are benign and not precancerous but may grow rapidly especially during puberty (**Figure 147-11**).

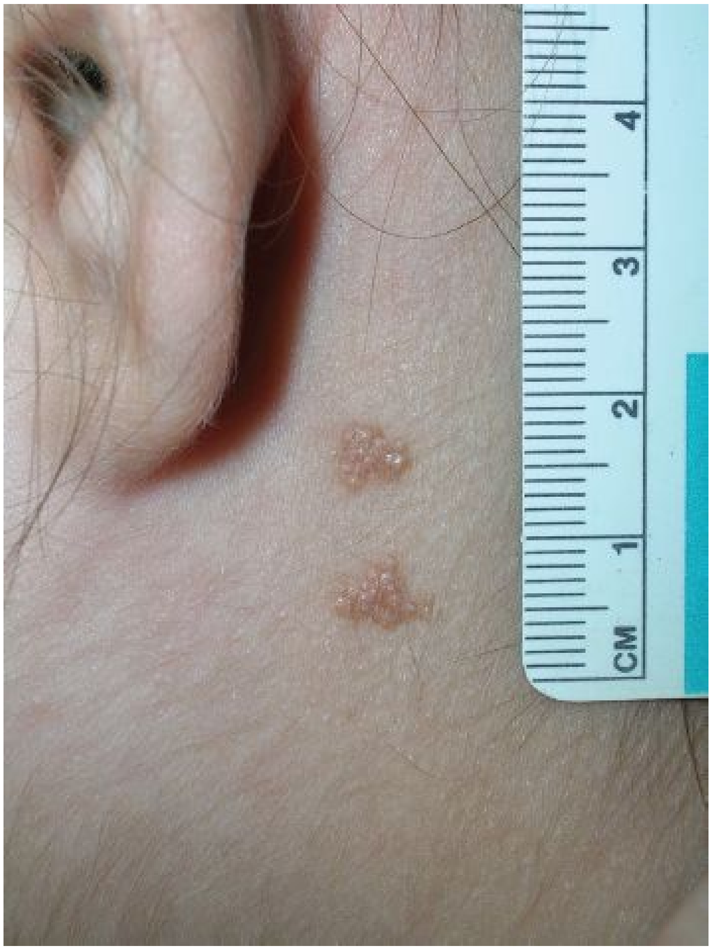

FIGURE 147-11 These epidermal nevi were increasing in size, but are not melanocyctic in origin and have no potential to become melanoma. (*Used with permission from Richard P. Usatine, MD*.)

- Pyogenic granulomas are benign vascular neoplasms that grow rapidly and are often friable. They are frequently associated with pregnancy, but can occur without a clear cause and mimic an amelanotic nodular melanoma (**Figures 147-12** and **147-13**).

MD.)

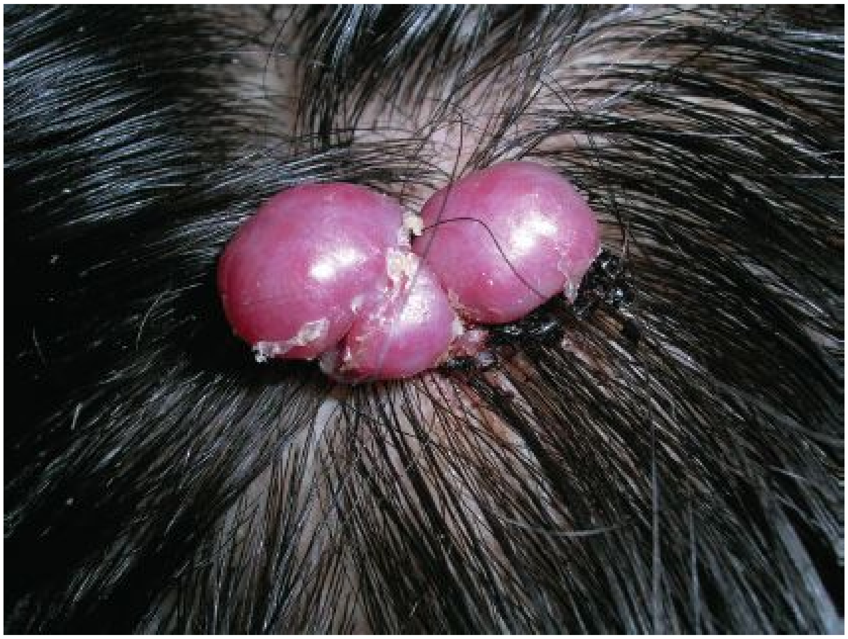

FIGURE 147-12 This pyogenic granuloma formed rapidly and bled easily on the scalp of this teenager. It was excised and sent for pathology to make sure it was not an amelanotic melanoma. (*Used with permission from Richard P. Usatine, MD*.)

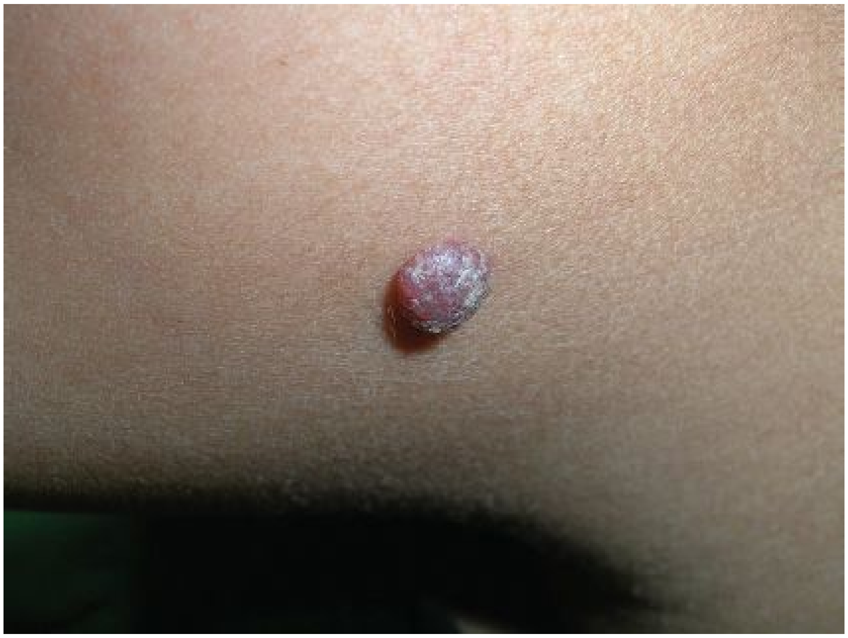

FIGURE 147-13 A pyogenic granuloma on the arm of a young boy mimics an amelanotic melanoma. (*Used with permission from Richard P. Usatine, MD*.)

- Pseudolymphoma presents as a pink papule or plaque without significant scaling that persists for weeks to months and may be associated with a history of an insect or spider bite (**Figure 147-14**).

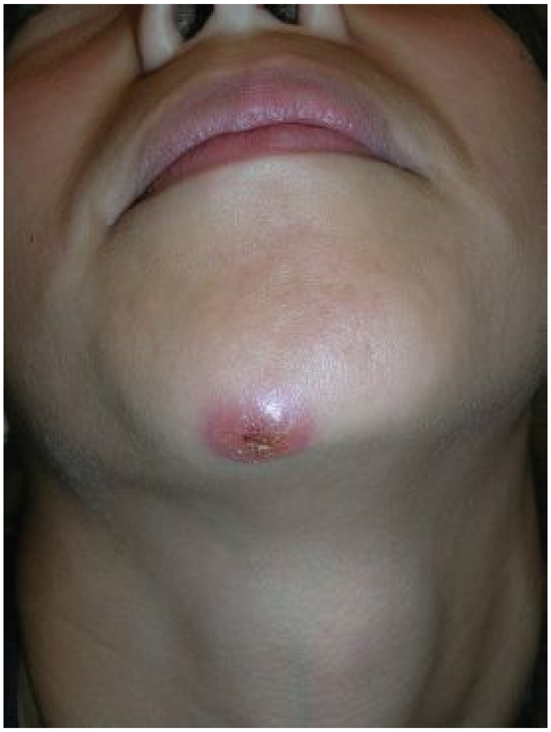

FIGURE 147-14 This pink nodule developed rapidly on the chin of a 11-year-old girl and did not resolve after several months. Pathology was consistent with pseudolymphoma. (*Used with permission from Richard P. Usatine, MD.*)

- Dermatofibromas are fibrotic nodules that occur most frequently on the legs and arms. They can be any color from skin color to black and often have a brown halo surrounding them. A pinch test will produce a dimpling of the skin in most cases.
- Warts in children may mimic melanocytic lesions including Spitz nevi and melanoma (**Figures 147-15** and **147-16**).

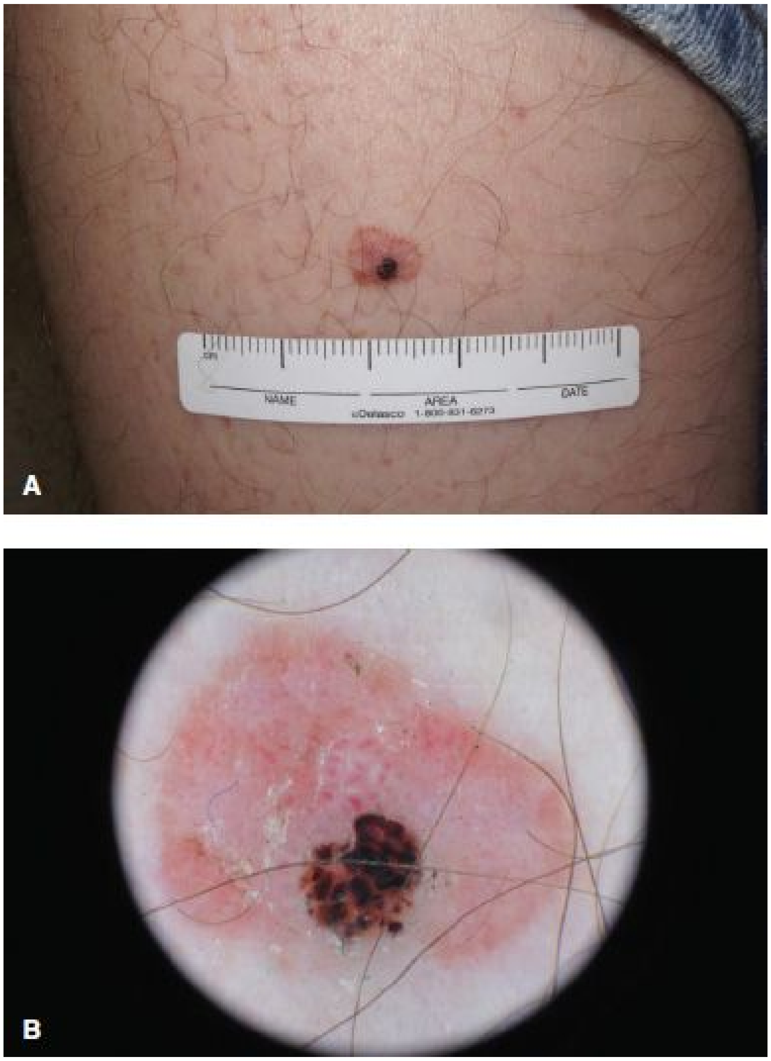

FIGURE 147-15 This pink and black wart with dotted vessels appeared suddenly on the leg of a teenage boy and shares some features of melanoma. (A) Clinical (B) Dermoscopy. (*Used with permission from Jonathan B. Karnes, MD.*)

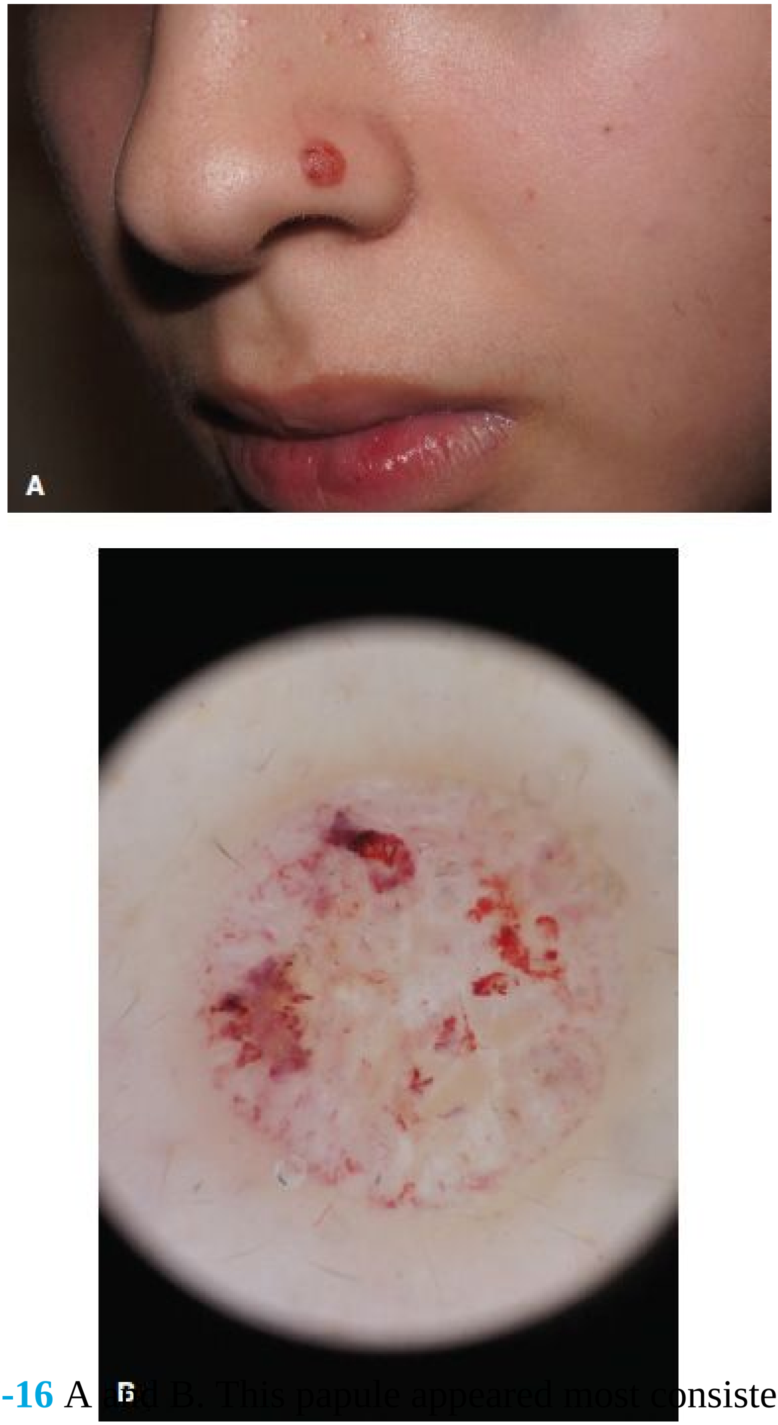

FIGURE 147-16 A and B. This papule appeared most consistent with a Spitz nevus, but histology revealed a wart with unusual pseudoepitheliomatous hyperplasia. (*Used with permission from Jonathan B. Karnes, MD*.)

- Benign adnexal tumors such as pilomatricomas may appear similar to a nodular melanoma and can occur on the head and neck (**Figure 147-17**).

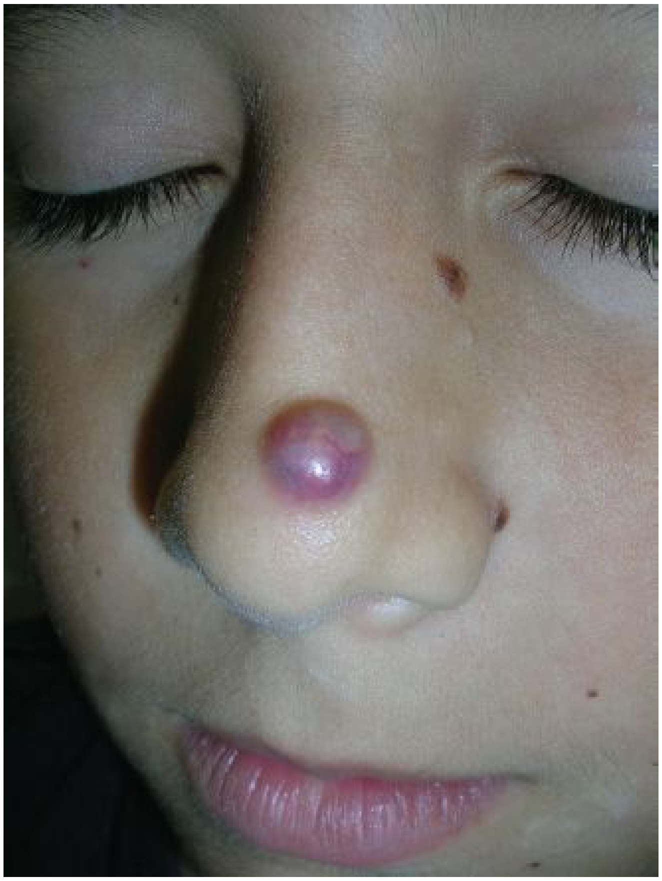

FIGURE 147-17 A pink and purple nodule on the nose that had grown over several months. This was excised and turned out to be a benign pilomatricoma. This is clinically suspected when rock hard calcifications are palpable within the tumor. (*Used with permission from Richard P. Usatine, MD*.)

MANAGEMENT

- Cutaneous melanoma is surgically treated with complete full skin depth excision using margins determined by the Breslow depth. This depth is a measure of tumor thickness from the granular layer of the epidermis to the point of deepest invasion using an ocular micrometer.
- Current recommendations for excision margins range from 5 mm for in situ lesions to 1 to 2 cm for invasive lesions. A recent study showed

significant benefit with a 9 mm margin on Mohs excision of melanoma in situ compared with 6 mm margins at a referral center.[14]

- Sentinel lymph node biopsies are recommended for tumors of greater than or equal to 1 mm in depth (**Figure 147-18**) and should be considered for thinner lesions with ulceration or more than 1 mitosis per mm^2. Even in patients with thin melanoma with mitoses above 1 per mm^2 sentinel lymph node biopsy should be considered according to the most recent guidelines.[15] In these guidelines, mitoses per mm^2 has replaced Clark's levels to distinguish T1a from T1b tumors.[15]

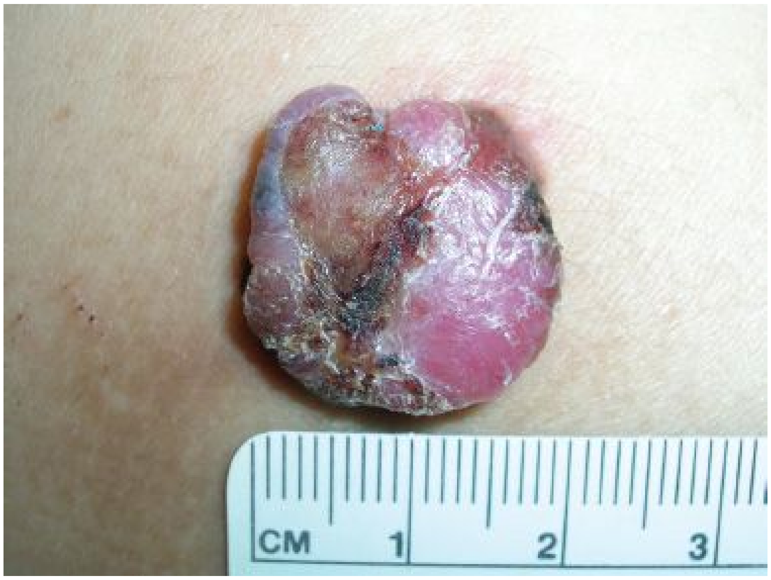

FIGURE 147-18 Thick ulcerated nodular melanoma on the back was mostly amelanotic in appearance. The melanoma depth was greater than 1 mm and the patient was sent for a complete excision with a sentinel node biopsy. (*Used with permission from Richard P. Usatine, MD*.)

- Melanoma staging takes into account tumor thickness and metastasis and prognosis worsens statistically with each increasing stage from 0 to IV. A patient with an in situ melanoma and no nodal metastasis is considered stage 0. Thicker tumors that remain localized to the skin may be staged as high as stage IIC and subcategories are based on tumor thickness and presence of ulceration. Any lymph node metastasis is considered stage III or higher and any distant metastasis beyond lymph nodes is categorized as stage IV.[16]

- Patients with advanced melanoma should be referred to medical oncology and may receive combination therapy with multiple chemotherapeutic agents and immunotherapy. Many trials are ongoing and three new drugs including interferon 2-alpha, vemurafenib, and ipilimumab have been approved for use in advanced melanoma. Treatment regimens in children are similar to regimens in adults.
- Recently two new chemotherapeutic agents have been FDA approved for the treatment of metastatic melanoma. One, vemurafenib is a monoclonal antibody targeting the BRAF mutation expressed on many melanomas. Ipilimumaub prevents dampening of the immune system by blocking a regulatory molecule CTLA-4. Both of these medications used in combination with dacarbazine have shown a small but significant increase in progression free survival in adults and are in ongoing trials in children.[17]

FOLLOW-UP

The need for follow-up is largely determined by the stage of the disease. Updates to the staging criteria are published by the American Joint Committee. As previously mentioned, the prognosis is worsened by increasing depth, mitotic rate, ulceration, positive lymph nodes, and metastases.

The follow-up for stage 0 and 1 cutaneous melanoma includes regular skin examinations by a physician trained in skin screening. Total body photography is available in limited areas, but may be of benefit in monitoring patients with multiple nevi. The rate of subsequent cutaneous melanomas among persons with a history of melanoma was found to be more than 10 times the rate of a first cutaneous melanoma and the highest incidence of recurrence was in the first 3 to 5 years after initial diagnosis.[18],[19]

PATIENT EDUCATION

Advise patients to avoid future sun exposure and monitor their skin for new and changing moles. Advise avoidance of artificial tanning. Recommend a complete skin examination yearly by a physician trained to detect early melanoma. A large portion of adult melanoma is caused from childhood exposure.[4]

SECTION 11 INFILTRATIVE IMMUNOLOGIC

148 GRANULOMA ANNULARE

Melissa Muszynski, MD
Richard P. Usatine, MD

PATIENT STORY

A 3-year-old boy presents with an annular eruption on the dorsum of his foot for 6 months. Prior to this visit the child was treated with multiple topical antifungal creams prescribed by other health care providers for presumed tinea corporis. The absence of significant scaling and the failure to respond to topical antifungals point to the diagnosis of granuloma annulare (GA). Also, this is a common location for GA. A KOH preparation was also negative for hyphae. The diagnosis was discussed with the parents and the decision was made to try a mid-potency corticosteroid topically for treatment. While intralesional steroids are more effective this is not a viable option for 3-year-old child.

INTRODUCTION

GA is a common dermatologic condition that presents as small, light-red, dermal papules coalescing into annular plaques without scale. As the previous vignette describes, it is often mistaken as nummular eczema or tinea corporis. Distribution, pattern, and lack of scale are important diagnostic clues.

EPIDEMIOLOGY

- GA affects twice as many females than males.[1]
- The four presentations of GA are localized, disseminated/generalized, perforating, and subcutaneous.
- Of the four variations, the localized form is seen most often.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Benign cutaneous, inflammatory disorder of unknown origin.[1]
- Disease may be self-limiting, but may persist for many years.
- There is a reported association between type 1 diabetes and subcutaneous granuloma annulare in children. One retrospective study looked at 34 children less than 10 years of age with subcutaneous granuloma annulare and found 2 of these children (5.9%) had type 1 diabetes.[2,3] While this is much higher than the prevalence of childhood type 1 diabetes, this does not prove causality.
- Reported associations include viral infections (including HIV), *Borrelia* and streptococcal infections, insect bites, lymphoma, tuberculosis, and trauma.[4,5]
- One proposed mechanism for GA is a delayed-type hypersensitivity reaction as a result of T-helper–type cell (Th)-1 lymphocytic differentiation of macrophages. These macrophages become effector cells that express tumor necrosis factor (TNF)-a and matrix metalloproteinases. The activated macrophages are responsible for dermal collagen matrix degradation.[6]
- An association between high expression of gil-1 oncogene and granulomatous lesions of the skin, including GA, has been established.[7]

RISK FACTORS

The only identifiable risk factor is being a female. There are several associations, but nothing has been shown to be causative.

DIAGNOSIS

CLINICAL FEATURES

Annular lesions have raised borders that are skin-colored to erythematous (**Figures 148-1** and **148-2**). The rings may become hyperpigmented or violaceous (**Figure 148-3**). There is often a central depression within the ring. These lesions range from 2 mm to 5 cm. Although the classical appearance of GA is annular, the lesions may be arcuate instead of forming a complete ring (**Figure 148-4**). Most importantly, there should be no scaling as seen in tinea corporis (ringworm).

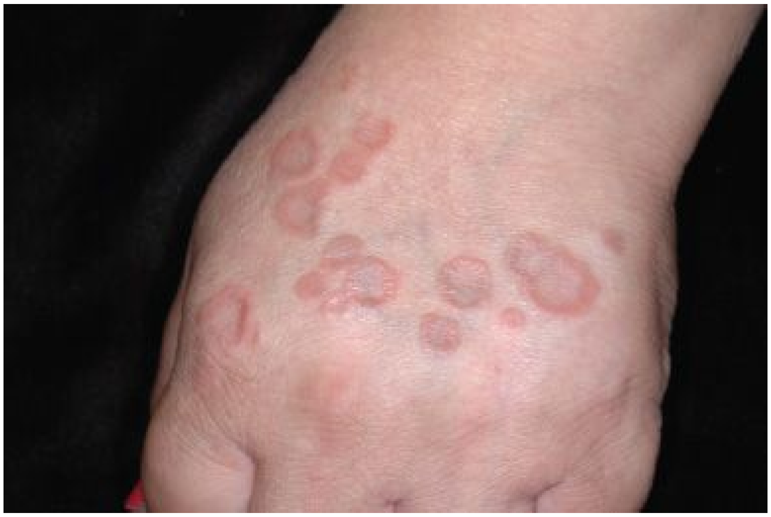

FIGURE 148-2 Disseminated granuloma annulare on the dorsum of the hand. (*Used with permission from Richard P. Usatine, MD.*)

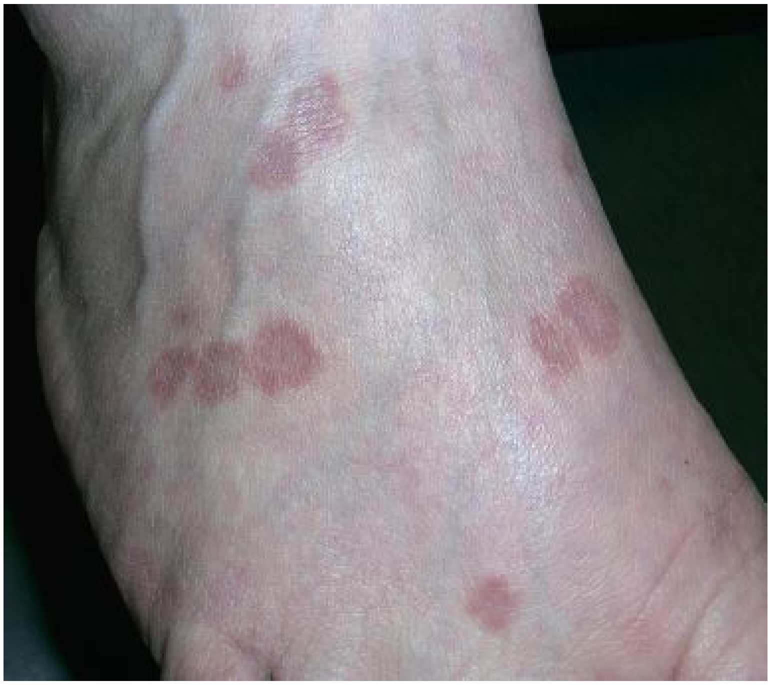

FIGURE 148-3 Disseminated granuloma annulare on the dorsum of the foot. The rings are flatter and many are conjoined. Note the hyperpigmentation. (*Used with permission from Richard P. Usatine, MD.*)

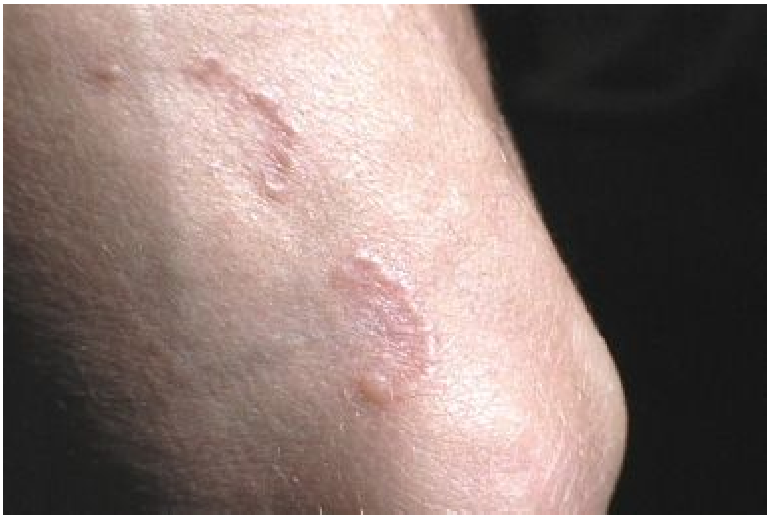

FIGURE 148-4 Granuloma annulare on the elbow showing how the rings may not be complete. (*Used with permission from Richard P. Usatine, MD*.)

TYPICAL DISTRIBUTION

Each of the four types of GA has a different distribution. Localized and disseminated GA differ only in that disseminated lesions can spread to the trunk and neck and may be more pronounced in sun-exposed areas.[8]

1. Localized—This is the most common form of GA affecting 75 percent of GA patients.[1] It typically presents as solitary lesions on the dorsal surfaces of extremities, especially of hands and feet (**Figures 148-1** to **148-3**).
2. Disseminated or generalized—Adults are most affected by this form, which begins in the extremities and can spread to the trunk and neck (**Figures 148-2** and **148-3**).
3. Perforating—Children and young adults present with 1 to hundreds of 1- to 4-mm pinpoint to annular papules (**Figure 148-5**). They may coalesce to form a typical annular plaque. Although this form can appear anywhere on the body, it has an affinity for extremities, especially the hands and fingers.[9] The papules may exude a thick and creamy or clear and viscous fluid.

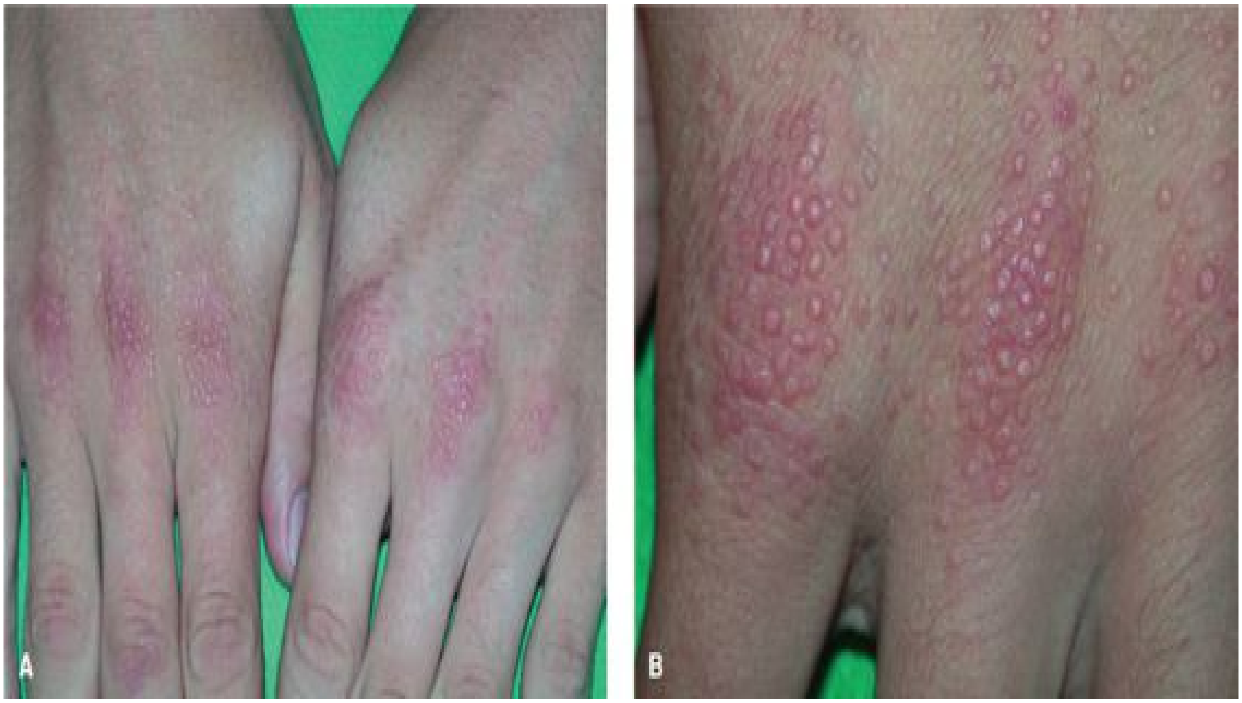

FIGURE 148-5 A. Perforating granuloma annulare in a 17-year-old boy with asymptomatic dorsal hand lesions since 9 months of age. Within the previous six months lesions began to appear on both elbows. This was previously misdiagnosed as molluscum contagiosum. B. This rare perforating subset of granuloma annulare affects the dorsum of the hands and extensor surfaces in children and young adults. (*Used with permission from Eric Kraus, MD.*)

4. Subcutaneous—These lesions present as rapidly growing, nonpainful, subcutaneous or dermal nodules on the feet, fingers, hands, scalp, and forehead. Subcutaneous GA most commonly affects children, with a mean age of 3.9 years (**Figure 148-6**).[8,10] These lesions are often ill-defined and less discrete (**Figure 148-7**). They can erupt as a single lesion or crops of lesions.

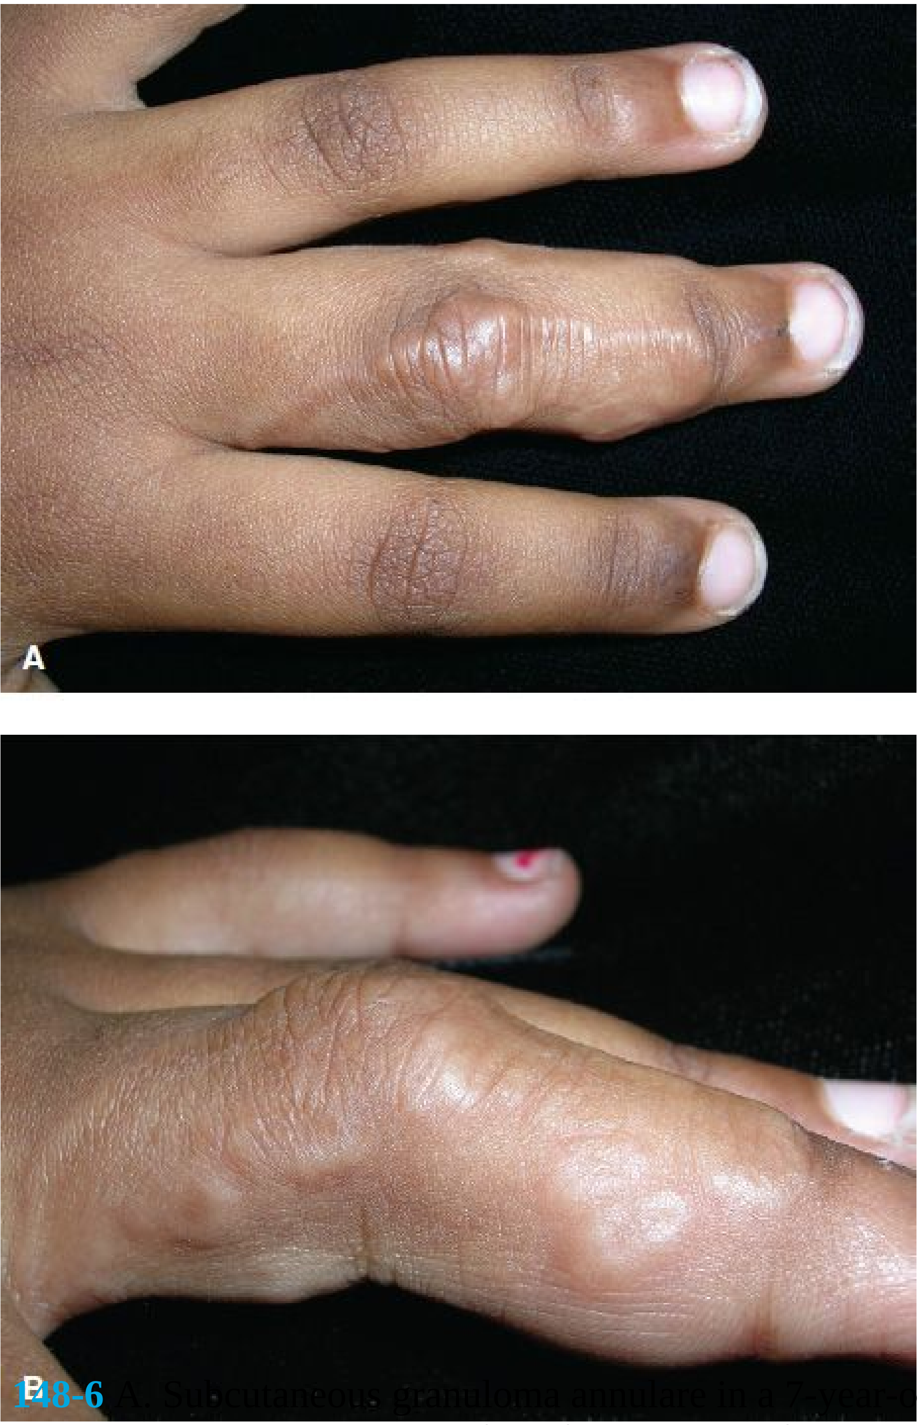

FIGURE 148-6 A. Subcutaneous granuloma annulare in a 7-year-old girl showing one large ring on the dorsum of the finger with soft-tissue infiltration. B. Subcutaneous GA in a 7-year-old girl showing thickening of the involved finger along with the small annular patterns. Note the soft-tissue infiltration that has distorted the finger anatomy. (*Used with permission from Richard P. Usatine, MD*.)

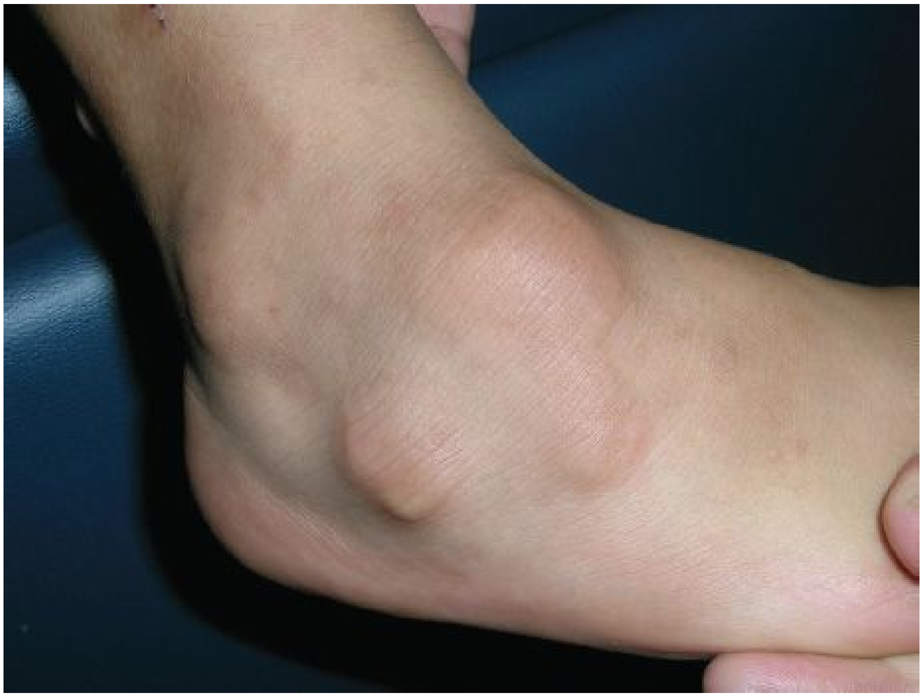

FIGURE 148-7 Subcutaneous granuloma annulare in a 4-year-old boy over the lateral foot with soft-tissue infiltration. The rings are less discrete than localized granuloma annulare. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY STUDIES

Often a diagnosis of GA is made on clinical presentation alone, without the need for biopsy. Subcutaneous GA may be an exception, as the unusual appearance may be mistaken for a rheumatoid nodule. Histologic examination reveals an increase of mucin, which is a hallmark of GA. There is also a dense infiltrate of histiocytes in the mid-dermis and sparse perivascular lymphocytic infiltrate. The histiocytes are either organized as palisading cells lining a collection of mucin or as a diffuse interstitial pattern. There are no signs of epidermal change.[5]

DIFFERENTIAL DIAGNOSIS

- Tinea corporis has a raised, scaling border and can present on any body surface. KOH preparation reveals hyphae with multiple branches (see Chapter 123, Tinea Corporis).
- Erythema annulare centrifugum has an affinity for thighs and legs. The diameter of these lesions can expand at a rate of 2 to 5 mm/day and may present with a trailing scale inside the advancing border.[2] Biopsy is helpful to differentiate this condition from GA.
- Nummular eczema presents commonly on extremities, but is almost always associated with scaling plaques and intense itching (see Chapter 133, Nummular Eczema).
- Pityriasis rosea often has oval lesions with a trailing collarette of scale. The lesions are minimally raised and have scale that is absent in GA (see Chapter 137, Pityriasis Rosea).
- Rheumatoid nodules may mimic appearance of subcutaneous GA. These nodules are often seen over the elbows, fingers, and other joints in a patient with joint pains and other clinical signs of arthritis (see Chapter 172, Juvenile Rheumatoid Arthritis). Rheumatoid nodules have fibrin deposition on histologic examination, in contrast to mucin in GA.

MANAGEMENT

The evidence for various treatments is at best small series of cases that are not randomized controlled trials. This disease is asymptomatic, and treatments only improve cosmetic appearance. Many patients may want intervention as diffuse lesions can cause psychological distress. Although GA will eventually resolve, some treatments may cause pigment change or atrophy that might be permanent. Several of the treatments below have shown promise, but these treatments may appear to work when in fact the resolution was natural.

LOCALIZED GA

- In a retrospective study of children with localized GA (mean age: 8.6 years), 39 of 42 presented with complete clearance within 2 years. The average duration was 1 year. Researchers of this study consider most treatments unnecessary because of the self-limiting nature of this variation.[9] One treatment option is watchful waiting, and may be the most appropriate in children with this condition after discussing other options with the parents.[10,11] SOR Ⓑ
- Intralesional corticosteroids can be injected into GA lesions with resolution of the area injected. Inject directly into the ring itself with 3 to 5 mg/mL triamcinolone acetonide (Kenalog) using a 27-gauge needle. SOR Ⓒ A large completed ring may take 4 injections to reach 360 degrees of the circle. The major complications include hypopigmentation and skin atrophy at the injected sites.
- Cryotherapy was studied using nitrous oxide for 9 patients and liquid nitrogen for 22 patients. The results showed 80 percent clearing after a single freeze; however, 4 of 19 patients treated with liquid nitrogen developed atrophic scars when lesions were larger than 4 cm. All patients developed blisters.[12] Cryoatrophy may possibly be prevented by avoiding freeze thaw cycles greater than 10 seconds and not overlapping treatment areas.[13] SOR Ⓒ

GENERALIZED/DISSEMINATED GA

- This variant is more difficult to treat, and often has a longer duration than localized GA. It is very rare in children and all the studies have been performed in adults only. Even these studies involved small sample sizes and were not randomized. The studies often involved the use of antibiotics with some reported benefits (rifampin, ofloxacin, minocycline and dapsone).[14,15] SOR Ⓒ
- UVA1 phototherapy provided good or excellent results in 10 of 20 patients with disseminated GA. In patients with only a satisfactory treatment response, the disease reappeared soon after phototherapy was discontinued.[16] SOR Ⓒ

- Topical 5 percent imiquimod cream and 0.1 percent tacrolimus ointment were also touted as beneficial in small studies of adults.[17,18] SOR C
- Three adults were treated with vitamin E 400 IU daily and zileuton 2400 mg daily. All responded within 3 months with complete clinical clearing.[20] SOR C

PERFORATING, SUBCUTANEOUS

- Although we could find no specific data to inform the treatment of these less-common types of GA, treatments for both localized and disseminated GA could be applied based on clinical judgment along with patient’s severity and preferences.

PROGNOSIS

In 50 percent of cases, there is spontaneous resolution within 2 years; however, recurrence rate is as high as 40 percent.[21] In the study of 34 children with SGA, local recurrence occurred in 38 percent within 1 month to 7 years and recurrences at other locations were documented in 15 percent. Three patients with skin of color may have postinflammatory hyperpigmentation once the papules and plaques resolve.

FOLLOW-UP

Follow-up visits should be offered to patients who want active treatment.

PATIENT EDUCATION

It is important to reassure patients and parents that this disease is self-limiting. Despite a displeasing appearance, the best treatment may be to let lesions resolve naturally. Numerous individual case studies and treatments have been attempted without consistent success. Treatments may produce side effects that are equally as unwanted, but more permanent, than the GA.

149 PYODERMA GANGRENOSUM

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

During a medical mission trip to Africa a child was seen with pyoderma gangrenosum on the dermatology ward of a hospital. She has had a long history of pyoderma gangrenosum with ulcerations on her face, neck, and chest (**Figure 149-1**). The scarring has caused adhesions between the face, neck, and chest.

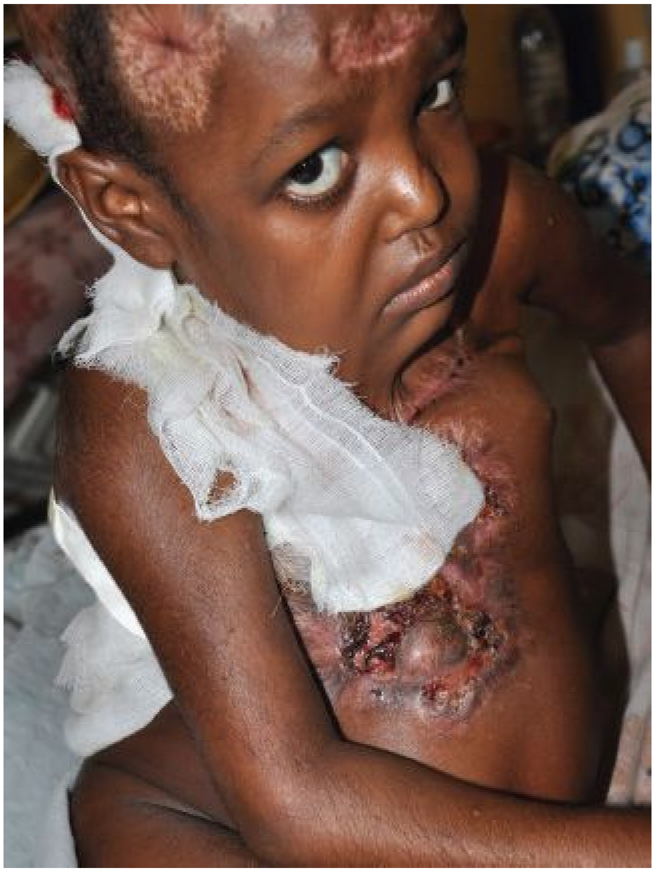

FIGURE 149-1 Pyoderma gangrenosum on the face, neck, and chest of a child in Africa. The scarring has caused adhesions between the face, neck, and chest. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Pyoderma gangrenosum (PG) is an uncommon ulcerative disease of the skin of unknown origin that affects both children and adults. It is a type of neutrophilic dermatosis.

EPIDEMIOLOGY

- PG occurs in approximately 1 person per 100,000 people of all ages each year.[1]
- Children account for only 3 to 4 percent of the total number of cases. There is nothing clinically distinctive about pyoderma gangrenosum in children and adolescents other than the age of the patients.[2]
- No racial predilection is apparent.
- A slight female predominance may exist.
- Predominately occurs in fourth and fifth decade, but all ages may be affected.

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology is poorly understood.
- Pathergy (initiation at the site of trauma or injury) is a common process and it is estimated that 30 percent of patients with PG experienced

pathergy.[1]

- Up to 50 percent of all cases are idiopathic.[3]
- At least 50 percent of cases are associated with systemic diseases such as inflammatory bowel disease, hematologic malignancy, and arthritis.[3]
- It occurs in up to 5 percent of patients with ulcerative colitis and 2 percent of those with Crohn disease (**Figure 149-2**).[4,5]

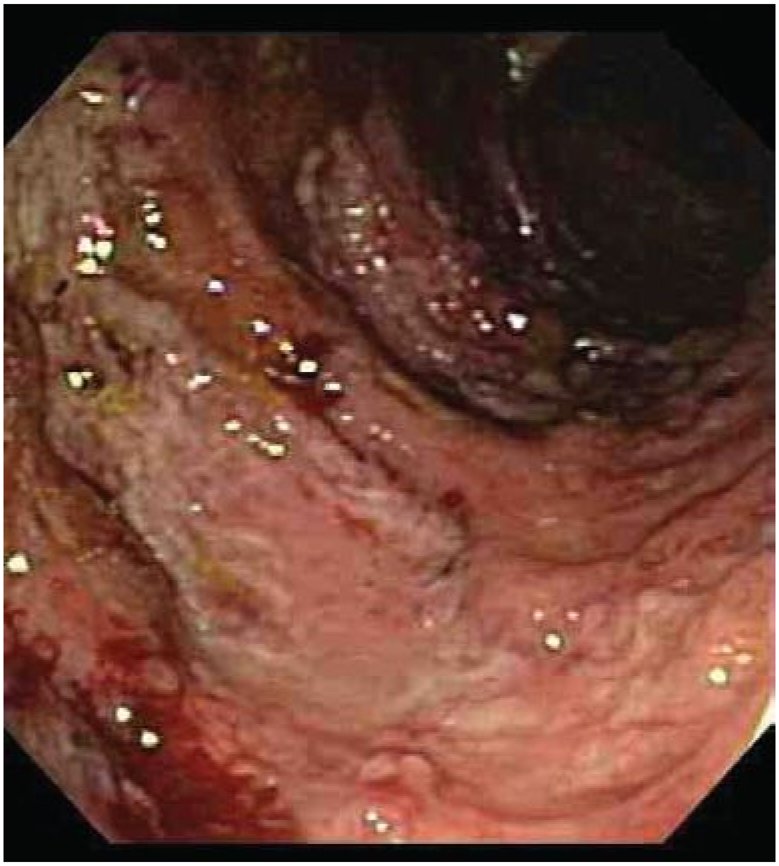

FIGURE 149-2 Friable inflamed mucosa of the colon in Crohn disease. (*Used with permission from Shashi Mittal, MD*.)

- In one study of 46 patients 18 years of age or younger with pyoderma gangrenosum, an underlying systemic disease was present in 74 percent of the older children, and as in adults it was most commonly ulcerative colitis.[2]
- The lesions tend to affect the lower extremities (**Figure 149-3**), but infants tend to have ulcers more commonly than adults in the genital and

perianal distribution,[6] the head and face (**Figure 149-1**), and the buttocks (**Figure 149-4**).[7]

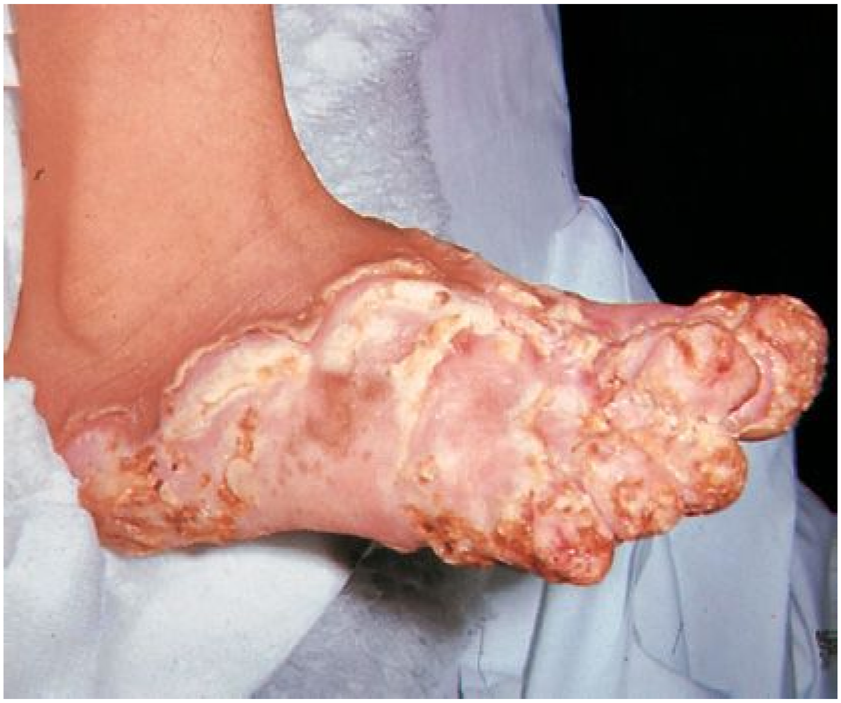

FIGURE 149-3 Pyoderma gangrenosum on the foot of a child. The lower extremity is the most common location for this rare disease in children. (*Used with permission from Weinberg SW, Prose NS, Kristal L, Color Atlas of Pediatric Dermatology, 4th edition, Figure 15-29, New York, NY: McGraw-Hill, 2008*.)

- Biopsies usually show a polymorphonuclear cell infiltrate with features of ulceration, infarction, and abscess formation.

RISK FACTORS

- Ulcerative colitis.
- Crohn disease.[3,8]
- Polyarthritis (seronegative or seropositive).

- Hematologic diseases/disorders such as leukemia (predominantly myelocytic).
- Monoclonal gammopathies (primarily immunoglobulin A).
- Psoriatic arthritis and rheumatoid arthritis.
- Hepatic diseases (hepatitis and primary biliary cirrhosis).
- Immunologic diseases (lupus erythematosus and Sjögren syndrome).

DIAGNOSIS

CLINICAL FEATURES

- Typically PG presents with deep painful ulcer with a well-defined border, which is usually violet or blue (**Figures 149-3** and **149-4**). The color has also been described as the color of gun metal. The ulcer edge is often undermined and the surrounding skin is erythematous and indurated. It usually starts as a pustule with an inflammatory base, an erythematous nodule, or a hemorrhagic bulla on a violaceous base. The central area then undergoes necrosis to form a single ulcer.[8]

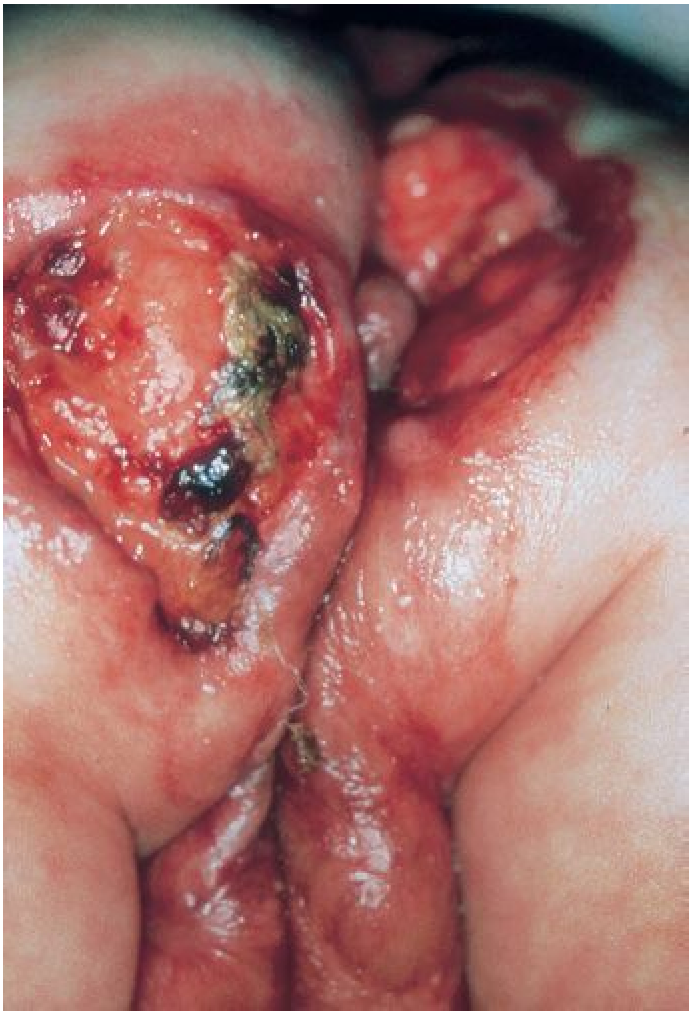

FIGURE 149-4 Pyoderma gangrenosum on the buttocks of an infant. Note the necrotic ulcers with undermined borders. (*Used with permission Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 15-17, New York, NY:McGraw-Hill, 2009*.)

- The lesions are painful and the pain can be severe.[3] Patients may have malaise, arthralgia, and myalgia.
- Two main variants of PG exist: classic and atypical.[3]
  - Classic PG is characterized by a deep ulceration with a violaceous border that overhangs the ulcer bed.[3] These lesions of PG most commonly occur on the legs (**Figure 149-3**).[3]

  - Atypical PG has a vesiculopustular wet component. This is usually only at the border, is erosive or superficially ulcerated, and most often occurs on the dorsal surface of the hands, the extensor parts of the forearms, or the face.[3]

- Other variants:
  - Peristomal PG may occur around stoma sites. This form is often mistaken for a wound infection or irritation from the appliance.[9]
  - Vulvar or penile PG occurs on the genitalia and must be differentiated from ulcerative sexually transmitted diseases (STDs) in adolescents such as chancroid and syphilis.[3]
  - Intraoral PG is known as pyostomatitis vegetans. It occurs primarily in patients with inflammatory bowel disease.[3]

TYPICAL DISTRIBUTION

- Most commonly seen on the legs and hands, but can occur on any skin surface including the genitalia, buttocks, head and around a stoma. PG can be seen on the scalp, head, and neck (**Figure 149-1**).

LABORATORY TESTING

- Complete blood count (CBC), urinalysis (UA), and liver function tests (LFTs) should be obtained. Order a hepatitis profile to rule out hepatitis.[3] Systemic disease markers may be elevated if associated conditions exist, that is, erythrocyte sedimentation rate (ESR), antinuclear antibody (ANA), and rheumatoid factor. Obtain rapid plasma reagin (RPR), protein electrophoresis, and skin cultures as indicated. Consider culturing the ulcer/erosion for bacteria, fungi, atypical *Mycobacteria*, and viruses.[3]

- If GI symptoms exist, perform or refer for colonoscopy to look for inflammatory bowel disease.

BIOPSY

- Although there are no specific pathologic signs of PG, a biopsy of an active area of disease along with the border, can be used to rule out other causes of ulcerative skin lesions.
- The pathologist may be able to confirm your clinical impression. Biopsy of the earliest lesions reveal a neutrophilic vascular reaction. Fully developed lesions exhibit dense neutrophilic infiltrate, and some lymphocytes and macrophages surrounding marked tissue necrosis. Ulceration, infarction of tissue, and abscess formation with fibrosing inflammation at the edge of the ulcer may be seen.[10]

DIFFERENTIAL DIAGNOSIS

- PG is sometimes a diagnosis of exclusion diagnosed with successful wound healing following immunosuppressant therapy.[11] When misdiagnosed it is often confused for vascular occlusive or venous disease, vasculitis, cancer, primary infection, drug-induced or exogenous tissue injury, and other inflammatory disorders.[12] Biopsy of a questionable lesion may be the only way to ultimately distinguish PG as the cause of ulcerative skin lesions.
- Ulcerative STDs, such as chancroid and syphilis, can resemble vulvar or penile PG. These STDs are more common than PG and should be diagnosed with appropriate tests, including RPR and bacterial culture for *Haemophilus ducreyi*. If these tests are negative, then PG should be considered. RPR should also be repeated in 2 weeks if it is initially negative at the start of a chancre—it takes some weeks to become positive and syphilis is easily treatable (see Chapter 75, Ulcerative Mucosal Disorders and Chapter 181, Syphilis).
- Acute febrile neutrophilic dermatosis (Sweet syndrome) is a neutrophilic dermatosis like PG, but the patients are generally febrile with systemic symptoms (**Figure 149-5**). The diagnosis of Sweet syndrome is made when the patient fulfills 2 of 2 major criteria and 2 of 4 minor criteria. The 2 major criteria are (a) an abrupt onset of tender or painful erythematous plaques or nodules occasionally with vesicles, pustules, or

bullae, and (b) predominantly neutrophilic infiltration in the dermis without leukocytoclastic vasculitis. Minor criteria include specific preceding or concurrent medical conditions, fever, abnormal lab values, including leukocytosis and an elevated sedimentation rate, and a rapid response to systemic steroids.

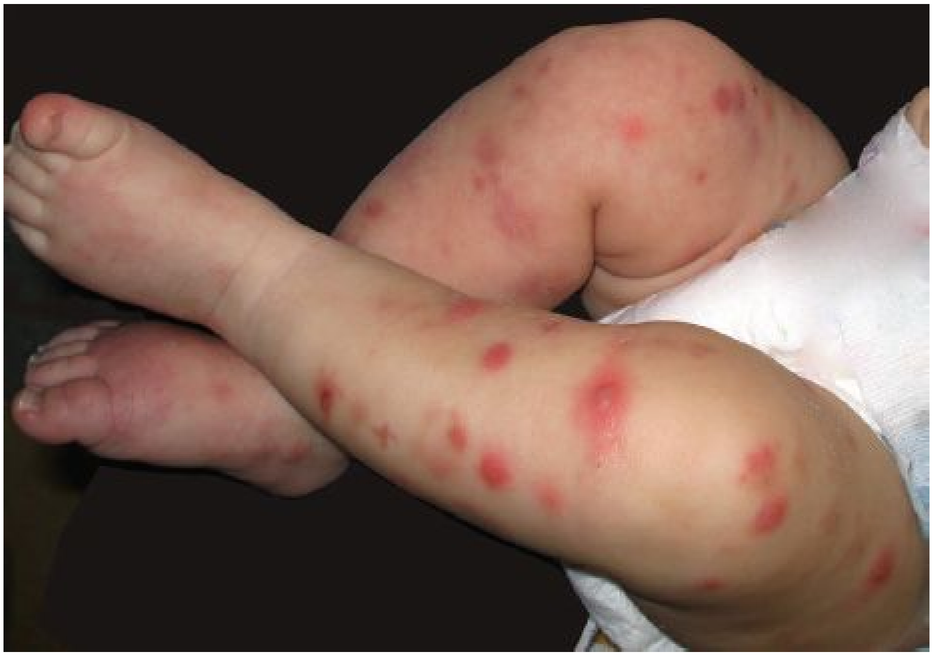

FIGURE 149-5 Sweet’s syndrome in an infant. Erythematous plaques and nodules with central bullous changes are present on the legs. (*Used with permission Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 15-16, New York, NY: McGraw-Hill, 2009*.)

- Systemic vasculitis is perhaps the most difficult to differentiate, but history of minor trauma in the area preceding lesion formation (pathergy) and undermining of the violaceous border should lead one toward the diagnosis of PG.[12]
- Ecthyma is a type of impetigo in which ulcers form. Bacterial cultures will be positive and this disease should respond to cephalexin or other oral antibiotics (see Chapter 99, Impetigo).
- Spider bites from the black recluse spider can easily resemble PG when they ulcerate. The history of a spider bite can help differentiate this from

PG.

- Sporotrichosis is a fungal infection that often starts from an injury while gardening with roses. It is usually on the arm or hand and can resemble PG (**Figure 149-6**). Use fungal culture to diagnose this when the history suggests this as the diagnosis. Oral antifungal medications can treat this.

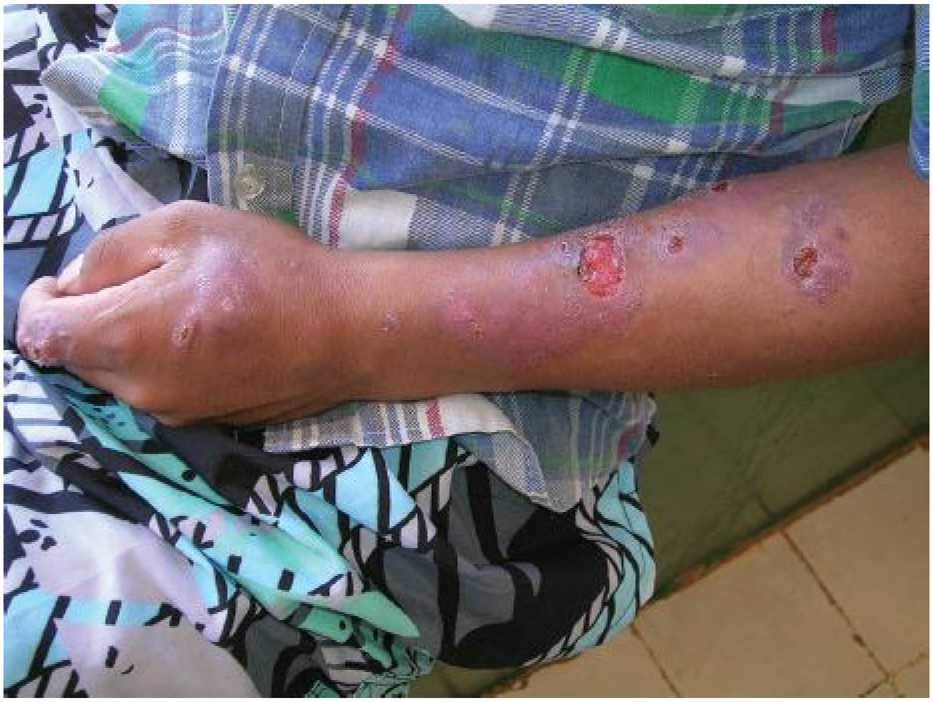

FIGURE 149-6 Sporotrichosis (fungal infection) with the typical sporotrichoid spread up the arm from an inoculation of the hand. Note the ulcers that resemble pyoderma gangrenosum on the arm of this Panamanian child. (*Used with permission from Richard P. Usatine, MD.*)

- Venous insufficiency ulcers are typically seen around the medial malleolus and the most severe of these ulcers resembles PG, although they are rare in children and usually associated with other severe vaso-occlusive problems. The presence of signs and symptoms of venous insufficiency should help differentiate this from PG.

MANAGEMENT

NONPHARMACOLOGIC

- At each visit, measure and document the lesion’s depth, length, and width to track treatment progression.[13]
- Surgical debridement is contraindicated as pathergy occurs in 25 to 50 percent of cases and surgery will make the lesions worse. SOR Ⓑ

MEDICATIONS

- Patients frequently are in pain from the lesions, so treatment is aimed at pain relief as well as healing the skin lesions.
- Therapy directed at the underlying inflammatory bowel disease (IBD), when present, usually results in healing, although treatment with steroids is often necessary.[13] SOR Ⓑ
- Topical medications are first-line therapy in cases of localized PG that are not severe. Start with potent corticosteroid ointments or tacrolimus ointment (over age 2 years).[13–16] SOR Ⓑ
- Small ulcers can be managed with topical steroid creams, silver sulfadiazine, or potassium iodide solution. SOR Ⓒ
- Intralesional injections with corticosteroids are also an option.[13, 14] SOR Ⓑ
- Systemic treatment with oral corticosteroids, such as methylprednisolone (0.5–1.7 mg/kg/day divided q12hr IV for 3 days), prednisone (0.5–1 mg/kg/day PO qDay or divided BID; not to exceed 80 mg/day), or oral cyclosporine (e.g., 5 mg/kg per day) alone or together appears to be effective (in the absence of controlled trials) in many cases and should be considered first-line therapy.[9,14] SOR Ⓑ Response is usually rapid, with stabilization of the PG within 24 hours.[17]
- In steroid-refractory PG associated with IBD, infliximab 5 mg/kg IV at 0, 2 and 6 weeks then every 8wk was effective in case series and a small placebo-controlled trial.[18,19] SOR Ⓑ Other biologic therapies reported to improve symptoms include etanercept and adalimumab.[13] SOR Ⓒ

- To date, case reports have been published that show therapeutic efficacy of oral dapsone, azathioprine, mycophenolate mofetil, cyclophosphamide, and tacrolimus.[14,20] SOR Ⓒ

REFERRAL

In most cases, referral to a dermatologist is needed.

PROGNOSIS

- The prognosis of PG is generally good, but residual scarring is common (**Figure 149-1**) and recurrences may occur.
- Although many patients improve with initial immunosuppressive therapy, patients may follow a refractory course and require multiple therapies.

FOLLOW-UP

- All patients suspected of having PG need close and frequent follow-up to obtain a definitive diagnosis and treat this challenging condition.

PATIENT EDUCATION

- PG is a rare ulcerative skin condition that is poorly understood.
- A skin biopsy is needed to rule out other diagnoses.
- Most treatments are empirical and based on small studies.
- The risks and benefits of steroids and/or other immunosuppressive medications need to be explained.

- Surgical treatments are contraindicated because they increase the ulcer size.

150 PEDIATRIC SARCOIDOSIS

Yoon-Soo Cindy Bae-Harboe, MD
Khashayar Sarabi, MD
Amor Khachemoune, MD

PATIENT STORY

A 4-year-old boy presents with “multiple bumps” that have been growing on his face (**Figure 150-1**). The differential diagnosis of these lesions included cutaneous sarcoidosis and granuloma annulare. A punch biopsy was performed and the diagnosis of sarcoidosis was made.

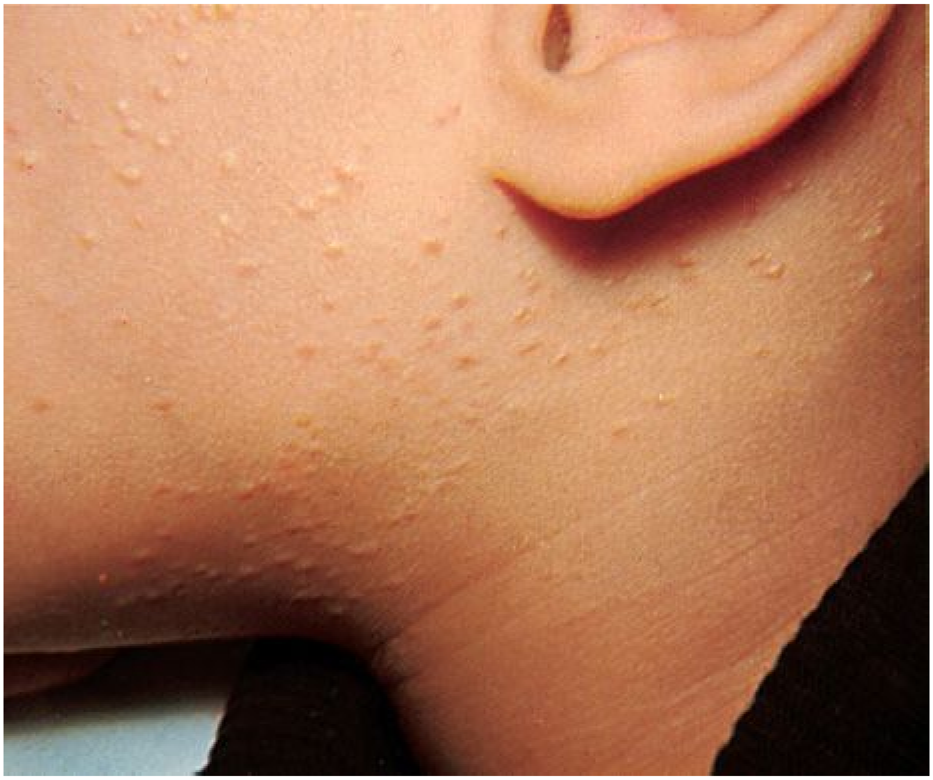

FIGURE 150-1 Papular lesions of sarcoidosis on the face of a 4-year-old boy. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color*

Atlas of Pediatric Dermatology, 4th edition, Figure 15-23, New York, NY:McGraw-Hill, 2008.)

INTRODUCTION

Sarcoidosis is a multisystem granulomatous disease most commonly involving the skin, lungs, lymph nodes, liver, and eyes. There is no clear gender predominance in childhood sarcoidosis.[1] Of interest, outside the US sarcoidosis mainly occurs in the predominant race of the country.[2] Higher incidences of cases occur in certain parts of the world, including Sweden in Europe and the South Atlantic and Gulf States in the US.[3–5]

In the pediatric population, sarcoidosis is divided into early and late onset. Early onset involves children in their first four years of life, presenting with a triad of arthritis, rash, and uveitis.[4] In this patient population, typical pulmonary disease occurs in about 22 percent of children in this age group.[6] Early onset sarcoidosis is seen mostly in Caucasian patients and these patients may have a protracted course with severe morbidity and residual impairments.[7,8]

Late onset sarcoidosis in children presents as a multisystem disorder, with lung involvement most common.[6] Up to 60 percent of children have an abnormal chest x-ray at initial presentation, with the predominant symptom being a mild, dry, chronic cough.[6] The eyes are also affected in older children (20 to 30%).[3,9] Symptoms include eye redness, blurred vision, photophobia, and ocular pain. Ophthalmic sarcoidosis manifests as uveitis with anterior segment involvement (84% of cases).[9] Other complications include optic neuritis, band keratopathy, cataracts, glaucoma, and retinal vasculitis. Other organ systems may be involved including the reticuloendothelial system (enlargement of lymph nodes),[1] cutaneous (erythema nodosum),[2] musculoskeletal (joint effusions, arthralgias, myositis),[2] renal (nephrocalcinosis, abnormal urinalysis),[3,10] cardiovascular (arrhythmias, sudden death),[11] central nervous system (seizures, cranial neuropathies, diabetes insipidus, growth hormone deficiency),[6,12,13] and hepatic (abnormal liver function tests) systems.[14]

SYNONYMS

- Juvenile early onset sarcoidosis.
- Juvenile late onset sarcoidosis.
- Juvenile systemic granulomatosis.
- Childhood sarcoidosis.
- Lupus pernio (sarcoidosis of the face that resembles cutaneous lupus).

EPIDEMIOLOGY

- Rare in pediatric age group; more common in adolescents and young adults.
- Male/female ratio = 1.
- Two distinct forms of juvenile sarcoidosis—Early onset and late onset.
  - Early:
    - Presents within the first four years of life.
    - Triad of arthritis/rash/uveitis.
    - Predominantly Caucasian patients.
    - Progressive and debilitating course
  - Late:
    - Older children, adolescence.
    - Multi organ involvement.
    - Predominantly African American patients.
- Common types are maculopapular, lupus pernio, cutaneous, or subcutaneous nodules, and infiltrative scars.
- Erythema nodosum (EN) occurs in 31 percent of patients with sarcoidosis and is the most common associated skin finding (see Chapter 152, Erythema Nodosum).

ETIOLOGY AND PATHOPHYSIOLOGY

- Studies reveal that siblings of patients with sarcoidosis exhibit an increased risk of involvement thus implying a genetic component.[15]
- Sarcoidosis is a granulomatous disease with involvement of multiple organ systems with an unknown etiology.
- The typical findings in sarcoid lesions are characterized by the presence of circumscribed granulomas of epithelioid cells with little or no caseating necrosis, although fibrinoid necrosis is not uncommon.
- Granulomas are usually in the superficial dermis but may involve the thickness of dermis and extend to the subcutaneous tissue. These granulomas are referred to as “naked” because they only have a sparse lymphocytic infiltrate at their margins.

RISK FACTORS

- Positive family history.
- African descent, as familial clustering is more commonly observed in this population.

DIAGNOSIS

CLINICAL FORMS OF DISEASE

Cutaneous involvement is either *specific* or *nonspecific*.

- Specific:

Typical noncaseating granulomas, no evidence of infection, foreign body, or other causes.

  - May be disfiguring, but almost always nontender and rarely ulcerate.
  - Papules, plaques or nodules is most common, red-brown or purplish, usually smaller than 1 cm, and found mostly on face, neck, upper back, and limbs (**Figure 150-2**).

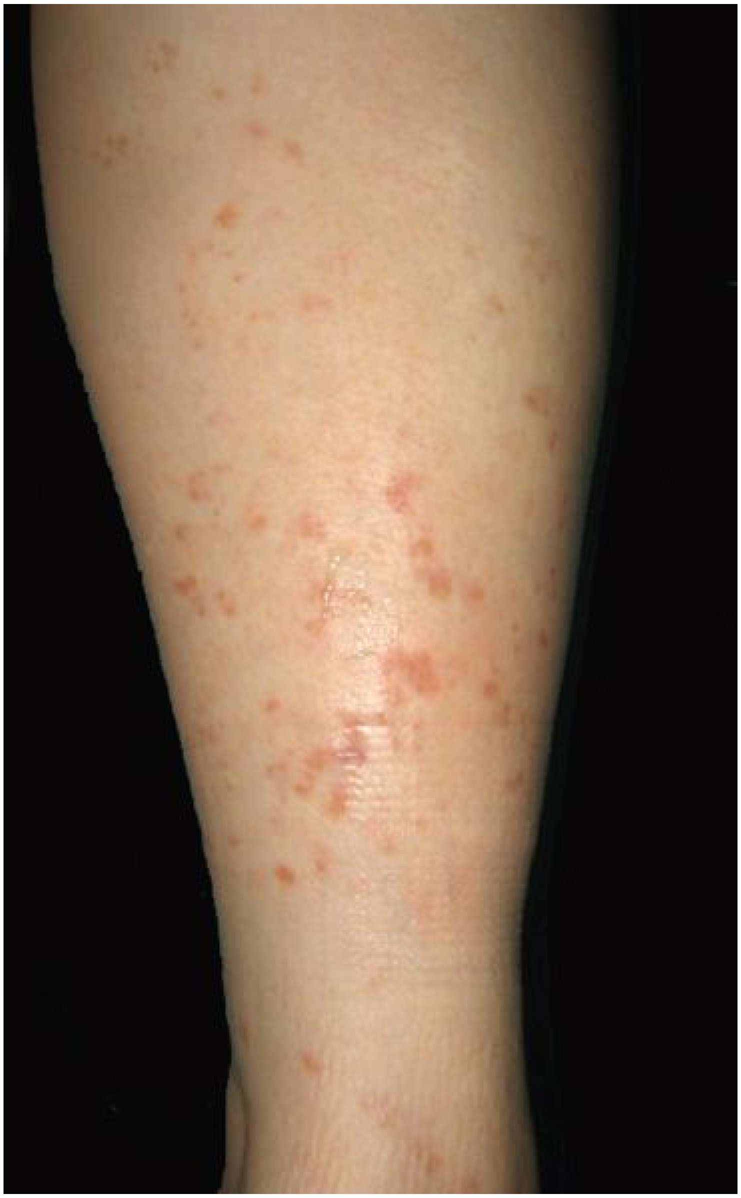

FIGURE 150-2 Maculopapular sarcoidosis on the leg. (*Used with permission from Amor Khachemoune, MD*.)

- Lupus pernio type sarcoidosis (**Figures 150-3** to **150-5**) presents as purplish lesions resembling frostbites with shiny skin covering them, typically affecting nose, cheeks, ears, and lips.

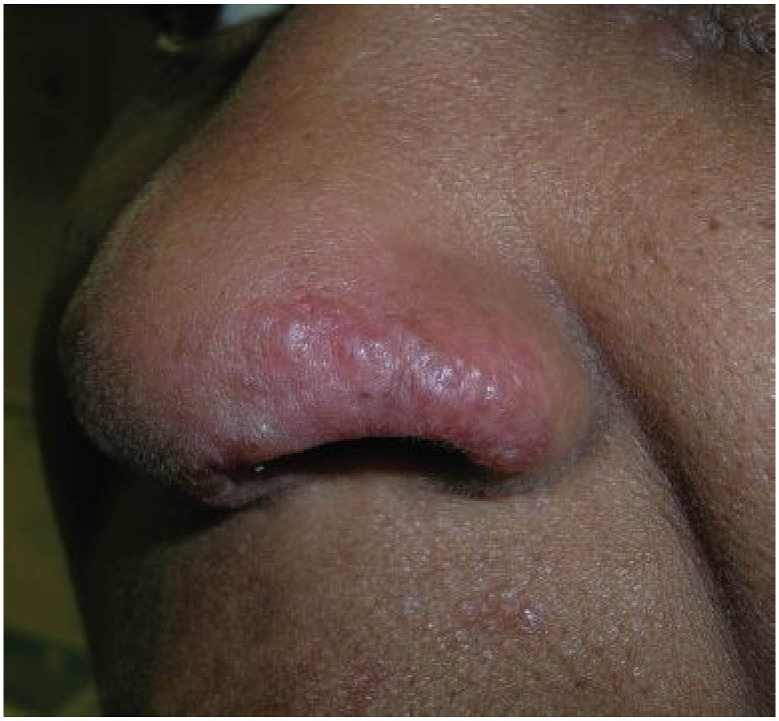

FIGURE 150-3 Lupus pernio type sarcoidosis involving the nasal rim. (*Used with permission from Richard P. Usatine, MD.*)

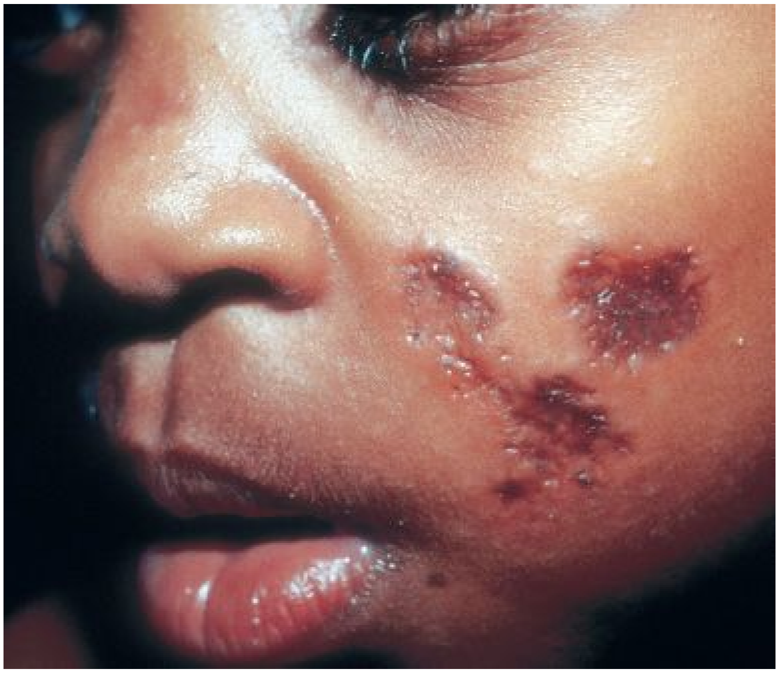

FIGURE 150-4 Lupus pernio type sarcoidosis with violaceous scarred plaques on cheek of a child. (*Used with permission from Kane K, Lio PA, Stratigos AJ, Johnson RA. Color Atlas & Synopsis of Pediatric Dermatology, 2nd edition, Figure 15-18, New York, NY: McGraw-Hill, 2009*

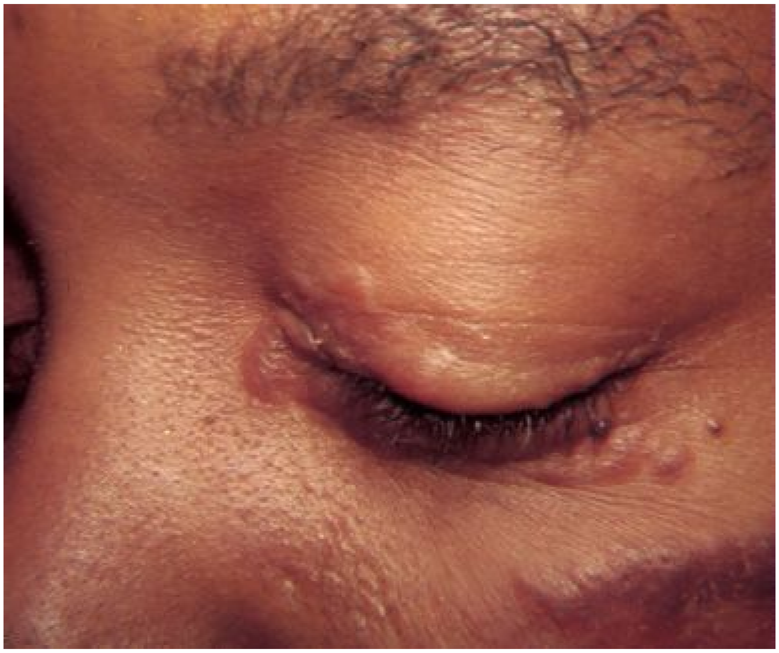

FIGURE 150-5 Lupus pernio (sarcoidosis) with violaceous papules and plaques around the eye and on the cheek of a child. (*Used with permission from Weinberg S, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Fig. 15-25, McGraw-Hill, 2008*.)

- Plaque sarcoidosis is typically chronic, occurring over the forehead, extremities, and shoulders, but may heal without scarring.
- Nodular cutaneous and subcutaneous plaques that are skin-colored or violaceous without epidermal involvement are typically seen in advanced systemic sarcoidosis.
- Areas of old scars that are damaged by trauma, radiation, surgery, or tattoo may also be infiltrated with sarcoid granulomas (**Figures 150-6** and **150-7**). Lesions may be tender and appear indurated with red or purple discoloration.

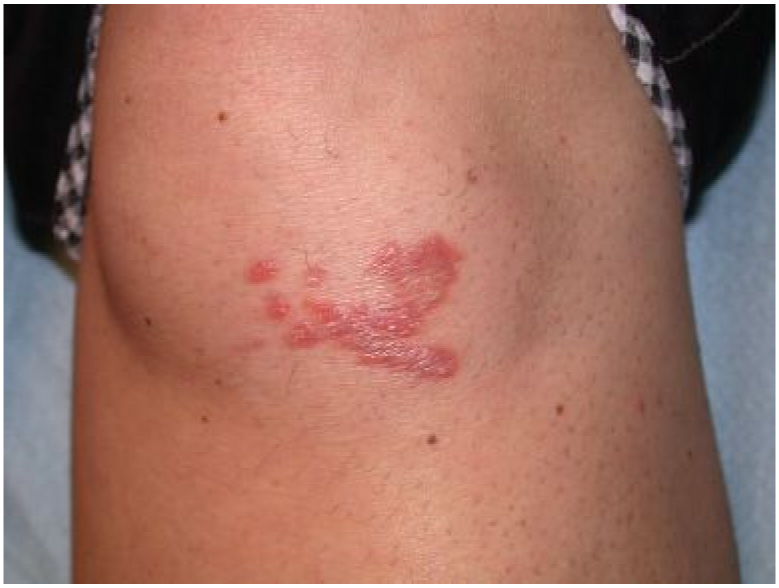

FIGURE 150-6 Sarcoidal plaque of the knee, which appeared after a trauma to the knee. (*Used with permission from Amor Khachemoune, MD*.)

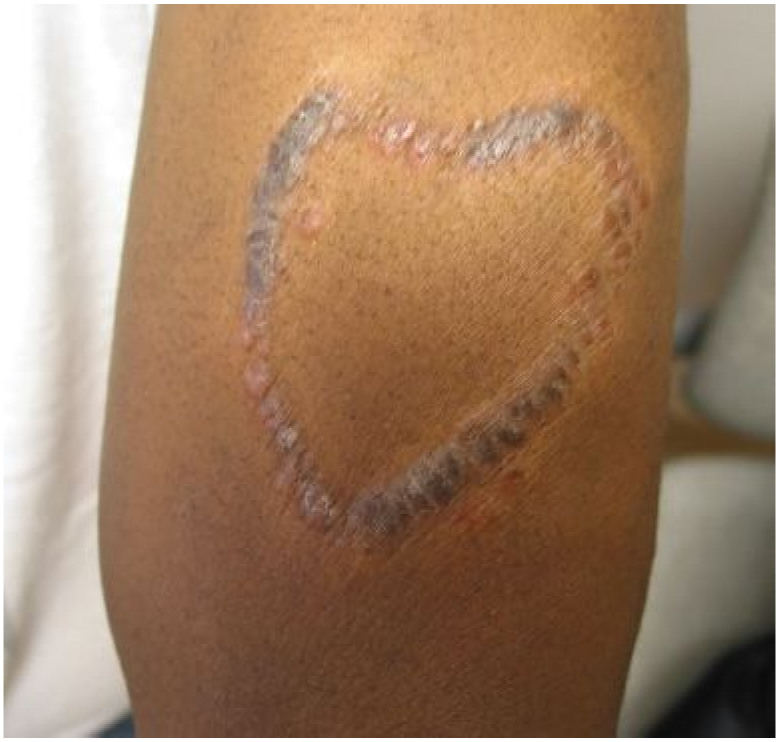

FIGURE 150-7 Sarcoid on a heart-shaped homemade tattoo over the knee. (*Used with permission from Amor Khachemoune, MD*.)

- Nonspecific:

  - Erythema nodosum (EN) lesions usually are not disfiguring, but tender to touch, especially when they occur with fever, polyarthralgias, and sometimes arthritis and acute iritis.
  - EN appears abruptly with warm, tender, reddish nodules on the lower extremities, most commonly the anterior tibial surfaces, ankles, and knees.
  - EN nodules are 1 to 5 cm, usually bilateral, and evolve through color stages: first bright red, then purplish, and lastly a bruise-like yellow or green appearance.
  - EN is seen in the setting of Löfgren syndrome, appearing in conjunction with hilar lymphadenopathy (bilateral most often), and occasionally anterior uveitis and/or polyarthritis.
  - Ulceration is typically not observed in EN, which heals without scarring.
  - Early-onset childhood sarcoidosis may present with enchondromatosis.[16]

LABORATORY STUDIES

- Complete blood count (CBC) count with differential:
  - Leukopenia, eosinophilia, and anemia may be seen.
  - Serum calcium and 24-hour urine calcium levels:
  - Hypercalciuria has been found in 49 percent of patients in some studies, whereas 13 percent of patients had hypercalcemia.
  - Hypercalcemia occurs in sarcoidosis because of increased intestinal absorption of calcium that results from overproduction of a metabolite of vitamin D by pulmonary macrophages.
- Serum angiotensin-converting enzyme (ACE) level is elevated:
  - Age related variations in normal serum ACE levels should be taken into account as values of 40 to 50 percent higher than in adults have been observed in children younger than 15 years.[11,17]
- Chitotriosidase involved in the defense against pathogens containing chitin may be a potential marker for disease activity:

  - Chitotriosidase activity was found to be correlated with SACE and lung CT scores for sarcoidosis.[18]
- Serum chemistries, such as alanine aminotransferase, aspartate aminotransferase, alkaline phosphatase, blood urea nitrogen (BUN), and creatinine levels. In addition, urinalysis may reveal proteinuria, hematuria, leucocyturia and concentration defect. These levels may be elevated with hepatic and renal involvement.
- Other—Elevated erythrocyte sedimentation rate, diabetes insipidus, and renal failure may be noted.

IMAGING STUDIES

- Chest x-ray (CXR):
  - Intrathoracic lymphadenopathy involving the right paratracheal area and both hila are detected in 95 percent of cases.[19]
  - Stage I disease shows bilateral hilar lymphadenopathy (BHL). Stage II disease shows BHL plus pulmonary infiltrates. Stage III disease shows pulmonary infiltrates without BHL. Stage IV disease shows pulmonary fibrosis.
- CT of the thorax may demonstrate lymphadenopathy or granulomatous infiltration. Other findings may include small nodules with a bronchovascular and subpleural distribution, thickened interlobular septae, honeycombing, bronchiectasis, and alveolar consolidation.
- Pulmonary function tests—Evidence of both restrictive abnormalities and obstructive abnormalities may be found.

BIOPSY

- Punch biopsy is adequate to obtain a sample of skin that includes dermis.
- If EN nodules are deep, a biopsy should also include subcutaneous tissue.
- Biopsy specimens are sent for histologic examination, as well as stains and cultures to rule out infectious causes.

DIFFERENTIAL DIAGNOSIS

- Granulomatous sarcoidosis of the skin (**Figure 150-8**).

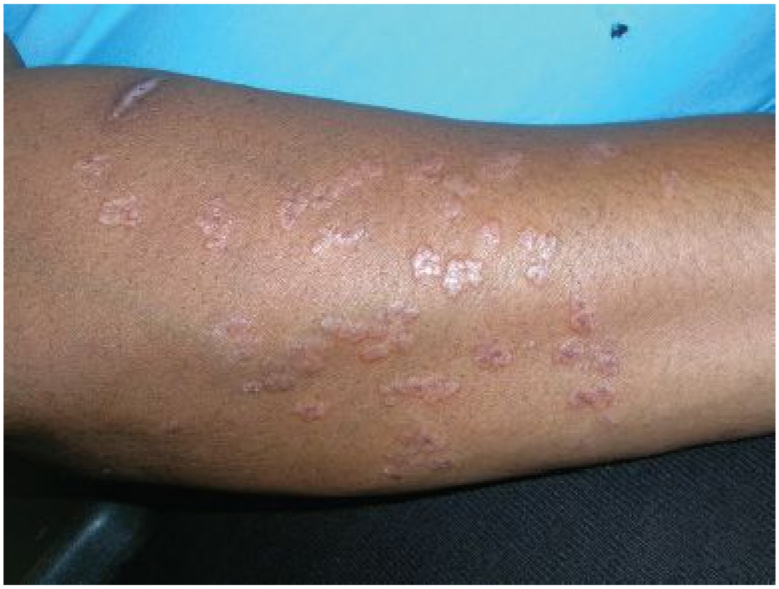

FIGURE 150-8 Granulomatous plaques of biopsy proven sarcoidosis on the arm of a woman. She also has sarcoidosis of the lung. (*Used with permission from Richard P. Usatine, MD*.)

  - Granuloma annulare (GA) is also a granulomatous skin disease, which appears in single or multiple rings in adults and children (see Chapter 148, Granuloma Annulare).
  - Rheumatoid nodules—These usually appear in the context of a diagnosed rheumatoid arthritis with joint disease present (see Chapter 172, Juvenile Rheumatoid Arthritis).
  - Granulomatous mycosis fungoides—This is a type of cutaneous lymphoma with many clinical forms including granuloma formation.
  - Granulomatous periorificial dermatitis—Also known as facial Afro-Caribbean childhood eruption (FACE), GPD occurs in prepubertal children and is usually self limited.[20]

- Maculopapular type:

  - Lupus vulgaris—This is a type of cutaneous involvement with *Mycobacterium tuberculosis*.
  - Syringoma—These are small firm benign adnexal tumors usually appearing around the upper cheeks and lower eyelids.
  - Xanthelasma—These are the most common type of xanthomas. They are benign yellow macules, papules, or plaques often appearing on the eyelids. Approximately one half of the patients with xanthelasma have a lipid disorder (see Chapter 193, Hyperlipidemia and Xanthomas).
  - Lichen planus—This is a very pruritic skin eruption with pink to violaceous papules and plaques. It may present in different body locations but the most common areas are the wrists and ankles (see Chapter 138, Lichen Planus).
  - Granulomatous rosacea—This is a variant of rosacea made of uniform papules involving the face.
  - Acne keloidalis nuchae—This is commonly seen in dark-skinned patients. It presents with multiple perifollicular papules and nodules. The most common location is the back of the neck at the hairline.
  - Pseudofolliculitis barbae—This is most commonly seen in patients with darker skin color, triggered by ingrown hair involving the beard area.
- Annular or circinate type of sarcoidosis (**Figure 150-9**):

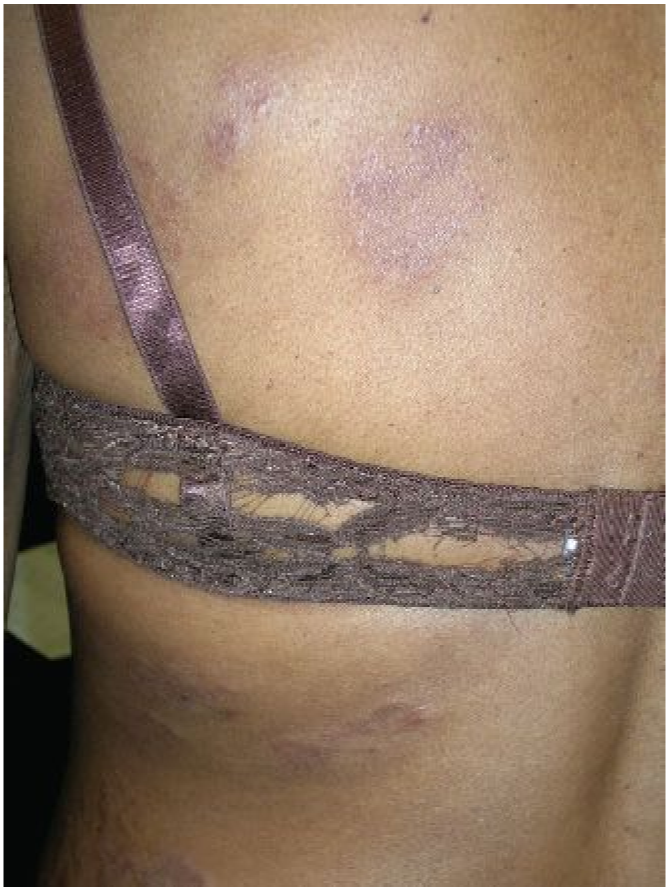

FIGURE 150-9 Violaceous sarcoidal papules coalescing into annular plaques on the back. (*Used with permission from Richard P. Usatine, MD.*)

  - Granuloma annulare—Annular type (described previously, see also Chapter 148, Granuloma Annulare).

MANAGEMENT

- Cutaneous involvement of sarcoidosis is typically not life-threatening and, therefore, the major rationale for treatment is to prevent or minimize disfigurement. Cosmetic issues are particularly important on the face. Also, the lesions can be painful.
- Corticosteroids (oral and topical) are the mainstay of treatment.[3] SOR B

- Steroid sparing agents used to treat sarcoidosis include methotrexate, azathioprine cyclophosphamide and cyclosporin.[21,22] SOR Ⓒ

REFERRAL

- A multidisciplinary approach is imperative in patients with systemic sarcoidosis.
- Patients with eye symptoms should be referred to an ophthalmologist (**Figure 150-10**).

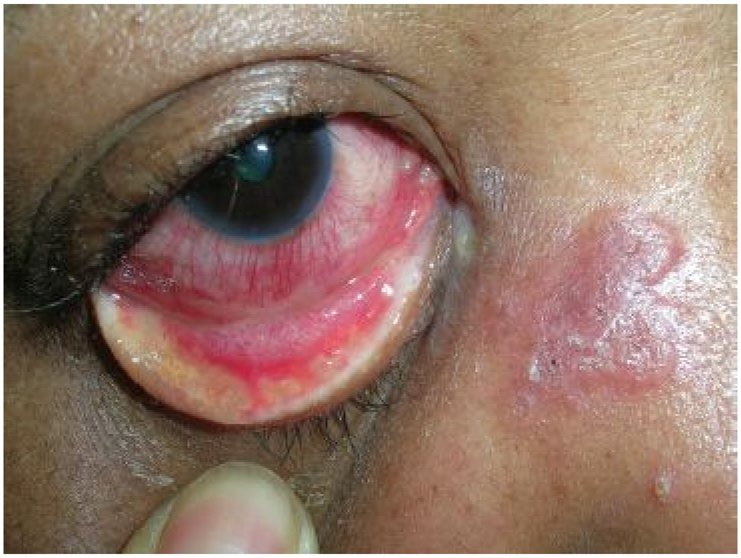

FIGURE 150-10 Sarcoidosis of the eye with involvement of the conjunctiva and infiltration of the inner lower eyelid. (*Used with permission from Richard P. Usatine, MD.*)

- Patients with lung involvement should be referred to a pulmonologist.
- Sarcoidosis may affect the following organ systems: pulmonary, reticuloendothelial, musculoskeletal, renal, cardiovascular, neurologic, hepatic; thus, thorough review of systems and results from laboratory work-up should dictate appropriate referral.

PREVENTION AND SCREENING

As the cause remains to be elucidated, no preventative measures have been established. Patients presenting with cutaneous sarcoidosis should be screened as clinically indicated.

PROGNOSIS

- The prognosis of sarcoidosis in children is unclear as the disease is rare and the number of the reported cases is small.
- Generally the prognosis is poorer in the African-American adult population.

In early onset disease, 80 to 100 percent of patients suffer from chronic debilitating sequelae.[7,8]

- Hilar lymphadenopathy in combination with acute or subacute onset (fever, arthralgia, erythema nodosum) is associated with a remission rate of 80 to 90 percent.[23]
- Hypercalcemia, cutaneous sarcoid lesions, and generalized lymphadenopathy are associated with poorer prognosis.[11]
- Mortality rate has been estimated to be about 1 to 5 percent.[24]

FOLLOW-UP

Patients with cutaneous sarcoidosis should be worked up for systemic sarcoidosis. Regular follow-up is necessary.

PATIENT EDUCATION

Inform patients about the risk that systemic sarcoidosis can occur even if the skin is the only area currently involved.

SECTION 12 HYPERSENSITIVITY SYNDROMES AND DRUG REACTIONS

151 ERYTHEMA MULTIFORME, STEVENS-JOHNSON SYNDROME, AND TOXIC EPIDERMAL NECROLYSIS

Carolyn Milana, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A 14-year-old boy presents to the emergency department with a 1-day history of fever associated with lip swelling and peeling (**Figure 151-1A**). Within 48 hours, he developed involvement of his ocular (**Figure 151-1B**) and urethral mucosa along with an erythematous papular rash on his trunk that spread to his extremities. In **Figure 151-1C**, target lesions can be seen on the back. He was diagnosed with Stevens-Johnson syndrome and admitted to the hospital.

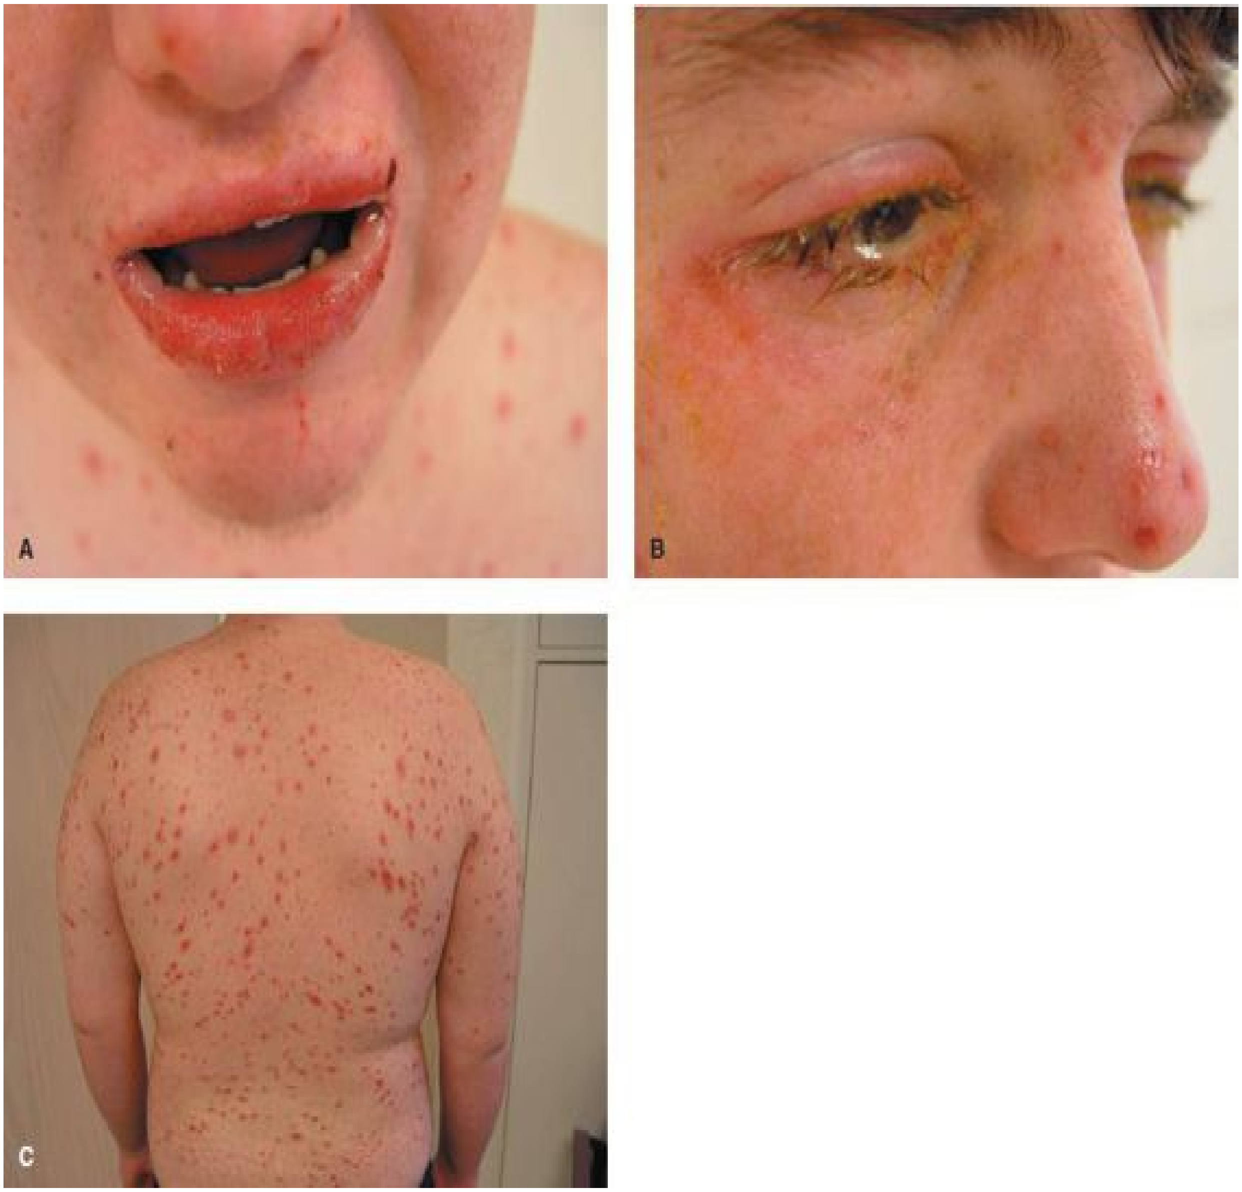

FIGURE 151-1 Stevens-Johnson syndrome in a 14-year-old boy who received penicillin for pneumonia. A. Lips and mouth are involved. B. Eye involvement. C. Target lesions on his back. (*Used with permission from Dan Stulberg, MD*.)

INTRODUCTION

Erythema multiforme (EM), Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN) are skin disorders thought to be types of hypersensitivity reactions (undesirable reactions produced by a normal immune system in a presensitized host) that occur in response to medication, infection, or illness. Both SJS and TEN are severe cutaneous reactions thought to describe the same disorder, only differing in severity (TEN, more severe); however, there is debate as to whether these three fall into a spectrum of disease that includes EM.

SYNONYMS

- EM has also been called EM minor.
- SJS has been called EM major in the past but it is now thought to be a distinct entity different from all types of EM.
- TEN is also known as Lyell syndrome.

EPIDEMIOLOGY

- The incidence of EM has been estimated to range from 1 in 1000 persons to 1 in 10,000 persons.[1] The true incidence of the disease is unknown.[1]
- SJS and TEN are rare severe cutaneous reactions often caused by drugs. Reports of incidence vary from 1.2 to 6 per 1 million for SJS and from 0.4 to 1.2 per 1 million for TEN.[2–4]
- EM most commonly occurs between the ages of 10 and 30 years, with 20 percent of cases occurring in children and adolescents.[5]
- With respect to EM, males are affected slightly more often than females.[5]

ETIOLOGY AND PATHOPHYSIOLOGY

Numerous factors have been identified as causative agents for EM:

- Herpes simplex virus (HSV) I and HSV II are the most common causative agents, having been implicated in at least 60 percent of the cases (**Figure 151-2**).[6,7] The virus has been found in circulating blood,[8] as well as on skin biopsy of patients with EM minor.[6]

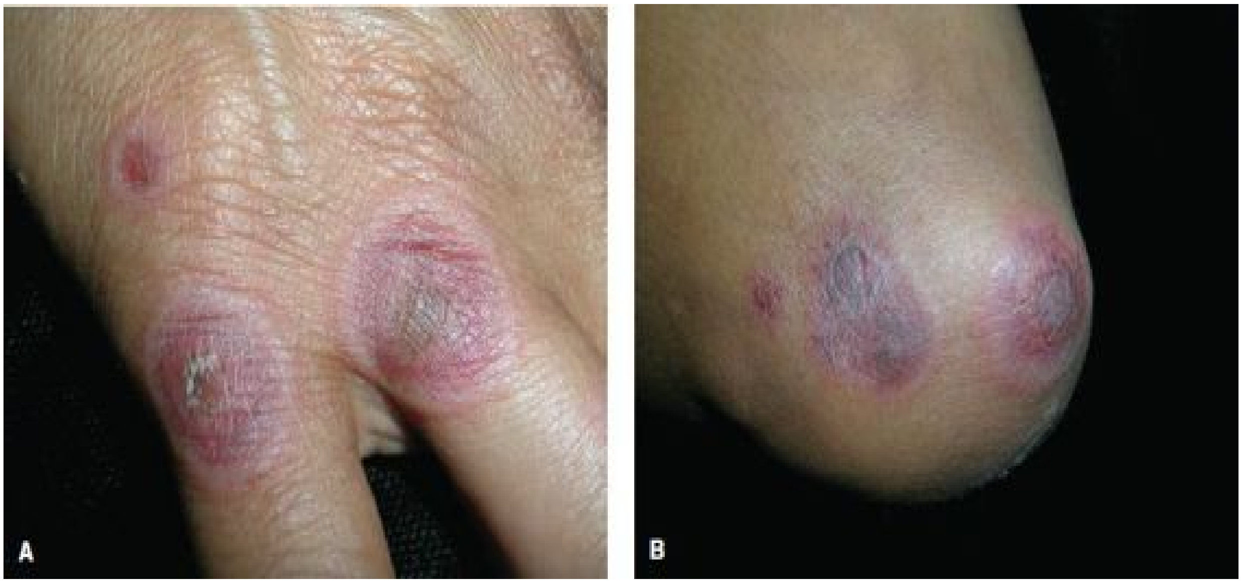

FIGURE 151-2 Erythema multiforme in a woman that recurs every time she breaks out with genital herpes. A. Target lesions on hand. B. Target lesions on elbow. (*Used with permission from Richard P. Usatine, MD*.)

- For SJS and TEN, the majority of cases are drug induced. Drugs most commonly known to cause SJS and TEN in children are the anticonvulsants phenytoin, carbamazepine, and lamotrigine followed by sulfonamide antibiotics.[3]
- *Mycoplasma pneumoniae* has been identified as the most common infectious cause for SJS (**Figure 151-3**).[7]

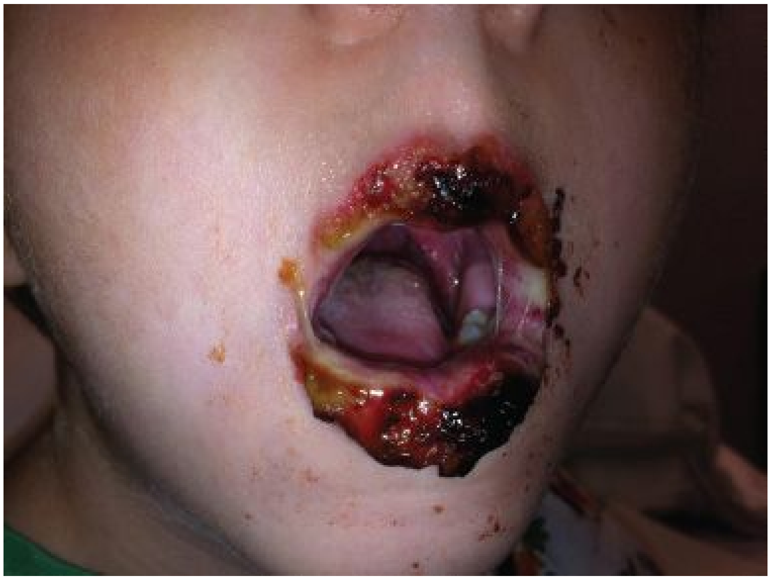

FIGURE 151-3 Stevens-Johnson syndrome with typical appearing oral mucosa showing hemorrhagic ulcerations and crusting in this young child. The child was diagnosed with a respiratory Mycoplasma infection. (*Used with permission from Camille Sabella, MD*.)

Other less-common causative agents for EM, SJS, and TEN include:

- Infectious agents such as *Mycobacterium tuberculosis*, group A streptococci, hepatitis B, Epstein Barr virus, *Francisella tularensis*, *Yersinia*, enteroviruses, *Histoplasma*, and *Coccidioides*.[1]
- Neoplastic processes, such as leukemia and lymphoma.[1]
- Drugs including antibiotics (e.g., penicillin, isoniazid, tetracyclines, cephalosporins, and quinolones), other anticonvulsants (e.g., phenobarbital and valproic acid),[1,7] and NSAIDS.
- Immunizations, such as diphtheria-tetanus toxoid, hepatitis B, measles-mumps-rubella, poliomyelitis, and Calmette-Guérin bacillus.[6]
- Other agents or triggers, including radiation therapy, sunlight, pregnancy, connective tissue disease, and menstruation.[1]

Although the pathogenesis of EM, SJS, and TEN remains unknown, recent studies show that it may be as a result of a host-specific cell-mediated immune response to an antigenic stimulus that activates cytotoxic T-cells and results in damage to keratinocytes.[6]

- The epidermal detachment (skin peeling) seen in SJS and TEN appears to result from epidermal necrosis in the absence of substantial dermal inflammation.

RISK FACTORS

- Recent evidence shows individuals with certain human leukocyte antigen (HLA) alleles may be predisposed to developing SJS/TEN when taking certain drugs.[2]
- Certain diseases, such as HIV/AIDS, malignancy, or autoimmune disease, also predispose individuals to SJS/TEN.[2,9]

DIAGNOSIS

CLINICAL FEATURES

In all of these conditions, there is a rapid onset of skin lesions. EM is a disease in which patients present with the following lesions:

- Classic lesions begin as red macules and expand centrifugally to become target-like papules or plaques with an erythematous outer border and central clearing (iris or bull’s-eye lesions) (**Figures 151-4** to **151-7**). Target lesions, although characteristic, are not necessary to make the diagnosis. The center of the lesions should have some epidermal disruption, such as vesicles or erosions.

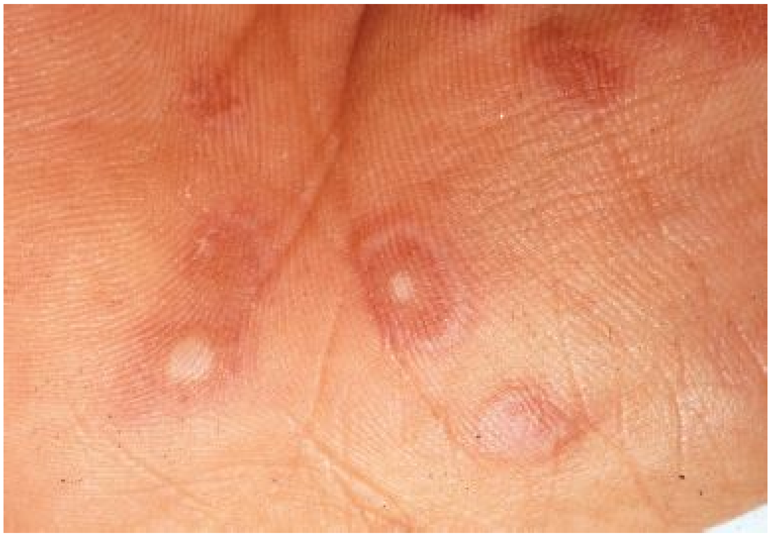

FIGURE 151-4 Erythema multiforme on the palm with target lesions that have a dusky red and white center. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

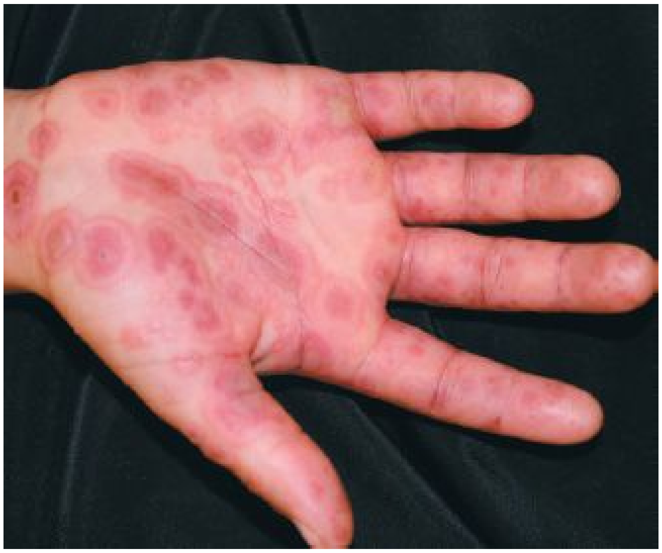

FIGURE 151-5 Erythema multiforme with target lesions on the palms. Note that there are some central bulla and crusts. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 13-8, 2008, New York: McGraw-Hill*.)

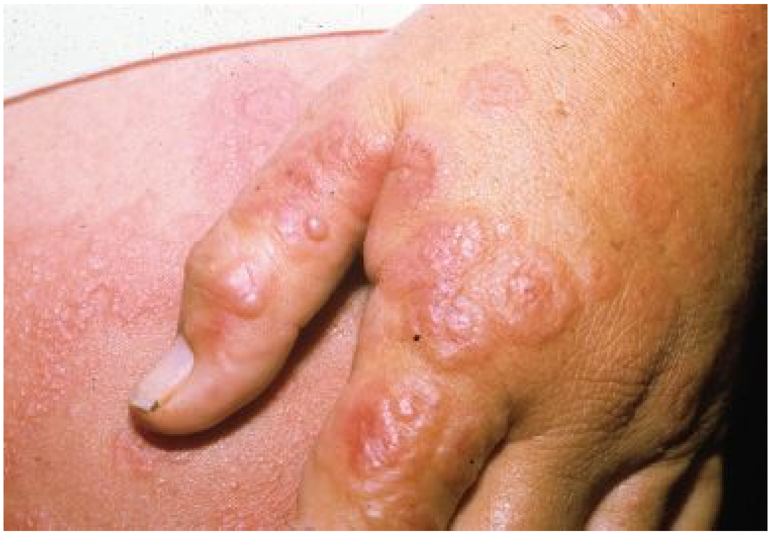

FIGURE 151-6 Erythema multiforme with vesicles and blistering of the target lesions on the hand. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

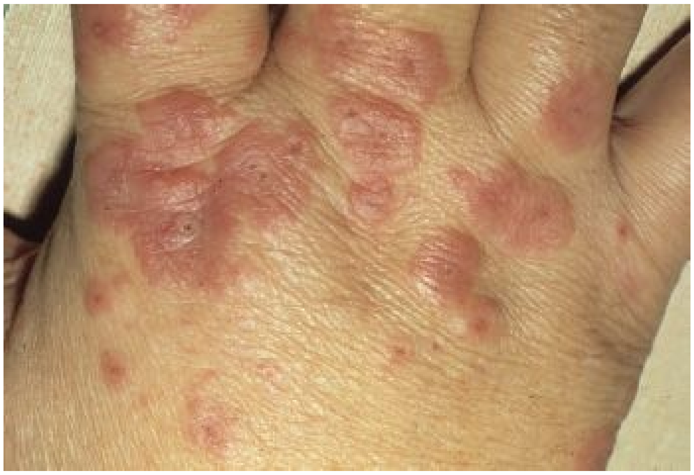

FIGURE 151-7 Erythema multiforme on the dorsum of the hand showing targets with small, eroded centers. There should be some epidermal erosion to diagnose erythema multiforme. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

- Lesions can coalesce and form larger lesions up to 2 cm in diameter with centers that can become dusky purple or necrotic.
- Unlike urticarial lesions, the lesions of EM do not appear and fade; once they appear they remain fixed in place until healing occurs many days to weeks later.

- Patients are usually asymptomatic, although a burning sensation or pruritus may be present.
- Lesions typically resolve without any permanent sequelae within 2 weeks.
- Recurrent outbreaks are often associated with HSV infection (**Figure 151-2**).[6,7]

In both SJS and TEN, patients may have blisters that develop on dusky or purpuric macules. SJS is diagnosed when less than 10 percent of the body surface area is involved, SJS/TEN overlap when 10 to 30 percent is involved, and TEN when greater than 30 percent is involved.

- Lesions can become more widespread and rapidly progress to form areas of central necrosis, bullae, and areas of denudation (**Figure 151-8**).

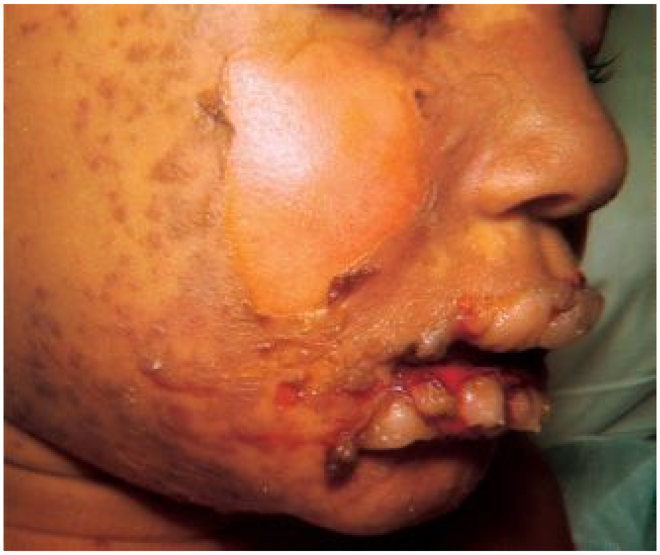

FIGURE 151-8 Toxic epidermal necrolysis with extensive desquamation of the skin on the face and lips of a young child. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 13-13, 2008, New York: McGraw-Hill.*)

- Fever higher than 39°C (102.2°F) is often present.
- In addition to skin involvement, there is involvement of at least 2 mucosal surfaces, such as the eyes, oral cavity, upper airway, esophagus, GI tract, or the anogenital mucosa (**Figures 151-1**, **151-3**, and **151-9**).

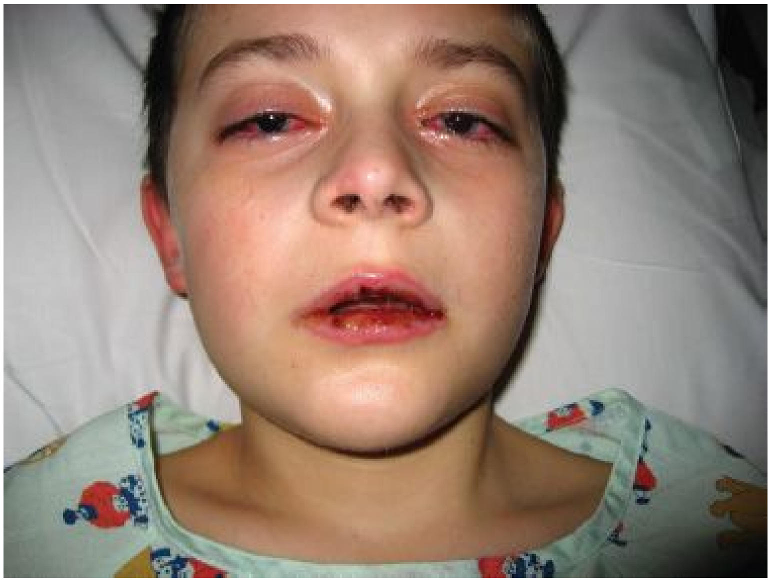

FIGURE 151-9 Stevens-Johnson syndrome with debilitating mucosal involvement of the eyes and mouth. Note the hemorrhagic ulcerations and crusting. This young boy required hospital admission for IV fluids and supportive care. (*Used with permission from Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 15-7, 2009, New York: McGraw-Hill.*)

- New lesions occur in crops and may take 4 to 6 weeks to heal.
- Large areas of epidermal detachment occur (**Figure 151-10**).

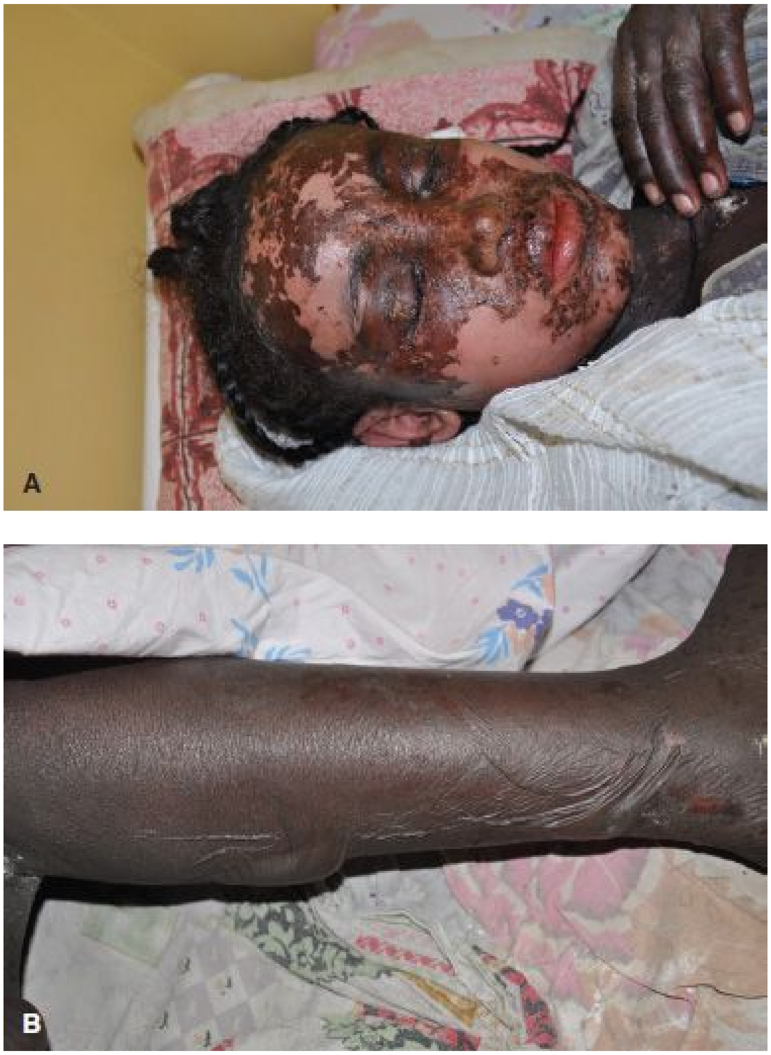

FIGURE 151-10 Toxic epidermal necrolysis secondary to amoxicillin. A. Face with large areas of desquamation and loss of pigmentation. B. Skin detaching from leg in large sheets and bullae. (*Used with permission from Richard P. Usatine, MD.*)

- Nikolsky's sign (denuding of skin when rubbed) may be seen when the child is handled.
- Severe pain can occur from mucosal ulcerations, but skin tenderness is minimal.
- Skin erosions lead to increased insensible blood and fluid losses as well as an increased risk of bacterial superinfection and sepsis.

- These patients are at high risk for ocular complications that can lead to blindness. Additional sequelae include bronchitis, pneumonitis, myocarditis, hepatitis, enterocolitis, polyarthritis, hematuria, and acute tubular necrosis.

TYPICAL DISTRIBUTION

- The distribution of the rash in EM can be widespread.
- The distal extremities, including the palms and soles, are most commonly involved.
- Extensor surfaces are favored.
- Oral lesions may be present, especially in SJS (**Figures 151-1**, **151-3**, and **151-9**).
- Severe lesions with exfoliation and extensive mucosal lesions occur in SJS and TEN (**Figures 151-8** and **151-10**).

LABORATORY AND IMAGING

- There are no consistent laboratory findings with these conditions. The diagnosis is usually made based on clinical findings.
- Routine blood work may show leukocytosis, elevated liver transaminases, and an elevated erythrocyte sedimentation rate.
- In TEN, leukopenia may occur.

BIOPSY

- A cutaneous punch biopsy can be performed to confirm the diagnosis or to rule out other diseases.
- Histologic findings of EM will show a lymphocytic infiltrate at the dermal–epidermal junction. There is a characteristic vacuolization of the epidermal cells and necrotic keratinocytes within the epidermis.[1]

DIFFERENTIAL DIAGNOSIS

- Urticaria—A skin reaction characterized by red wheals that are usually pruritic. Unlike EM, individual lesions rarely last more than 24 hours (Chapter 134, Urticaria and Angioedema). Giant urticaria (urticaria multiforme) can have targetoid patterns and be confused with EM (**Figure 151-11**).

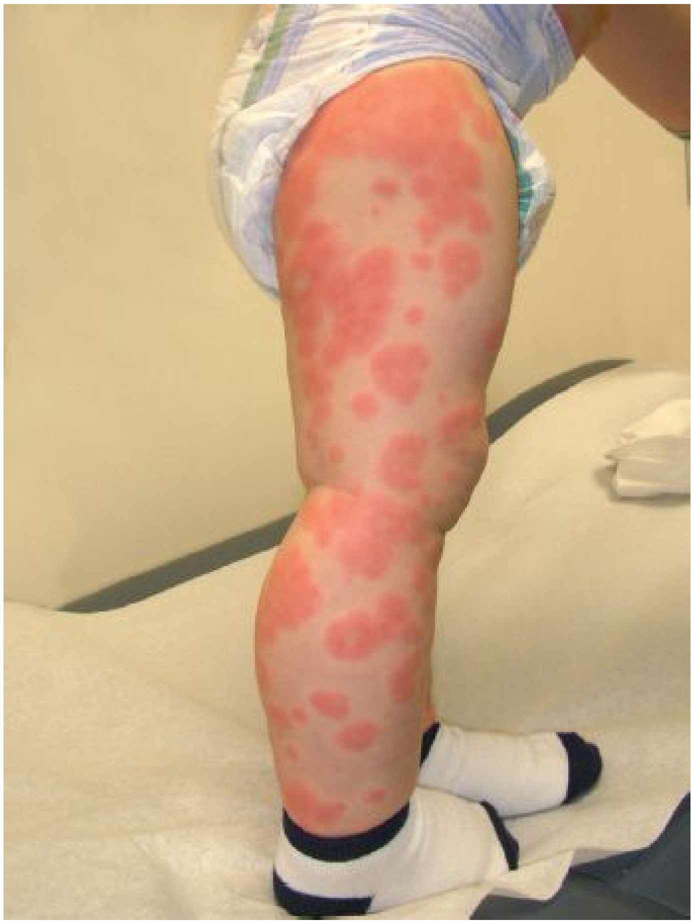

FIGURE 151-11 Well-appearing child with clinical pattern that could support a diagnosis of urticaria multiforme (UM) or erythema multiforme (EM). Some of the targetoid lesions have a dusky center (supporting EM) but there is no disruption of the epithelium and no palmar involvement (supporting UM). Clinically, if individual lesions last less than 24 hours, respond to antihistamines and they itch that supports UM. If they persist,

burn more than itch, involve palms and soles and don't respond to antihistamines it is more likely to be EM.

- Kawasaki disease (see Chapter 177, Kawasaki disease)—Fever persists at least 5 days and there must be at least four of the following features[10]:
  - Changes in extremities—*Acute*: erythema of palms, soles; edema of hands and feet; or *subacute*: periungual peeling of fingers and toes in weeks 2 and 3.
  - Polymorphous exanthem.
  - Bilateral bulbar conjunctival injection without exudate.
  - Changes in lips and oral cavity—Erythema, lips cracking, strawberry tongue (see Chapter 28, Scarlet Fever and Strawberry Tongue), diffuse injection of oral and pharyngeal mucosae.
  - Cervical lymphadenopathy (>1.5 cm diameter), usually unilateral.
- Cutaneous vasculitis (see Chapter 153, Vasculitis)—Also caused by a hypersensitivity reaction, lesions are palpable papules or purpura. Blisters, hives, and necrotic ulcers can occur on the skin. In Henoch-Schönlein Purpura (see Chapter 175, Henoch Schönlein Purpura), the most common cutaneous vasculitis of childhood, lesions are usually located on the legs, trunk, and buttocks.
- Staphylococcal scalded skin syndrome (see Chapter 105, Staphylococcal Scalded Skin Syndrome)—Rash may also follow a prodrome of malaise and fever but is macular, brightly erythematous, and initially involves the face, neck, axilla, and groin. Skin is markedly tender. Like SJS and TEN, large areas of the epidermis peel away. Unlike TEN, the site of the staphylococcal infection is usually extracutaneous (e.g., otitis media, pharyngitis) and not the skin lesions themselves (Chapter 99, Impetigo).

MANAGEMENT

EM

- The treatment is mainly supportive. Symptomatic relief may be provided with topical emollients, systemic antihistamines, and acetaminophen. These do not, however, alter the course of the illness.
- The use of corticosteroids has not been well studied, but is thought to prolong the course or increase the frequency of recurrences in HSV-associated cases.[7]
- Prophylactic acyclovir has been used to control recurrent HSV-associated EM with some success.[7]

SJS AND TEN

- Treatment again, is mainly supportive and may require intensive care or placement in a burn unit. Early diagnosis is imperative so that triggering agents can be discontinued.
- Oral lesions can be managed with mouthwashes and glycerin swabs.
- Skin lesions should be cleansed with saline or Burow solution (aluminum acetate in water).
- IV fluids should be given to replace insensible losses.
- Daily examinations for secondary infections should occur and systemic antibiotics should be started as needed.
- Consultation with an ophthalmologist is important because of the high risk of ocular sequelae.
- Pharmacologic therapy is widely debated in the literature and not well studied in children. Evidence suggests that intravenous immunoglobulin (IVIG) can help shorten the course and improve outcome if started early in the course of the disease in adults; however, there is an association between IVIG use and increased ocular complications in children.[3,11]
- Systemic corticosteroids have been the mainstay of treatment for SJS/TEN. Recent evidence, however, suggests there may be an increase in morbidity and mortality when used for TEN.[11]
- Although still debated, the use of these pharmacologic therapies (IVIG, corticosteroids or a combination of both) has been shown to alter severity

and improve overall outcome better than supportive therapy alone.[4]

- Other agents that have been tried with limited success include thalidomide, tumor necrosis factor (TNF)-a inhibitors, cyclophosphamide, cyclosporine, and plasmapheresis.

PREVENTION

Screening populations known to carry HLA alleles prior to starting medications with higher risks for SJS/TEN has been suggested by some researchers.[2]

PROGNOSIS

- EM usually resolves spontaneously within 1 to 2 weeks.
- Recurrence of EM is common, especially when preceded by HSV infection.
- Prognosis is poorer for patients with SJS and TEN if they are older, have a large percentage of body surface area involved, or have intestinal or pulmonary involvement.
- Mortality for SJS/TEN can be predicted based on the severity of illness score for TEN.[12] This scoring system, however, was based on adult literature and many of the criteria cannot be applied to children.
- Predictors for poor outcomes in children are unknown. Evidence suggests that approximately half of children with SJS/TEN develop long term sequelae, the most common involving the skin (hypopigmentation and scaring) and eye (uveitis, keratitis, corneal defects, and chronic conjunctivitis).[4]

FOLLOW-UP

- For uncomplicated cases, no specific follow-up is needed.
- For patients with EM major and any of the complications previously listed, follow-up should be arranged with the appropriate specialist.

PATIENT EDUCATION

- If an offending drug is found to be the cause, it should be discontinued immediately.
- Patients with HSV-associated EM should be made aware of the risk of recurrence.

152 ERYTHEMA NODOSUM

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 9-year-old boy presented to the office with a 2-day history of fever and sore throat. At the time of presentation, he and his mother noted some painful bumps on his lower legs, and denied trauma (**Figure 152-1**). No history of recent cough or change in bowel habits was reported. The patient had no chronic medical problems, took no medications and had no known drug allergies. On examination, his oropharynx revealed tonsillar erythema and exudates. Bilateral lower extremities were spotted with multiple slightly-raised, tender, erythematous nodules that varied in size from 2 to 6 cm. Rapid strep test was positive and he was diagnosed clinically with erythema nodosum (EN) secondary to group A b-hemolytic *Streptococcus*. He was treated with penicillin and NSAIDs. He experienced complete resolution of the EN within 6 weeks.

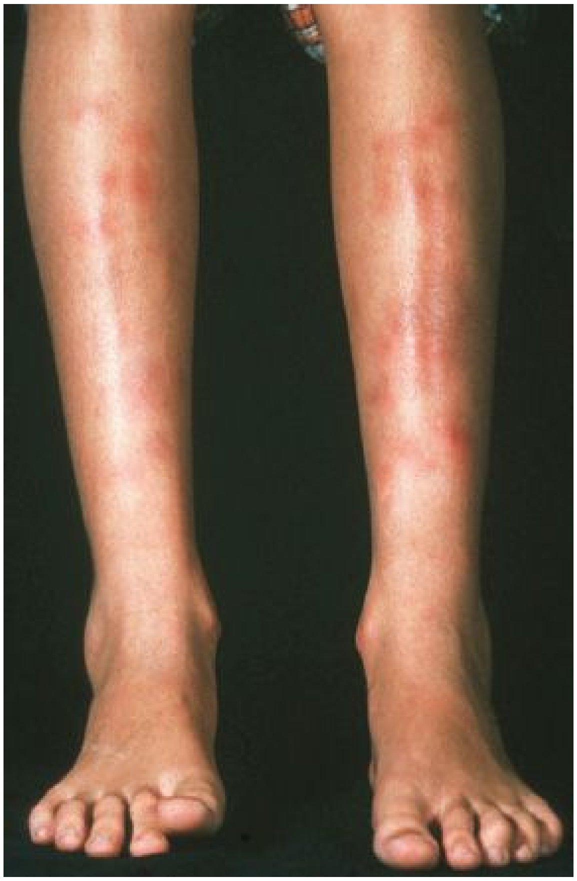

FIGURE 152-1 Erythema nodosum on the leg of a boy secondary to group A hemolytic Streptococcus. (Used with permission from Cleveland Clinic Children’s Hospital Photo Files.)

INTRODUCTION

EN is a common inflammatory panniculitis characterized by ill-defined, erythematous patches with underlying tender, subcutaneous nodules. It is a reactive process caused by chronic inflammatory states, infections, medications, malignancies, and unknown factors.

SYNONYMS

Lofgren syndrome (with hilar adenopathy).

EPIDEMIOLOGY

- Erythema nodosum occurs in approximately 1 to 5 per 100,000 persons.[1] It is the most frequent type of septal panniculitis (inflammation of the septa of fat lobules in the subcutaneous tissue).[2]
- In the childhood form, the sexes are equally represented. In adults EN tends to occur more often in women, with a male-to-female ratio of 1:4.5.[3]
- In 1 study, an overall incidence of 54 million people worldwide was cited in patients older than 14 years of age.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Most EN is idiopathic (**Figures 152-2**). Although the exact percentage is unknown, 1 study estimated that 55 percent of EN is idiopathic.[5] This may be influenced by the fact that EN may precede the underlying illness. The distribution of etiologic causes may be seasonal.[6] Identifiable causes can be infectious, reactive, pharmacologic, or neoplastic.

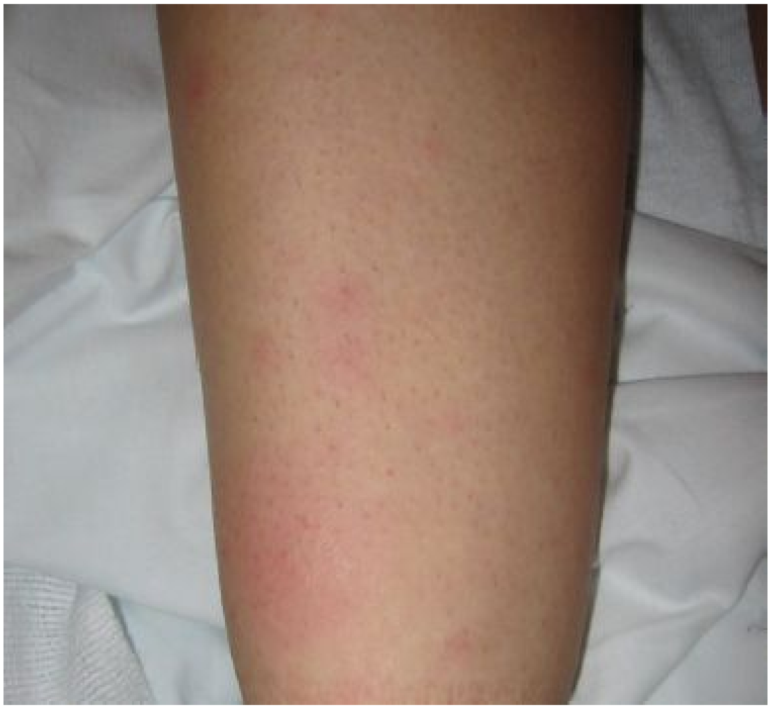

FIGURE 152-2 Erythema nodosum presenting with tender nodules on the pretibial area of an adolescent. (Used with permission Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 15-4, McGraw-Hill, 2009.)

- Histologic examination is most useful in defining EN. Defining characteristics of EN are a septal panniculitis without presence of vasculitis. That this pattern develops in certain areas of skin may be linked to local variations in temperature and efficient blood drainage.
- Septal panniculitis begins with polymorphonuclear cells infiltrating the septa of fat lobules in the subcutaneous tissue. It is thought that this is in response to existing immune complex deposition in these areas.[7] This inflammatory change consists of edema and hemorrhage which is responsible for the nodularity, warmth, and erythema.
- The infiltrate progresses from predominantly polymorphonuclear cells, to lymphocytes, and then histiocytes where fibrosis occurs around the lobules. There may be some necrosis though minimal as complete resolution without scarring is the typical course.
- The histopathologic hallmark of EN is the Miescher radial granuloma. This is a small, well-defined nodular aggregate of small histiocytes around

a central stellate or banana-shaped cleft.

RISK FACTORS

- Group A b-hemolytic streptococcal pharyngitis has been linked to EN (**Figure 152-1**). A retrospective study of 129 cases of EN over several decades reports 28 percent had streptococcal infection.[5]
- Nonstreptococcal upper respiratory tract infections may also play a role.[1]
- Historically, tuberculosis (TB) was a common underlying illness with EN, but TB is now a rare cause of EN in developed countries. There are reports of EN occurring in patients receiving the bacille Calmette-Guérin vaccination.[8]
- EN is less frequently associated with other infections agents, including *Yersinia* gastroenteritis, *Salmonella*, *Campylobacter*, toxoplasmosis, syphilis, amebiasis, giardiasis, brucellosis, leprosy, *Chlamydia*, *Mycoplasma*, *Brucella*, hepatitis B (infection and vaccine), Epstein-Barr virus, and *Bartonella*.[4,9,10]
- The literature reports that EN is seen in patients with inflammatory bowel diseases. It is usually prominent around the time of GI flare-ups, but may occur before a flare (**Figure 152-3**). Most sources report a greater association between Crohn disease and EN than between ulcerative colitis and EN. Other chronic diseases associated with EN include Behçet disease, sarcoidosis, and Sweet syndrome.[10,11]

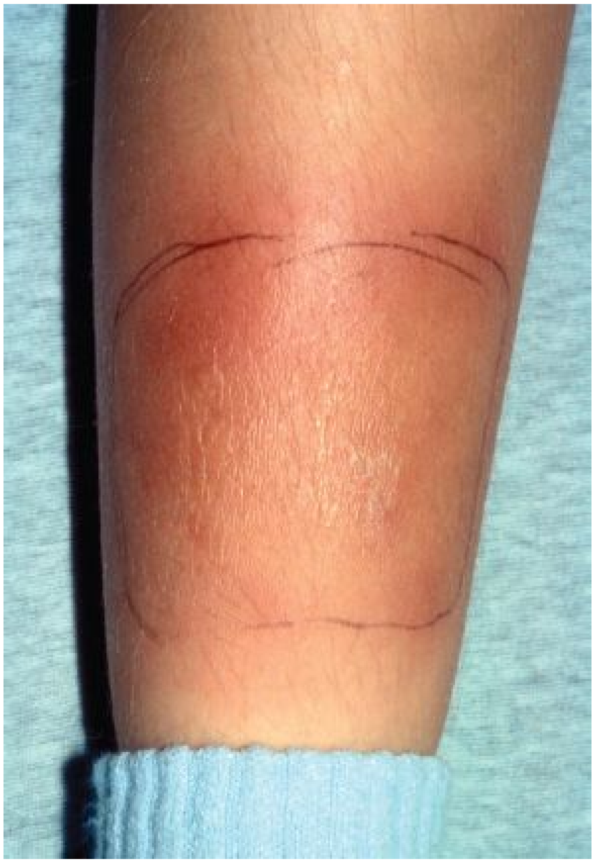

FIGURE 152-3 Erythema nodosum in a 14-year old who was diagnosed with inflammatory bowel disease. Erythema nodosum was the presenting manifestation in this child, prior to the development of gastrointestinal symptoms. (Used with permission from Camille Sabella, MD.)

- EN may be seen as a hypersensitivity reaction to a fungal infection, such as Histoplasmosis and Coccidioidomycosis.[12]
- Some debate exists over causality from pregnancy and oral contraceptives in the occurrence of EN.
- Besides oral contraceptives, medications implicated as causing EN are antibiotics including sulfonamides, penicillins, and bromides. However, the antibiotics may have been prescribed for the underlying infection that had caused EN.[10]
- Lymphomas, acute myelogenous leukemia, carcinoid tumor, and pancreatic carcinoma are associated with EN and should be considered in cases of persistent or recurrent EN.[10,13]

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis is usually clinical.
- The lesions of EN are deep-seated nodules that may be more easily palpated than visualized (**Figure 152-2**).
- Lesions are initially firm, round or oval, and are poorly demarcated.
- Lesions may be bright red, warm, and painful (**Figure 152-2**).
- Lesions number from 1 to more than 10.5 and vary in size from 1 to 15 cm.
- Over their course, the lesions begin to flatten and change to a purplish color before eventually taking on the yellowish hue of a bruise.
- A characteristic of EN is the complete resolution of lesions with no ulceration or scarring.
- EN is associated with systemic occurrence of fever, malaise, and polyarthralgia sometime near eruption.

TYPICAL DISTRIBUTION

- Lesions appear on the anterior/lateral aspect of both lower extremities (**Figures 152-1** and **152-2**).

LABORATORY TESTING

- Blood tests may help to identify the underlying cause. Typical tests include complete blood count, chemistries, liver function tests, and erythrocyte sedimentation rate. Erythrocyte sedimentation rate may be elevated.
- For suspected *Streptococcus* cases, rapid strep test or throat cultures are best during acute illness, whereas antistreptolysin O titers may be used in

the convalescent phase.[4]

- In sarcoid, angiotensin-converting enzyme levels may be helpful but are neither sensitive nor specific.[2] A chest x-ray and/or skin biopsy of a suspected sarcoid lesion can help make this diagnosis (see Chapter 150, Pediatric Sarcoidosis).
- Tuberculin skin test (PPD) or Interferon gamma release assay may be obtained when tuberculosis is a consideration.

BIOPSY

- The diagnosis of EN is mostly made on physical examination. When the diagnosis is uncertain, a biopsy that includes subcutaneous fat is performed. This can be a deep punch biopsy or a deep incisional biopsy sent for standard histology. If a biopsy is needed, this can be done by choosing a lesion not over a joint or vital structure and burying a 4-mm punch biopsy instrument to the hilt.

DIFFERENTIAL DIAGNOSIS

- Cellulitis should be considered and not missed. These patients tend to be sicker and have more fever and systemic symptoms. EN tends to appear in multiple locations while cellulitis is usually in one localized area (see Chapter 103, Cellulitis).
- Nodular cutaneous and subcutaneous sarcoid is skin-colored or violaceous without epidermal involvement. The lack of surface involvement makes this resemble EN. Subcutaneous sarcoid may be seen in advanced systemic sarcoidosis that can also be the cause of EN. Skin biopsy is the best method to distinguish between these two conditions. Either way, treatment is directed toward the sarcoidosis (see Chapter 150, Pediatric Sarcoidosis).
- Erythema induratum of Bazin is a lobular panniculitis that occurs on the posterior lower extremity of women with tendency of lesions to ulcerate

with residual scarring.[7] This condition is typically caused by TB and is more chronic in nature than EN.[2]

- Erythema nodosum leprosum may occur in patients with leprosy and probably represent an immune complex or hypersensitivity reaction (**Figure 152-4**). Erythema nodosum leprosum is typically seen as a type 2 reaction to standard leprosy therapy.[14] It is more common in multibacillary lepromatous leprosy. Although the lesions often look like standard EN, the lesions may also ulcerate.

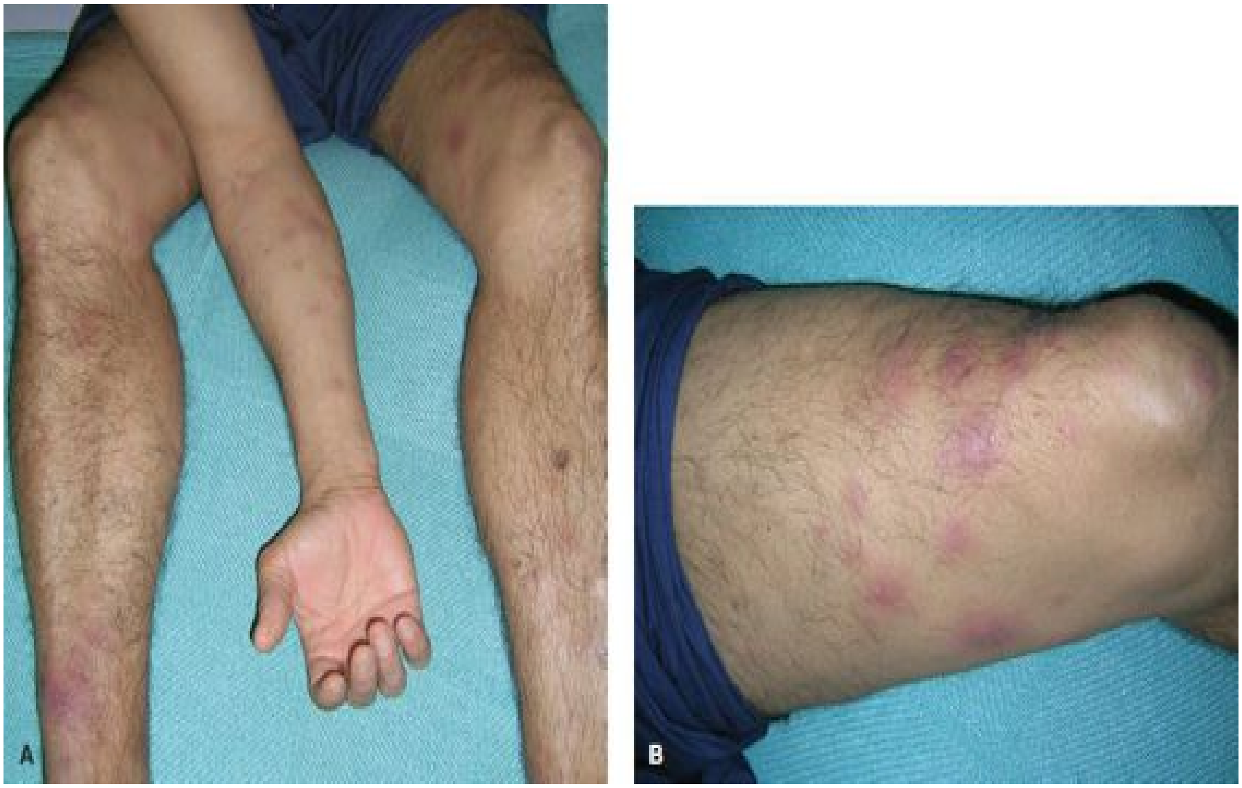

FIGURE 152-4 Erythema nodosum leprosum (ENL) in a patient who acquired multibacillary leprosy from handling and eating armadillos. His ENL started when he started the antibacterial treatment. A. Note the many subcutaneous nodules on his arms and legs. B. Close-up of the ENL lesions. (Used with permission from Richard P. Usatine, MD.)

- An infectious panniculitis should also be considered in the differential, especially in immunocompromised patients. These lesions are often asymmetric and the patient may be febrile. If suspected, a punch biopsy of a lesion should be sent for tissue culture (bacteria, fungus, and *Mycobacteria*).

MANAGEMENT

- Look for and treat the underlying cause. There is limited evidence to guide treatment unless an underlying cause is found.

NONPHARMACOLOGIC

- Cool, wet compresses, elevation of the involved extremities, bedrest, gradient support stockings, or pressure bandages may help alleviate the pain.[10] SOR Ⓒ

MEDICATIONS

- Treat the pain and discomfort of the nodules with NSAIDs and/or other analgesics.[15] SOR Ⓒ
- The value of oral prednisone is controversial and should be avoided unless it is being used to treat the underlying cause (such as sarcoidosis) and if underlying infection, risk of bacterial dissemination or sepsis, and malignancy have been excluded.[1] SOR Ⓒ
- Oral potassium iodide, which is contraindicated in pregnancy, led to resolution of EN in several small studies.[6,7] SOR Ⓑ
- Colchicine, hydroxychloroquine, and dapsone have been used as well.[2,7] SOR Ⓒ
- There are a few case reports of EN treated with penicillin, erythromycin, adalimumab, etanercept, infliximab, mycophenolate mofetil, cyclosporine, thalidomide, and extracorporeal monocyte granulocytapheresis.[1,16,17] SOR Ⓒ

- There is one case report of minocycline and tetracycline leading to EN improvement.[18] SOR C

PREVENTION

- Good hand washing and general health measures may prevent respiratory infections that may predispose to EN.

PROGNOSIS

- EN is usually self-limited or resolves with treatment of the underlying disorder.
- Patients may continue to develop nodules for a few weeks.
- The course depends on the etiology, but usually lasts only 6 weeks.
- Lesions completely resolve with no ulceration or scarring.
- Recurrences occur in 33 to 41 percent of cases, usually when the etiology is unknown.[17]

FOLLOW-UP

- Follow-up is needed to complete the work-up for an underlying cause and to make sure that the patient is responding to symptomatic treatment.

PATIENT EDUCATION

Reassure the patient that there is complete resolution in most cases within 3 to 6 weeks. Inform the patient that some EN outbreaks may persist for up to 12 weeks, and some cases are recurrent.[6]

153 VASCULITIS

E.J. Mayeaux, Jr., MD
Nathan Scott Martin, MD
Richard P. Usatine, MD

PATIENT STORY

A previously healthy 11-year-old girl presents to her pediatrician with a rash on her legs and knee pain. She admits to having abdominal pain the day before but her stomach is feeling better today. She denies fever, nausea, vomiting, and diarrhea. The right knee hurts sufficiently that she has been limping since she woke up. Upon exam the child is afebrile and does not appear to be in distress. She has an impressive rash on her legs with right knee swelling (**Figure 153-1**). The rash is petechial and purpuric and slightly palpable. The linear pattern running down the thigh matches the seams of her pants. A urinalysis performed in the office reveals blood in the urine but no protein. The pediatrician diagnoses Henoch Schonlein purpura (a type of vasculitis) and discusses the treatment plan with the girl and her mother.

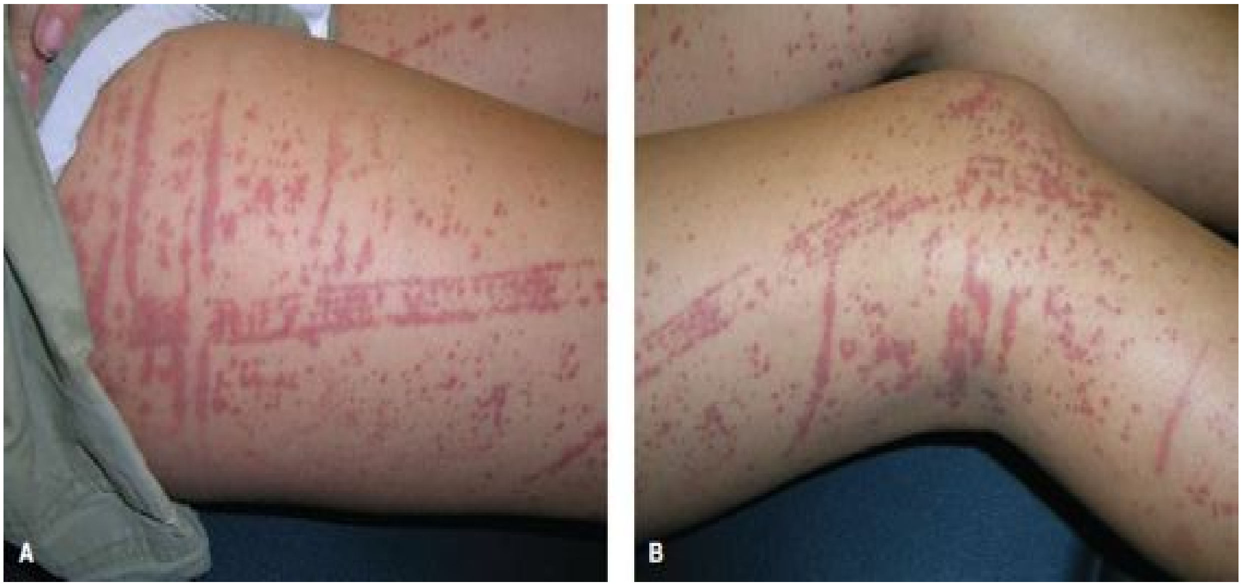

FIGURE 153-1 Henoch-Schonlein purpura in an 11-year-old girl. **A.** In addition to the palpable purpura, this patient also had abdominal pain. Note how the seam of her jeans is visible in the purpuric pattern. **B.** She also had knee pain and swelling and was walking with a limp. (Used with permission from Richard P. Usatine, MD.)

INTRODUCTION

Vasculitis refers to a group of disorders characterized by inflammation and damage in blood vessel walls. They may be limited to skin or may be a multisystem disorder. Cutaneous vasculitic diseases are classified according to the size (small versus medium to large vessel) and type of blood vessel involved (venule, arteriole, artery, or vein). Small and medium-size vessels are found in the dermis and deep reticular dermis, respectively. The clinical presentation varies with the intensity of the inflammation, and the size and type of blood vessel involved.[1] Hypersensitivity vasculitis (HSP) is also known as leukocytoclastic vasculitis. HSP is a type of leukocytoclastic vasculitis.

EPIDEMIOLOGY

- HSP (**Figures 153-1** to **153-3**) occurs mainly in children with an incidence of approximately 1 in 5000 children annually.[2] It is the most common vasculitis in the pediatric population.[3]

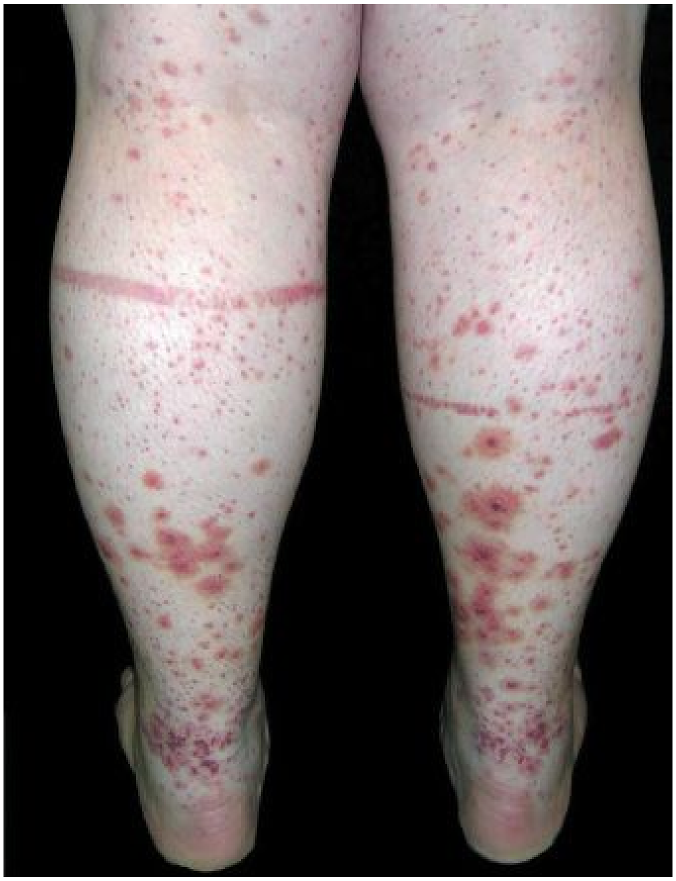

FIGURE 153-2 Henoch-Schonlein purpura presenting as palpable purpura on the lower extremity. The visible sock lines are from lesions that formed where the socks exerted pressure on the legs. (Used with permission from Richard P. Usatine, MD.)

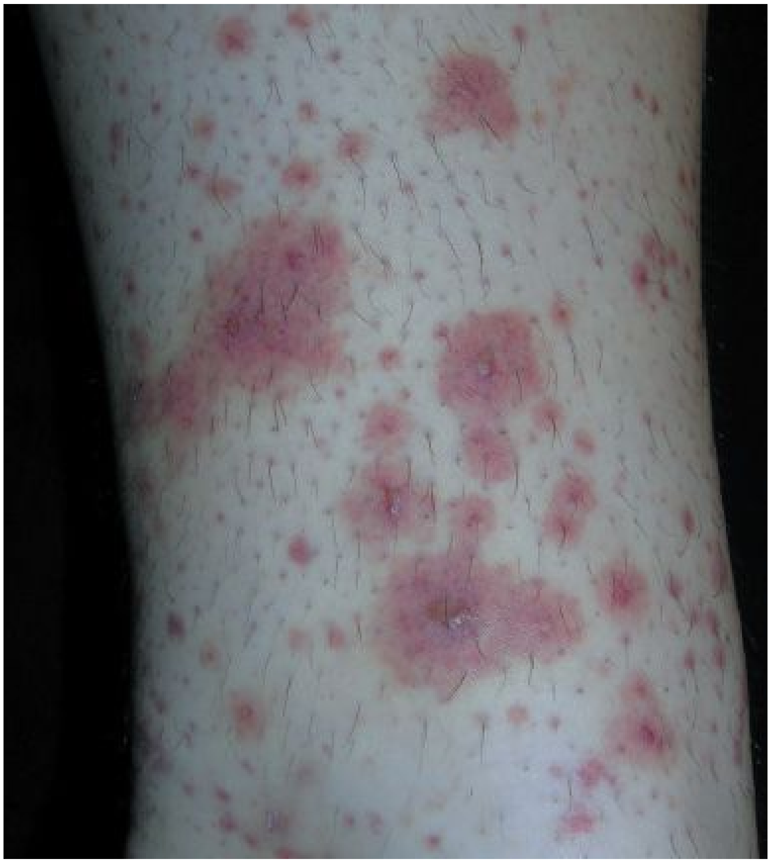

FIGURE 153-3 Close-up of palpable purpura from the patient in Figure 153-2. Some lesions look like target lesions but this is Henoch-Schonlein purpura and not erythema multiforme. (Used with permission from Richard P. Usatine, MD.)

- Although HSP affects all age groups, it is most common in children ages 2 to 6 years old.[3–5] The disease affects an estimated 70.3 per 100,000 children per year with a male to female ratio of 1.2:1.[3,4]
- White children have a much higher incidence of HSP compared to black children.[3,4]
- Although the incidence in children has been reported to be about 100 times greater than adults, HSP is typically less severe in the pediatric population.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

- HSP is usually benign and self-limiting, and tends to occur in the springtime. It results from immunoglobulin (Ig) A-containing immune complexes in blood vessel walls in the skin, kidney, and GI tract. A streptococcal or viral upper respiratory infection often precedes the disease by 1 to 3 weeks. Prodromal symptoms include anorexia and fever. Most children with HSP also have joint pain and swelling with the knees and ankles being most commonly involved (**Figure 153-1**). In half of the cases there are recurrences, typically in the first 3 months. Recurrences are more common in patients with nephritis and are milder than the original episode. To make the diagnosis of HSP, the patient should have palpable purpura or petechiae more in lower limbs and one or more of the following:[7,8]
- Bowel angina (pain).
- Arthritis or arthralgia.
- GI bleeding.
- Hematuria (renal involvement).
- Leukocytoclastic vasculitis (**Figures 153-4** and **153-5**) is the most commonly seen form of small vessel vasculitis. Prodromal symptoms include fever, malaise, myalgia, and joint pain. The palpable purpura begins as asymptomatic localized areas of cutaneous hemorrhage that become palpable. Few or many discrete lesions are most commonly seen on the lower extremities but may occur on any dependent area. Small lesions itch and are painful, but nodules, ulcers, and bullae may be very painful. Lesions appear in crops, last for 1 to 4 weeks, and may heal with residual scarring and hyperpigmentation. Patients may experience 1 episode (drug reaction or viral infection) or multiple episodes (RA or SLE). The disease is usually self-limited and confined to the skin. To make the diagnosis, look for presence of 3 or more of the following:[9]

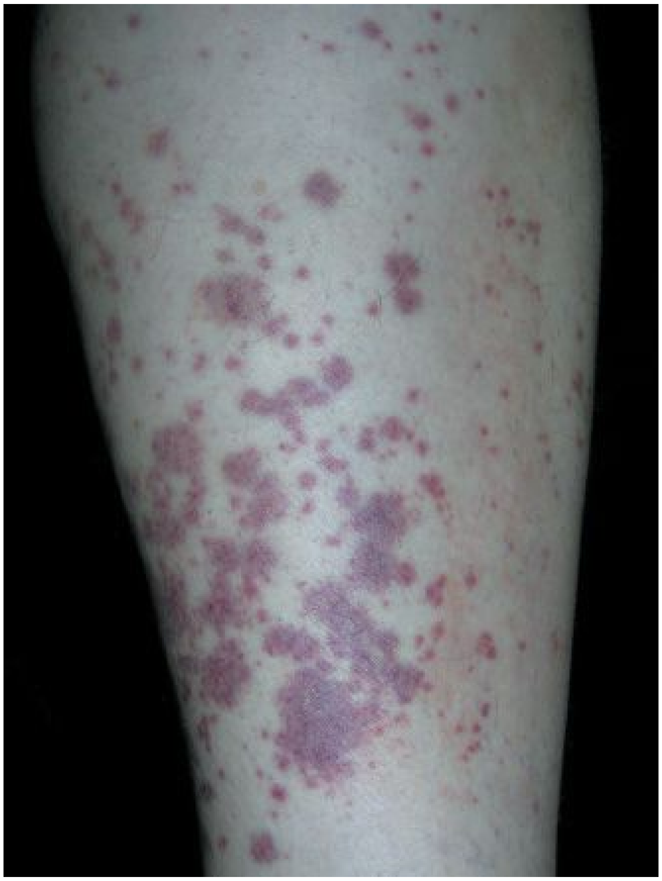

FIGURE 153-4 Leukocytoclastic vasculitis on the leg of a young woman. (Used with permission from Richard P. Usatine, MD.)

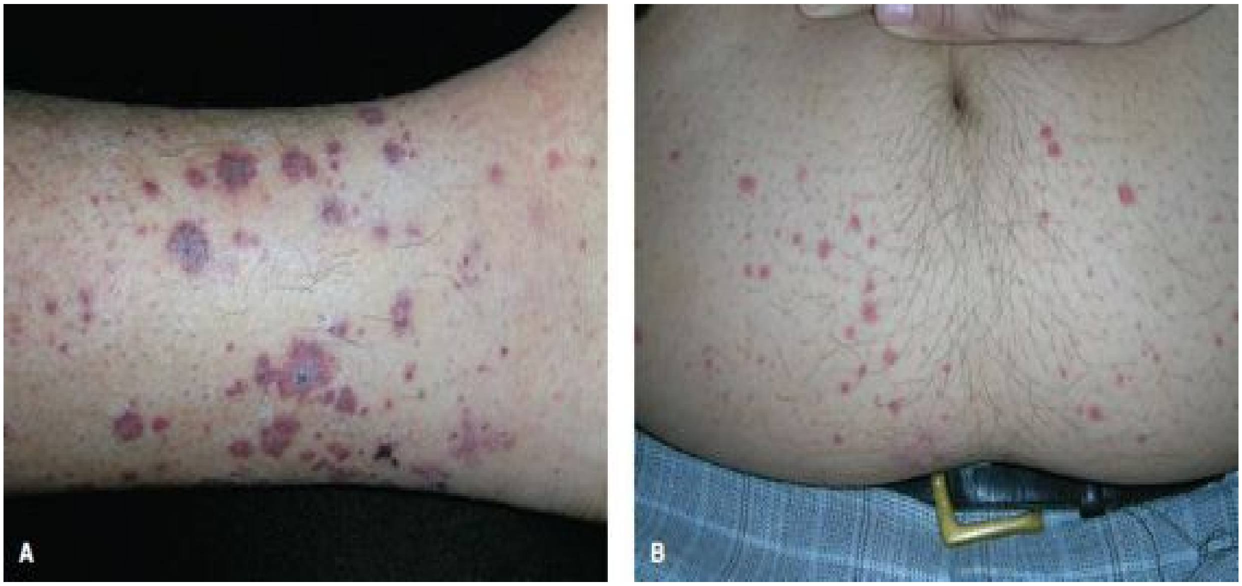

FIGURE 153-5 Leukocytoclastic vasculitis in a young man. **A.** Palpable purpura on the lower leg. **B.** Involvement of the lower abdomen. (Used with permission from Richard P. Usatine, MD.)

- Age older than 16 years (not for HSP).
- Use of a possible offending drug in temporal relation to the symptoms.
- Palpable purpura.
- Maculopapular rash.
- Biopsy of a skin lesion showing neutrophils around an arteriole or venule. Systemic manifestations of leukocytoclastic vasculitis may include kidney disease, heart, nervous system, GI tract, lungs, and joint involvement.
- Vasculitis is defined as inflammation of the blood vessel wall. The mechanisms of vascular damage consist of a humoral response, immune complex deposition, or cell-mediated T-lymphocyte response with granuloma formation.[10]
- Vasculitis induced injury to blood vessels may lead to increased vascular permeability, vessel weakening, aneurysm formation, hemorrhage, intimal proliferation, and thrombosis that result in obstruction and local ischemia.[10]
- Small-vessel vasculitis is initiated by hypersensitivity to various antigens (drugs, chemicals, microorganisms, and endogenous antigens), with formation of circulating immune complexes that are deposited in walls of postcapillary venules. The vessel-bound immune complexes activate complement, which attracts polymorphonuclear leukocytes. They damage the walls of small veins by release of lysosomal enzymes. This causes vessel necrosis and local hemorrhage.
- Small-vessel vasculitis most commonly affects the skin and rarely causes serious internal organ dysfunction, except when the kidney is involved. Small-vessel vasculitis is associated with leukocytoclastic vasculitis, HSP, essential mixed cryoglobulinemia, connective tissue diseases or malignancies, serum sickness, and serum sickness-like reactions, chronic urticaria, and acute hepatitis B or C infection.
- Hypersensitivity (leukocytoclastic) vasculitis causes acute inflammation and necrosis of venules in the dermis. The term *leukocytoclastic vasculitis*

describes the histologic pattern produced when leukocytes fragment.

- Some patients with systemic lupus erythematosus (SLE; **Figure 153-6**) and other connective tissue disorders develop an associated necrotizing vasculitis. It most frequently involves the small muscular arteries, arterioles, and venules. The blood vessels can become blocked leading to tissue necrosis (**Figure 153-6**). The skin and internal organs may be involved.

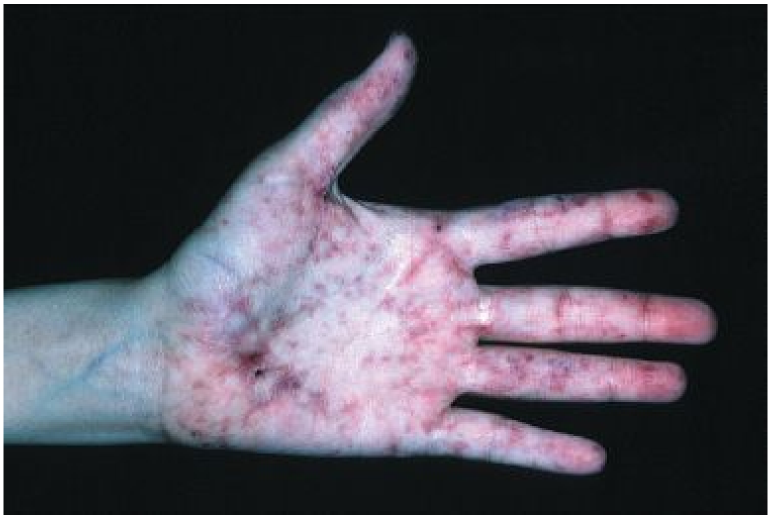

FIGURE 153-6 Necrotizing vasculitis in a young Asian woman with systemic lupus erythematosus. The circulation to the fingertips was compromised and the woman was treated with high-dose intravenous steroids and intravenous immunoglobulins to prevent tissue loss. (Used with permission from Richard P. Usatine, MD.)

RISK FACTORS

- Viral infections.
- Autoimmune disorders.
- Drug hypersensitivity.
- Cocaine (adulterated with levamisole; **Figure 153-7**).

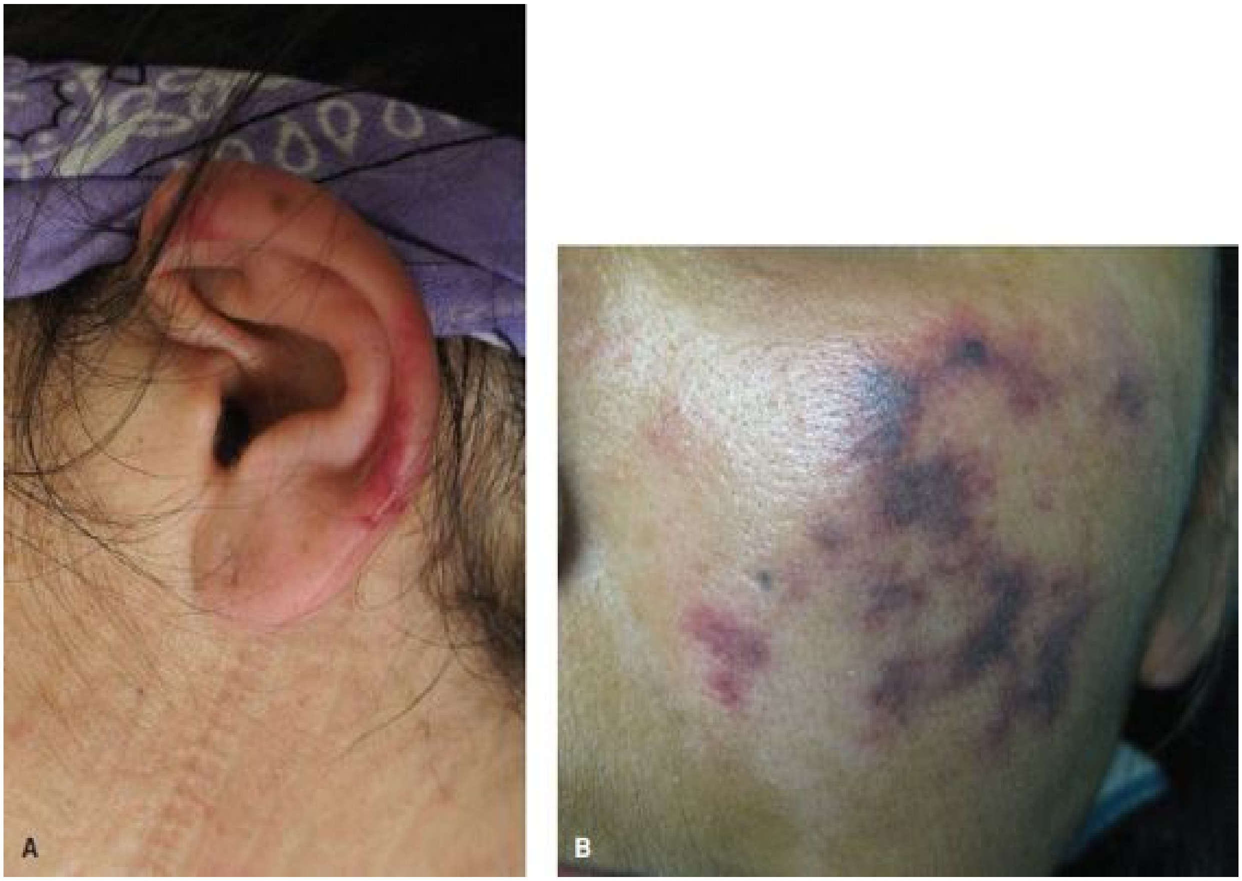

FIGURE 153-7 **A.** Cutaneous vasculitis of the ear caused by levamisole-adulterated cocaine. (Used with permission from Jonathan Karnes, MD.) **B.** Cutaneous vasculitis in a retiform (net-like) pattern caused by the use of levamisole-adulterated cocaine. This is called *retiform purpura. (Used with permission from John M. Martin IV, MD.)*

DIAGNOSIS

- Initially, determining the extent of visceral organ involvement is more important than identifying the type of vasculitis, so that organs at risk of damage are not jeopardized by delayed or inadequate treatment. It is critical to distinguish vasculitis occurring as a primary autoimmune disorder from vasculitis secondary to infection, drugs, malignancy, or connective tissue disease such as SLE.[10]

CLINICAL FEATURES

- The clinical features of HSP include nonthrombocytopenic palpable purpura mainly on the lower extremities and buttocks (**Figures 153-1** to **153-3**), GI symptoms, arthralgia, and nephritis.

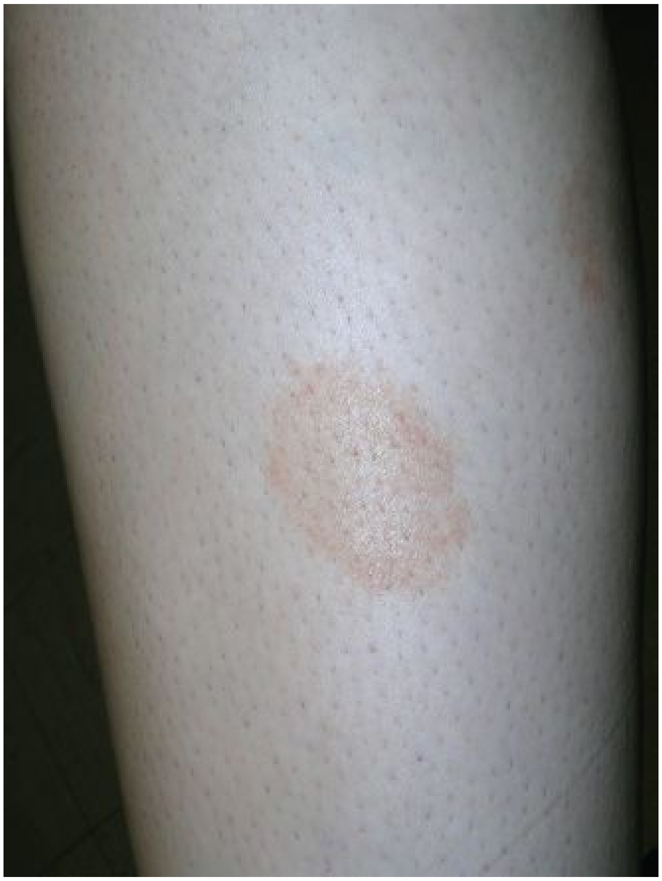

FIGURE 153-8 Lichen aureus on the leg of a 16-year-old girl. The light pink color is typical and it often is somewhat round or annular. Dermoscopy or magnification shows pinpoint capillaries with light hemosiderin deposits. (*Used with permission from Richard P. Usatine, MD*.)

- Small-vessel vasculitis is characterized by necrotizing inflammation of small blood vessels, and may be identified by the finding of “palpable purpura.” The lower extremities typically demonstrate “palpable purpura,” varying in size from a few millimeters to several centimeters (**Figures 153-1** to **153-5**). In its early stages, leukocytoclastic vasculitis may not be palpable.

TYPICAL DISTRIBUTION

- Cutaneous vasculitis is found most commonly on the legs, but may be seen on the hands and abdomen (**Figures 153-1 to 153-5**).

LABORATORY TESTING

- Laboratory evaluation is geared to finding the antigenic source of the immunologic reaction. Consider throat culture, antistreptolysin-*O*titer, erythrocyte sedimentation rate, platelets, complete blood count (CBC), serum creatinine, urinalysis, antinuclear antibody, serum protein electrophoresis, circulating immune complexes, hepatitis B surface antigen, hepatitis C antibody, cryoglobulins, and rheumatoid factor. The erythrocyte sedimentation rate is almost always elevated during active vasculitis. Immunofluorescent studies are best done within the first 24 hours after a lesion forms. The most common immunoreactants present in and around blood vessels are IgM, C3, and fibrin. The presence of IgA in blood vessels of a child with vasculitis suggests the diagnosis of HSP.
- Basic laboratory analysis to assess the degree and types of organs affected should include serum creatinine, creatinine kinase, liver function studies, hepatitis serologies, urinalysis, and possibly chest x-ray and ECG.

BIOPSY

- The clinical presentation is so characteristic that a biopsy is generally unnecessary. In doubtful cases, a punch biopsy should be taken from an early active (nonulcerated) lesion or, if necessary, from the edge of an ulcer.
- Renal biopsy is not usually required but may be considered In patients with nephritic/nephrotic presentation, raised creatinine, hypertension, oliguria, heavy proteinuria (urine albumin/urine creatinine Ratio persistently >100 mg/mmol), persistent proteinuria (>4 weeks), or GFR <80.[11]

DIFFERENTIAL DIAGNOSIS

- Lichen aureus is a localized pigmented purpuric dermatosis seen in younger persons that may occur on the leg or in other parts of the body (**Figures 153-8** to **153-10**). The color may be yellow brown or golden brown.

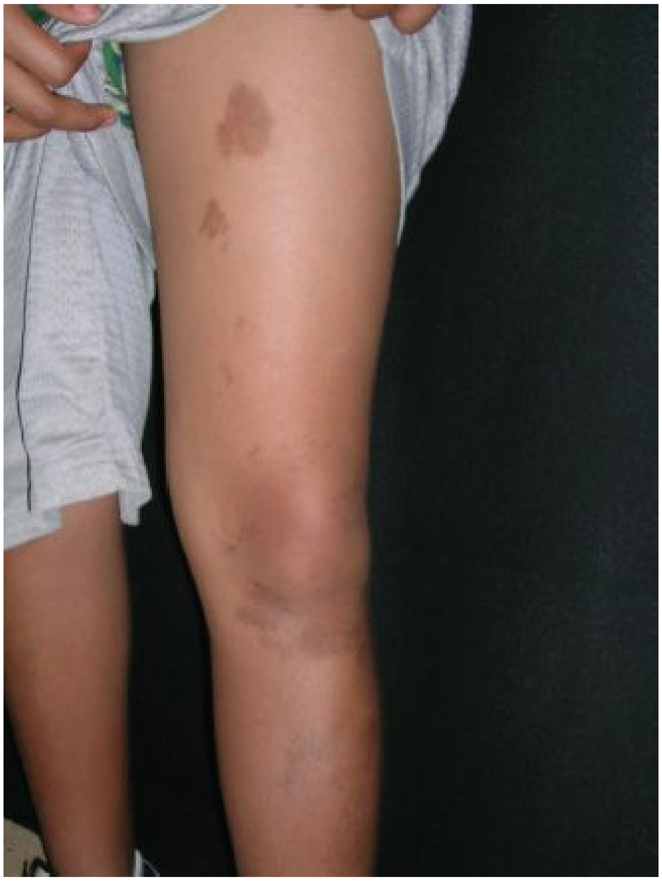

FIGURE 153-9 Lichen aureus (pigmented purpuric dermatosis) on the leg of an 8-year-old boy showing hemosiderin deposits and a cayenne pepper capillaritis. Note that this condition is hyperpigmented and not palpable. (Used with permission from Richard P. Usatine, MD.)

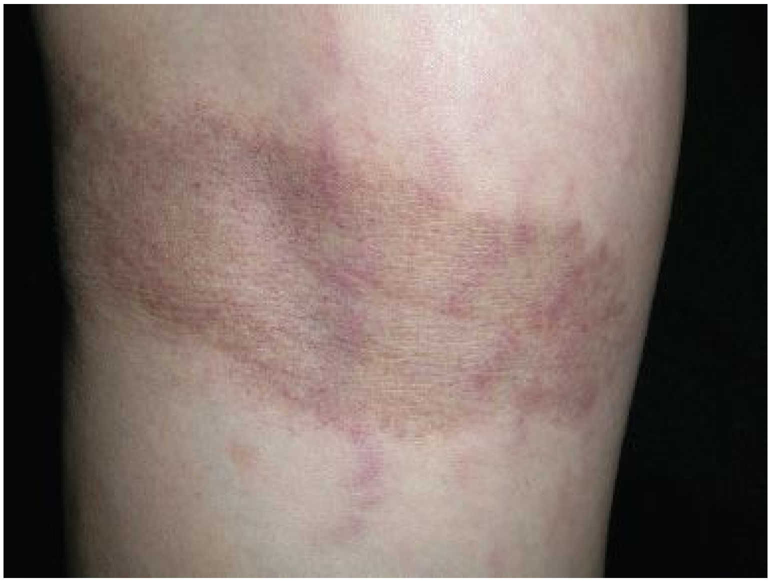

FIGURE 153-10 Lichen aureus (pigmented purpuric dermatosis) of the popliteal fossa in a teenage girl showing hemosiderin deposits and a cayenne pepper capillaritis. Note that this condition is not palpable but the cosmetic appearance is distressing to this teen. (Used with permission from Richard P. Usatine, MD.)

- There is also a pigmented purpuric dermatosis of the Majocchi type that has an annular appearance with prominent elevated erythematous borders that may have telangiectasias (**Figure 153-11**). A dermatoscope can help to visualize the red or pink dots that represent inflamed capillaries in these conditions.

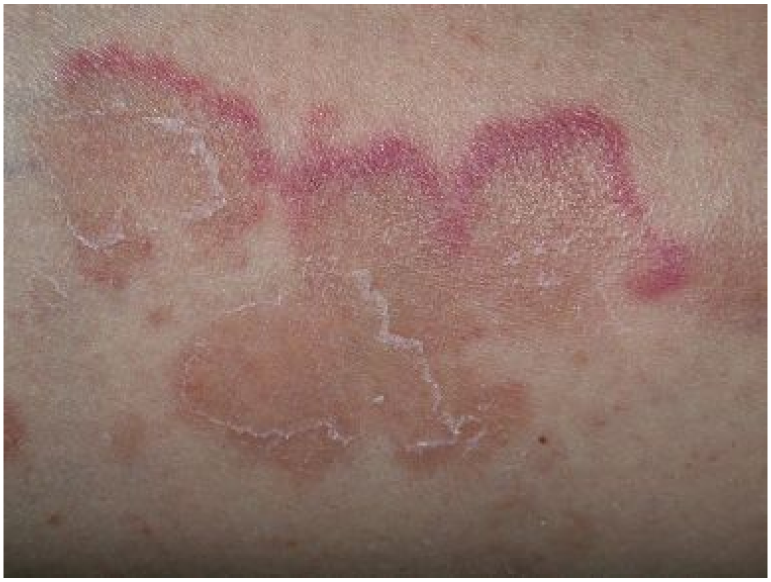

FIGURE 153-11 Pigmented purpuric dermatosis of the Majocchi type. Note the annular appearance and the prominent elevated erythematous borders. (Used with permission from Suraj Reddy, MD.)

- Meningococcemia that presents with purpura in severely ill patients with or without central nervous system symptoms (**Figure 153-12**).

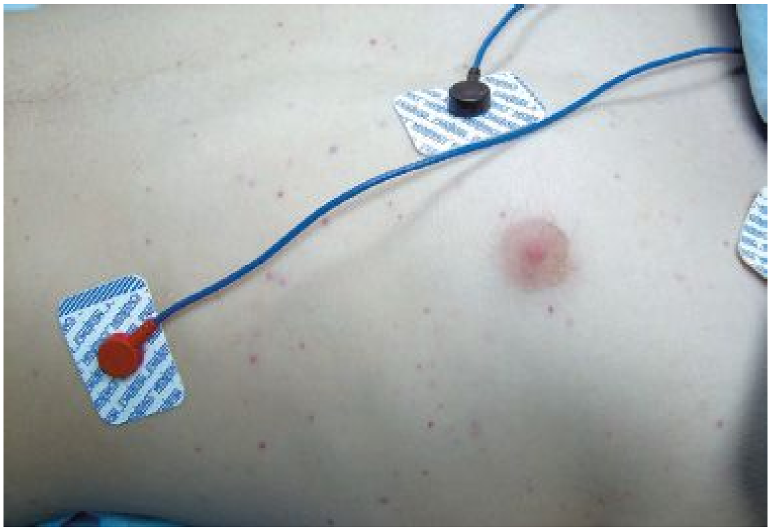

FIGURE 153-12 Petechiae of meningococcemia on the trunk of a hospitalized adolescent. (Used with permission from Tom Moore, MD.)

- Rocky Mountain spotted fever is a rickettsial infection that presents with pink to bright red, discrete 1- to 5-mm macules that blanch with pressure and may be pruritic. The lesions start distally and spread to the soles and palms (see **Figure 175-5**).
- Stevens-Johnson syndrome and toxic epidermal necrolysis (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Idiopathic thrombocytopenia purpura can be easily distinguished from vasculitis by measuring the platelet count. Also, the purpura is usually not palpable and the petechiae can be scattered all over the body (**Figure 153-13**).

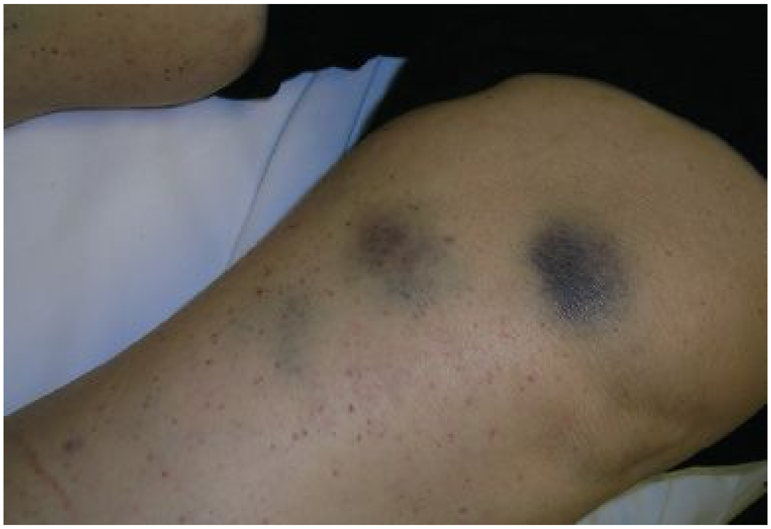

FIGURE 153-13 Petechiae and purpura in a patient with idiopathic thrombocytopenic purpura and a platelet count of 3000. Note that this purpura is not palpable. (Used with permission from Richard P. Usatine, M

- Wegener granulomatosis is an unusual multisystem disease characterized by necrotizing granulomatous inflammation and vasculitis of the respiratory tract, kidneys, and skin.
- Churg-Strauss syndrome (allergic granulomatosis) that presents with a systemic vasculitis associated with asthma, transient pulmonary infiltrates, and hypereosinophilia.
- Cutaneous manifestations of cholesterol embolism, which are leg pain, livedo reticularis (blue-red mottling of the skin in a net-like pattern), and/or blue toes in the presence of good peripheral pulses.

MANAGEMENT

NONPHARMACOLOGIC

- The offending antigen should be identified and removed whenever possible. With a mild hypersensitivity vasculitis is due to a drug, discontinuing the offending drug may be all the treatment that is necessary. SOR Ⓒ

MEDICATIONS

- In HSP and prolonged hypersensitivity vasculitis, treatment with nonsteroidal antiinflammatory drugs is usually preferred. Treatment with corticosteroids may be of more benefit in patients with more severe disease such as more pronounced abdominal pain and renal involvement.[14] SOR Ⓑ Adding cyclophosphamide to the steroids may also be effective. SOR Ⓒ Azathioprine also may be used.[15]
- An antihistamine might be used for itching. SOR Ⓒ
- Oral prednisone is used to treat visceral involvement and more severe cases of vasculitis of the skin. Short courses of prednisone (1 mg/kg/day) are effective and should be tapered slowly over 2 weeks.[12,13] SOR Ⓑ
- Colchicine and dapsone inhibit neutrophil chemotaxis and have been used in adults but data is limited on their effectiveness in pediatric patients. SOR Ⓑ
- There may be a role for the use of Ace inhibitors in patients with proteinuria related to vasculitis but data is still inconclusive on long-term benefit to preserving renal function.[17]

PROGNOSIS

- In leukocytoclastic (hypersensitivity) vasculitis, the cutaneous lesions usually resolve without sequelae. Visceral involvement (such as kidney and lung) most commonly occurs in HSP, cryoglobulinemia and vasculitis associated with SLE.[16] Extensive internal organ involvement should prompt an investigation for coexistent medium-size vessel disease and referral to a rheumatologist.

FOLLOW-UP

- Relapses may occur, especially when the precipitating factor is an autoimmune disease. Regular monitoring is necessary.

PATIENT EDUCATION

- Reassure patients and parents that most cases of acute cutaneous vasculitis resolve spontaneously.

154 CUTANEOUS DRUG REACTIONS

Richard P. Usatine, MD
Anna Allred, MD
Mindy A. Smith, MD, MS

PATIENT STORY

A young college student was seen for fatigue and an upper respiratory infection and started on amoxicillin for a sore throat. Six days later, she broke out with a red rash all over her body (**Figure 154-1**). She went to see her family physician back home with the rash and lymphadenopathy. A monospot was drawn and found to be positive. This morbilliform rash (like measles) is typical of an amoxicillin drug eruption in a person with mononucleosis. Amoxicillin was stopped, and diphenhydramine was used for the itching.

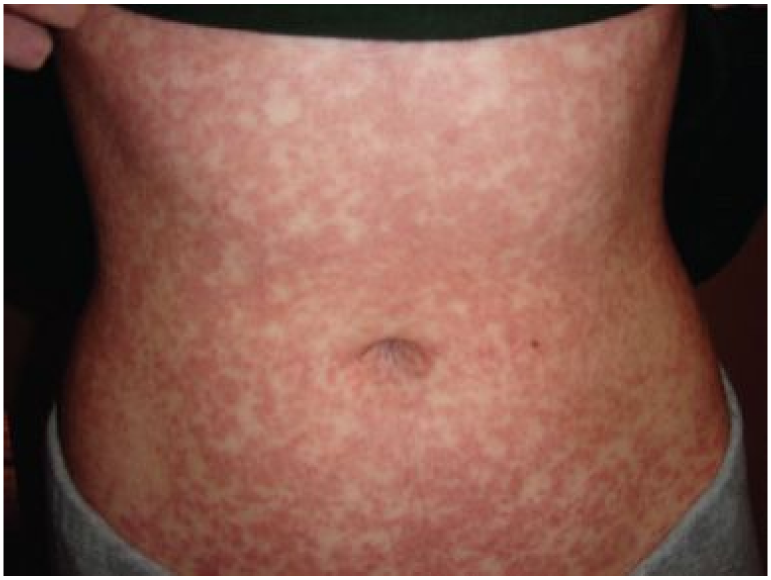

FIGURE 154-1 Amoxicillin rash in a teenage girl with mononucleosis. This is a morbilliform eruption. (Used with permission from Richard P. Usatine, MD.)

INTRODUCTION

Cutaneous drug reactions are skin manifestations of drug hypersensitivity. Drug hypersensitivity may be defined as symptoms or signs initiated by a drug exposure at a dose normally tolerated by non-hypersensitive persons.[1] Drug-induced adverse reactions are often classified as type A and type B. Type A reactions are common (80%) predictable side effects caused by a pharmacologic action of the drug, and type B reactions are uncommon (10% to 15%) and considered idiosyncratic, a result of individual predisposition (e.g., an enzyme defect).[2] Cutaneous drug reactions range from mild skin eruptions (e.g., exanthem, urticaria, and angioedema) to severe cutaneous drug reactions (SCARs), the latter category including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), and drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome.[3]

SYNONYMS

Cutaneous adverse reactions, drug reactions, medication reactions, adverse effects to drugs, or hypersensitivity reactions. DRESS syndrome is also called drug-induced hypersensitivity syndrome.

EPIDEMIOLOGY

- Cutaneous drug reactions are common complications of drug therapy occurring in 2 to 3 percent of hospitalized patients.[4]

- One study found that 45 percent of all adverse drug reactions were manifested in the skin.[4]
- Approximately 1 in 6 adverse drug reactions represents drug hypersensitivity, and are allergic or non–immune-mediated (pseudoallergic) reactions.[2]
- Maculopapular eruptions, also known as exanthematous drug eruptions, are the most frequent of all cutaneous drug reactions, representing 95 percent of skin reactions.[5] They are often confused with viral exanthems. This occurs most commonly with b-lactams such as amoxicillin, but also with barbiturates, gentamicin, isoniazid, phenytoin, sulfonamides, thiazides, and trimethoprim-sulfamethoxazole (**Figures 154-1** and **154-2**).

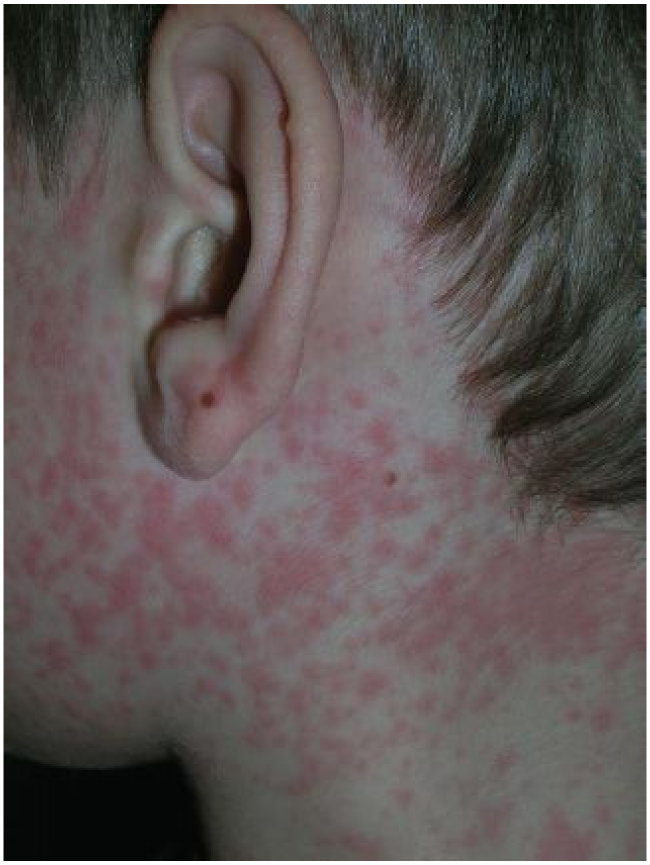

FIGURE 154-2 Maculopapular drug eruption in a 5-year-old boy with an upper respiratory infection started on amoxicillin for a questionable otitis media. Four days later he broke out with a red rash all over his face and body. This morbilliform rash (like measles) is typical of an amoxicillin drug eruption. (Used with permission from Robert Tunks, MD.)

- Urticarial drug reactions are the second most common skin eruptions, representing approximately 5 percent of cutaneous drug reactions.[5] This reaction can result from any drug but commonly occurs with aspirin, penicillin, sulfa, angiotensin-converting enzyme (ACE) inhibitors, aminoglycosides, and blood products. Urticaria results from immunoglobulin (Ig) E reactions within minutes to hours of drug administration (**Figures 154-3** and **154-4**).

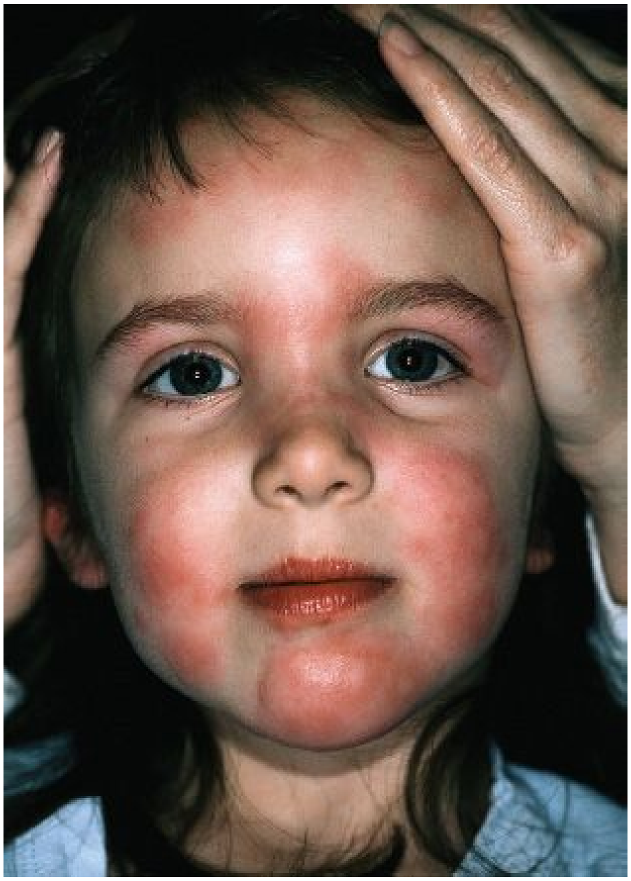

FIGURE 154-3 Urticarial drug eruption secondary to trimethoprim/sulfamethoxazole. (Used with permission from Richard P. Usatine, MD.)

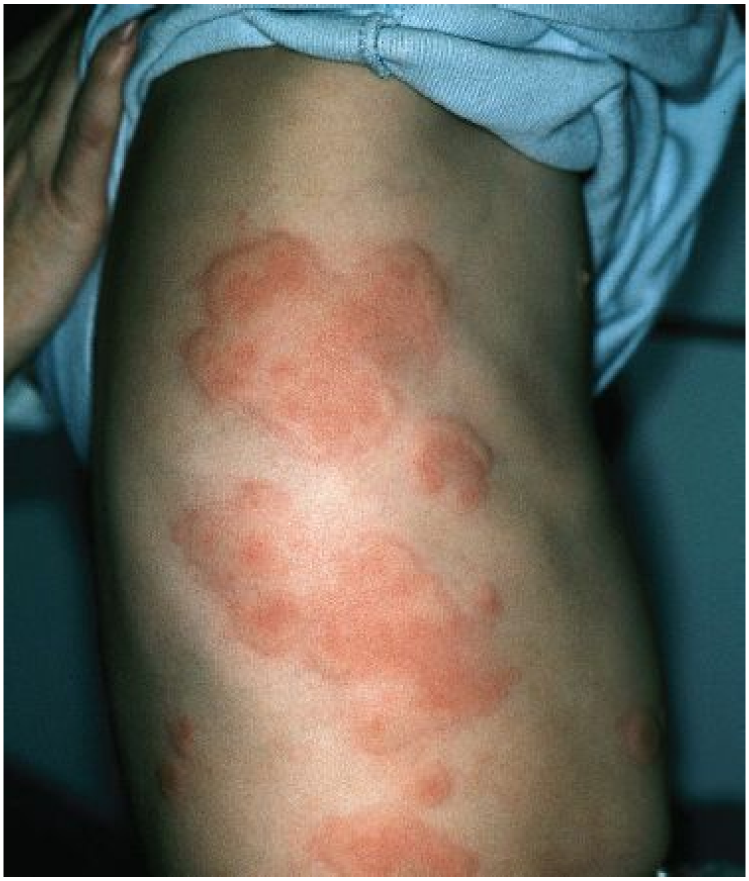

FIGURE 154-4 Giant urticarial eruption (urticaria multiforme) in the patient in Figure 154-3 with drug reaction to sulfa. (Used with permission from Richard P. Usatine, MD.)

- Drug-induced hyperpigmentation occurs with antiarrhythmics (amiodarone), antibiotics (minocycline), NSAIDs, and chemotherapy agents (Adriamycin).
- Fixed drug eruptions (FDEs) can occur with many medications, including phenolphthalein, doxycycline, ibuprofen, sulfonamide antibiotics, and barbiturates (**Figures 154-5** to **154-8**). FDEs are more commonly observed in males.

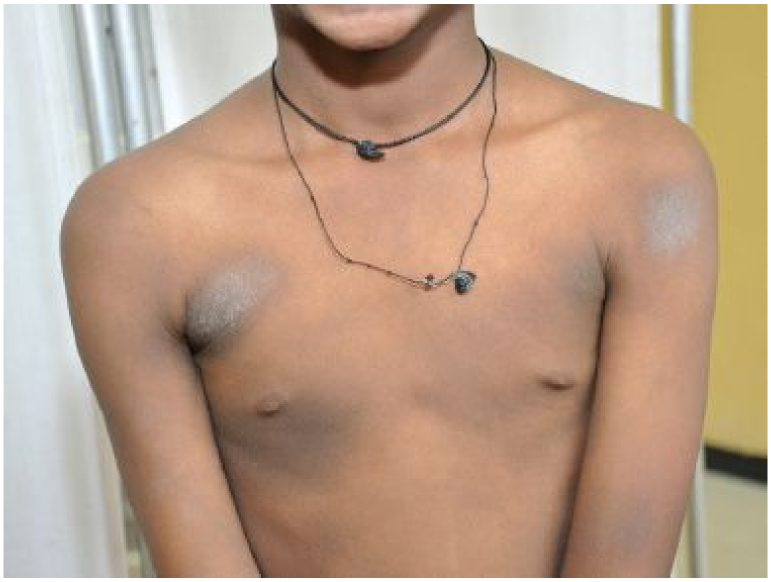

FIGURE 154-5 Fixed drug eruption to trimethoprim/sulfamethoxazole with hyperpigmented plaques in a 10-year-old boy. (Used with permission from Richard P. Usatine, MD.)

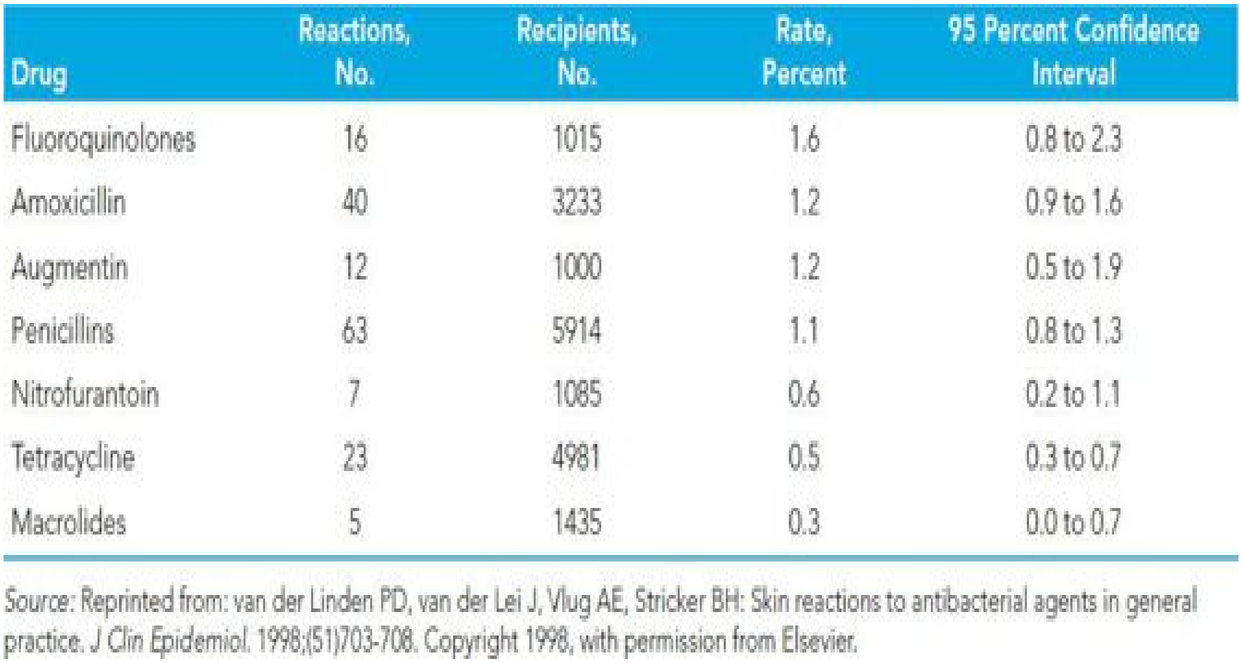
- Erythema multiforme (EM) and SJS can occur secondary to drug reactions (**Figure 154-9**). Incidence of SJS is estimated at 1.2 per 6 million people.[3]
- DRESS (drug reaction with eosinophilia and systemic symptoms) syndrome is also a severe adverse drug-induced reaction characterized by eosinophilia with liver involvement, fever, and lymphadenopathy. In a case series (N = 172), 44 drugs were associated with DRESS.[6] DRESS syndrome is estimated to occur in 1 per 1000 to 1 per 10,000 exposures to antiepileptic drugs.[7]
- **Tables 154-1** lists the most common medications associated with allergic cutaneous drug reactions and the rates of reactions found.[8]
- **Table 154-2** lists the frequency of various classes of drugs associated with an eruption (in cases with <4 suspected drugs) based on a 5-year study.[9]

TABLE 154-1 Allergic Cutaneous Reactions to Drugs Received by at Least 1000 Patients



Drug	Reactions, No.	Recipients, No.	Rate, Percent	95 Percent Confidence Interval
Fluoroquinolones	16	1015	1.6	0.8 to 2.3
Amoxicillin	40	3233	1.2	0.9 to 1.6
Augmentin	12	1000	1.2	0.5 to 1.9
Penicillins	63	5914	1.1	0.8 to 1.3
Nitrofurantoin	7	1085	0.6	0.2 to 1.1
Tetracycline	23	4981	0.5	0.3 to 0.7
Macrolides	5	1435	0.3	0.0 to 0.7

ETIO

- Two mechanisms are responsible for cutaneous drug reactions—Immunologic, including all four types of hypersensitivity reactions, and, more commonly, nonimmunologic (pseudoallergic). Although the precise mechanism of immune stimulation is unknown, it may be triggered by drug-protein (hapten-carrier) complexes or through direct interaction with immune receptors (p-i concept).[2] The mechanism for pseudoallergic reactions is pathogenetically poorly defined.[2]

- Hypersensitivity to NSAIDs is a nonimmunologic reaction that can be immediate (within hours after exposure) or delayed (more than 24 hours after administration).[1]
- SJS/TEN is most commonly associated with penicillins and sulfonamide antibiotics but can also occur with anticonvulsants, NSAIDs, allopurinol, and corticosteroids. It is hypothesized that a specific human leukocyte antigen (HLA)-B molecule may present the drug or its metabolites to naïve CD8 cells resulting in clonal expansion of CD8 cytotoxic lymphocytes and induction of cytotoxic effector responses, resulting in apoptosis of keratinocytes.[10] This pathway is not likely to be specific to SJS.

RISK FACTORS

- Drug hypersensitivity reactions increase with the drug dose, duration, route of administration (topical > subcutaneous > intramuscular > oral > intravenous),[11] immune activation of the individual, and immunogenetic predisposition; they are also more frequent in women.[2] Multiple drug therapy may also increase risk.[11]
- Patients with the following HLAs are at higher risk for cutaneous drug reactions: HLA-B*1502 (confers a very high risk of carbamazepine-induced and other antiepileptic drug-induced SJS among people of southeastern Asian ethnicity); HLA-B*5801 (higher risk of allopurinol-induced severe cutaneous reactions); HLA-B*5701 (higher risk of abacavir [an antiretroviral drug] hypersensitivity reactions); HLA-B*3501, HLA-B*3505, HLA-B*1402, and HLA-Cw8 (nevirapine [an antiretroviral drug] sensitivity with rash; the latter two found in a Sardinian population); HLA-DRB1*0101 (nevirapine hypersensitivity rash with hepatitis).[2,6]

- Prior drug reaction may result in a faster recurrence on reexposure.[11]
- Concomitant illness, especially viral infections and autoimmune disorders.[11]

DIAGNOSIS

CLINICAL FEATURES AND TYPICAL DISTRIBUTION (THE MOST COMMON AND IMPORTANT DRUG ERUPTIONS)

- Maculopapular—These eruptions, red macules with papules, can occur any time after drug therapy is initiated (often 7 to 10 days) and last 1 to 2 weeks. The reaction usually starts on the upper trunk or head and neck then spreads symmetrically downward to limbs. The eruptions may become confluent in a symmetric, generalized distribution that spares the face (**Figure 154-1**). Mild desquamation is normal as the exanthematous eruption resolves.
- Urticaria and angioedema—Urticaria reactions present as circumscribed areas of blanching-raised erythema and edema of the superficial dermis (**Figures 154-3** and **154-4**). They may occur on any skin area and are usually transient, migratory, and pruritic. Angioedema represents a deeper reaction, with swelling usually around the lips and eyes (see Chapter 150, Urticaria and Angioedema).

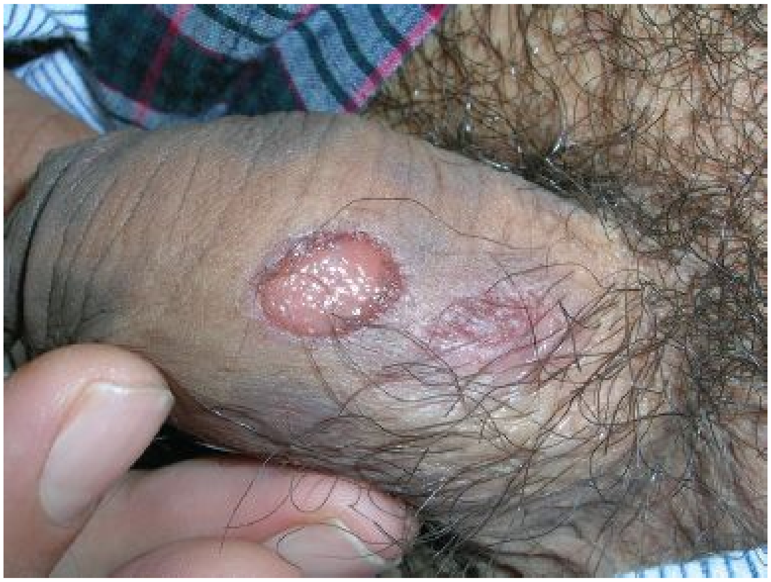

FIGURE 154-6 Fixed drug eruption to ibuprofen with violaceous and hyperpigmented macules and erosions on the penis. (Used with permission from Richard P. Usatine, MD.)

- Hyperpigmentation—Drug-induced hyperpigmentation presents in many ways. Amiodarone causes a dusky red coloration that turns blue-gray with time in photo-exposed areas. Minocycline can cause a blue-gray color in acne lesions, on the gingiva and on the teeth. Phenytoin (Dilantin) and other hydantoins may cause melasma-like brown pigmentation on the face.
- NSAIDs—The cutaneous reactions to NSAID-associated drug hypersensitivity are urticaria, angioedema, or anaphylaxis.[1] These reactions can be caused by a single NSAID or multiple NSAIDs. There is also an NSAID-exacerbated urticaria and angioedema that occurs in patients with chronic idiopathic urticaria.
- Fixed drug eruption (FDE)—Presents with single or multiple sharply demarcated circular, violaceous or hyperpigmented plaques that may include a central blister (**Figures 154-3** to **154-9**). The lesion(s) appear after drug exposure and reappear exactly at the same site each time the drug is taken. The site resolves, leaving an area of macular hyperpigmentation (**Figures 154-5** and **154-8**). Lesions can occur anywhere including the hands and feet, but are commonly found on the penis (**Figure 154-6**). The eruption presents 30 minutes to 8 hours after

drug administration. Bullous *fixed drug eruptions* occur when the lesion blisters and erodes, followed by desquamation and crusting (**Figure 154-9**).

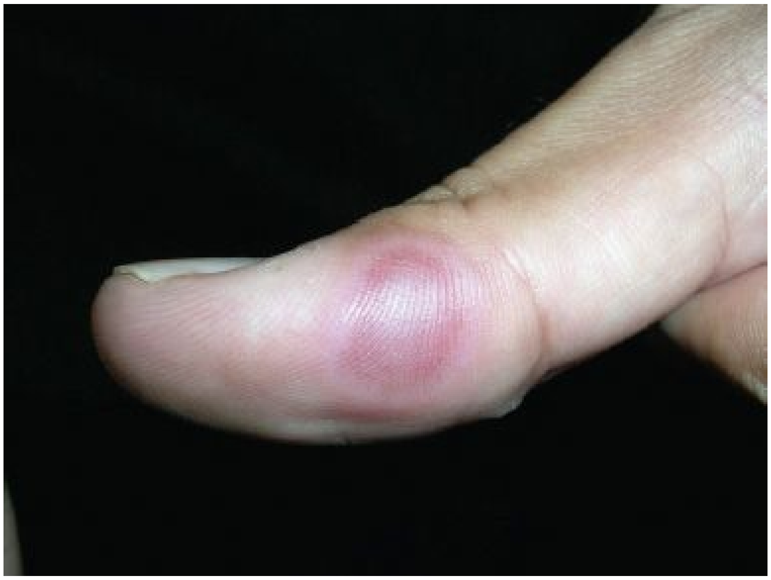

FIGURE 154-7 Third episode of fixed drug eruption to doxycycline. Note how the finger lesion is similar to a target lesion in erythema multiforme. However, there is no central epithelial disruption in this target lesion. (Used with permission from Richard P. Usatine, MD.)

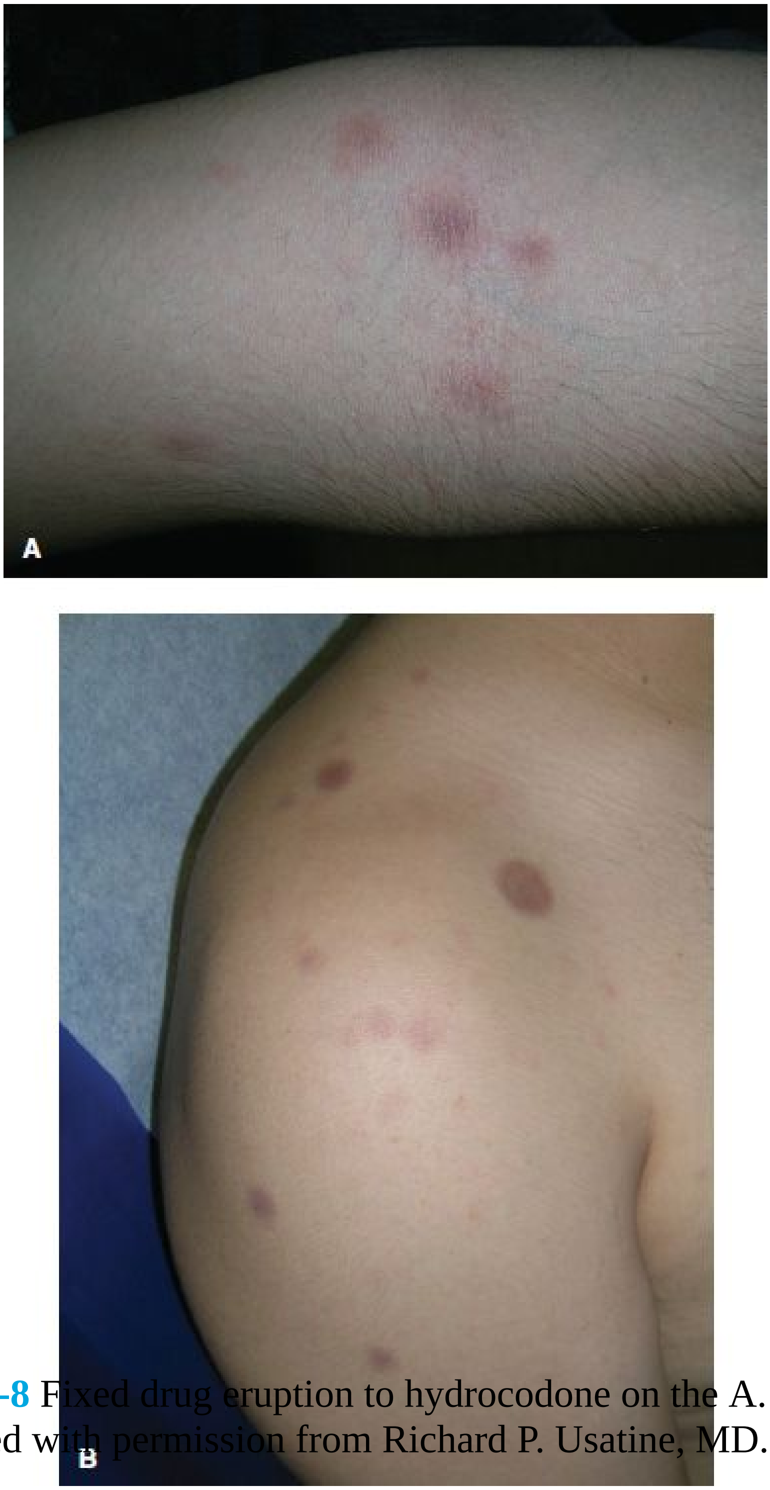

FIGURE 154-8 Fixed drug eruption to hydrocodone on the A. arm and B. shoulder. (Used with permission from Richard P. Usatine, MD.)

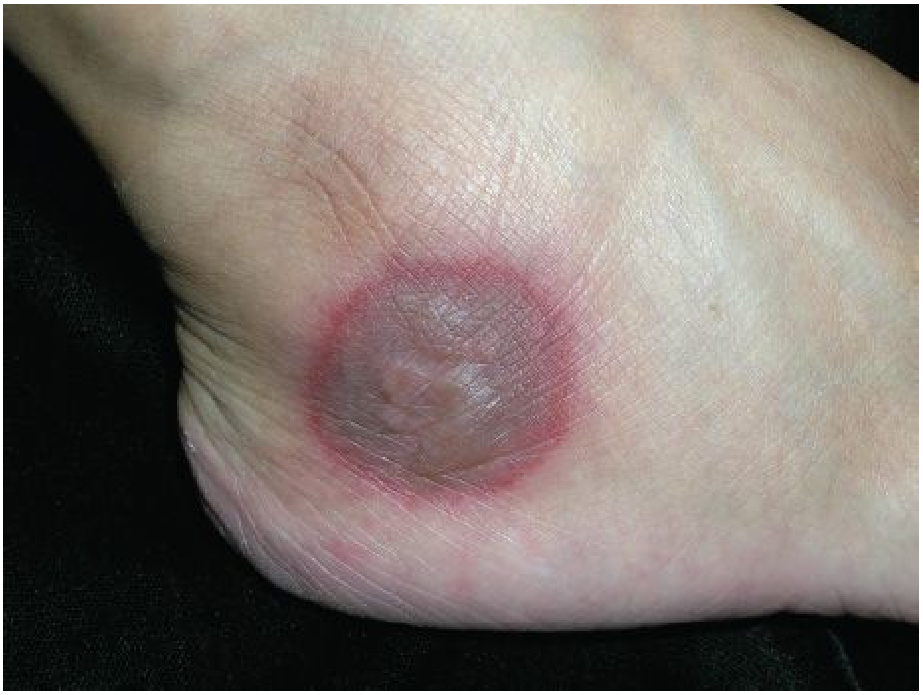

FIGURE 154-9 Bullous fixed drug eruption with a dusky color and an annular pink border on the ankle. (Used with permission from Richard P. Usatine, MD.)

- EM—It presents with typical target or raised edematous papules distributed acrally. Most importantly, there should be some type of epidermal disruption with bullae or erosions within the target lesions (**Figure 154-10**). Severe EM becomes and more widespread epidermal detachment may occur involving less than 10 percent of total body surface area (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).

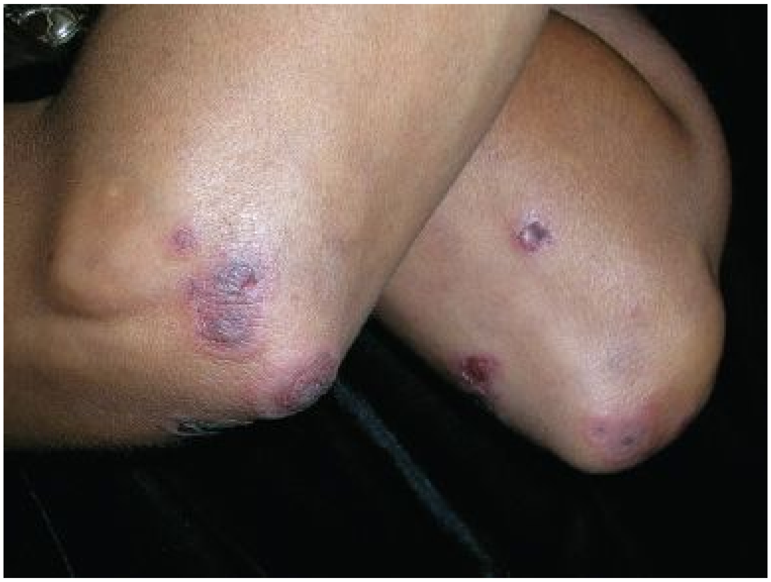

FIGURE 154-10 Erythema multiforme on the elbows. Note the epithelial disruption in the center of each target lesion. (Used with permission from Richard P. Usatine, MD.)

- SJS—It presents with erythematous or pruritic macules, widespread blisters on the trunk and face, and erosions of one or more mucous membranes (**Figure 154-11**). Atypical target lesions or widespread erythema, particularly in the upper chest and back, are potential early signs of both SJS and TEN.[11] Burning or painful skin can be a sign of increased severity. Epidermal detachment occurs and involves less than 30 percent of total body surface area.

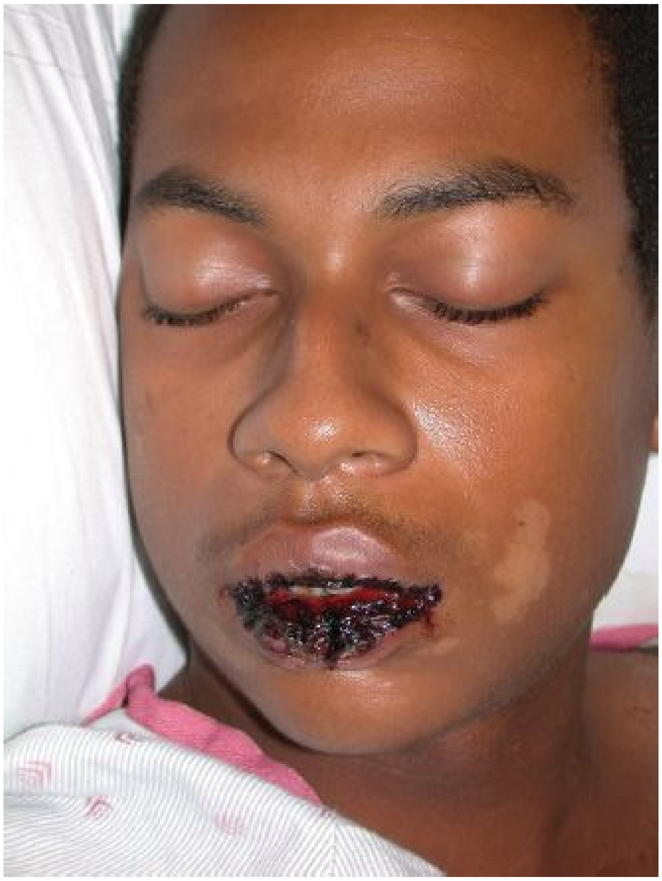

FIGURE 154-11 Stevens-Johnson syndrome secondary to a sulfa antibiotic. (Used with permission from Eric Kraus, MD.)

- Toxic epidermal necrolysis (TEN)—It is on the most severe side of the SJS spectrum. EM is diagnosed when less than 10 percent of the body surface area is involved, SJS/TEN when 10 to 30 percent is involved, and toxic epidermal necrolysis when more than 30 percent is involved (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis).
- Drug reaction with eosinophilia and systemic symptoms (DRESS) or drug-induced hypersensitivity syndrome (DIHS)—Infiltrated, palpable lesions are potential heralds of this disorder.[11] Central facial edema and erythema and a maculopapular rash are seen along with high fever, generalized lymphadenopathy, and arthralgias. Drug reaction with eosinophilia and systemic symptoms can also cause an erythroderma (**Figure 154-12**). Latency between starting a drug and first signs of drug reaction with eosinophilia and systemic symptoms can be up to 12 weeks.[11]

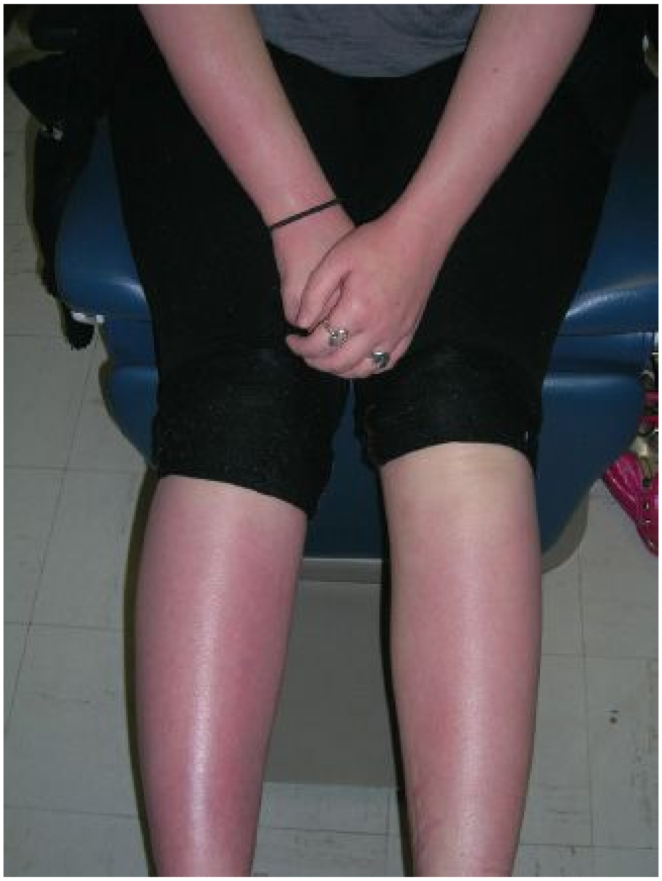

FIGURE 154-12 Drug reaction with eosinophilia and systemic symptoms syndrome (drug reaction, eosinophilia, systemic symptoms) in a teenage girl. Erythroderma has persisted but the patient is feeling better after treatment and discharge from the hospital. (Used with permission from Richard P. Usatine, MD.)

- Drugs most commonly known to cause SJS and TEN are sulfonamide antibiotics, allopurinol, nonsteroidal antiinflammatory agents, amine antiepileptic drugs (phenytoin and carbamazepine), and lamotrigine (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).[12] Fifty percent of SJS/TEN cases have no identifiable cause.
- Acute generalized exanthematous pustulosis (AGEP)—is a type of drug eruption that results in clusters of small pustules along with erythematous skin (**Figure 154-13**). The patients are often febrile and the pustules are primarily nonfollicular and sterile.

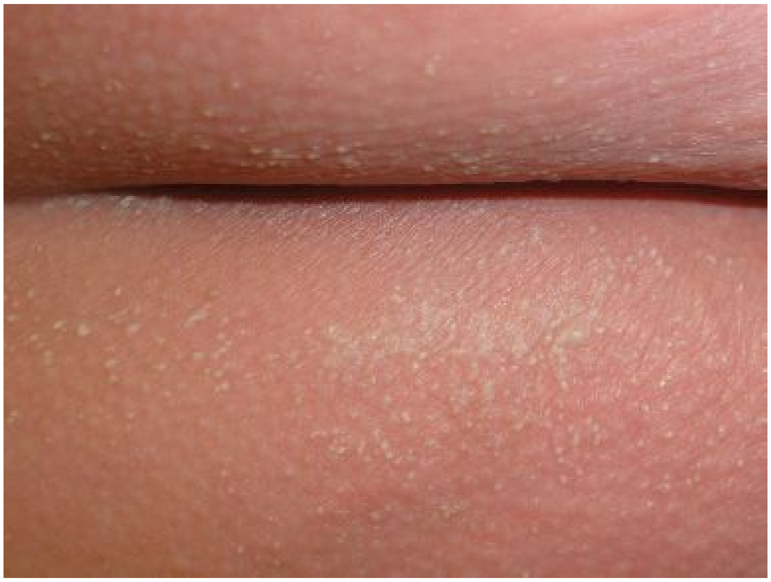

FIGURE 154-13 Acute generalized exanthematous pustulosis (AGEP) caused by a drug eruption. The clusters of small pustules with erythematous skin are seen on the buttocks. In this case, the pustules and erythema covered major portions of the back and buttocks. (Used with permission from Robert T. Gilson, MD.)

LABORATORY STUDIES

The diagnosis of drug eruptions is usually made based on history and physical examination.

- An FDE may be diagnosed by “provoking” the appearance of the lesion with an oral rechallenge with the suspected drug; however, this can be dangerous in bullous cases.
- Severe reactions may need a complete blood count (CBC) with differential and comprehensive serum chemistry panel to look for systemic involvement and check hydration status.
- In more challenging cases, a skin biopsy may be helpful to confirm the diagnosis.
- Intradermal skin testing may be hazardous to patients, and patch tests are not useful.

- Skin biopsies are usually not required for diagnosis of WISN, but may aid in the diagnosis.
- Testing for thrombophilia (high platelet count) may also be done in WISN.
- Laboratory tests in patients with DRESS/DIHS may show atypical lymphocytes, eosinophilia, lymphocytopenia, and thrombocytopenia; liver abnormalities are often seen.

DIFFERENTIAL DIAGNOSIS

- Viral exanthems look just like generalized maculopapular drug eruptions. Sometimes when a patient is given an antibiotic for an upper respiratory infection, the rash that ensues may be the viral exanthem rather than a drug eruption. The best way to avoid this confusion is only to use antibiotics when the evidence for bacterial infection is sufficient to justify the risks of a drug reaction (see Chapters 108 to 115 for more information on viral exanthems).
- Urticarial reactions present as transient migratory circumscribed areas of blanching-raised erythema and edema of the superficial dermis. Patients experience itching. Identifying urticaria is easy compared with finding the precipitating factors. If there is a temporal association with starting a new drug, it is best to stop the drug (in most cases) and see if the urticaria resolves (see Chapter 134, Urticaria and Angioedema).
- EM presents with sudden onset of rapidly progressive, symmetrical, and cutaneus lesions with centripetal spread. The patient may have a burning sensation in affected areas but usually has no pruritus. EM is most often caused by a reaction to an infection such as herpes simplex virus (HSV) or mycoplasma but may be caused by a drug reaction. Careful history and physical examination can help differentiate between the possible causes (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- SJS and TEN present with generalized cutaneous lesion with blisters, fever, malaise, arthralgias, headache, sore throat, nausea, vomiting, and diarrhea. The patient may also have difficulty in eating, drinking, or

opening his or her mouth secondary to erosion of oral mucous membranes (**Figure 154-11**). Not all SJS or TEN is secondary to drug exposure, but it is the job of the clinician to investigate this cause and stop any suspicious medications. SJS and TEN can be life-threatening (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).

- DRESS syndrome can be distinguished by involvement of organs other than skin including liver (hepatitis in 50% to 70%), kidney (nephritis in 10%), and, more rarely, pneumonitis, colitis, myocarditis, parotitis, meningitis, encephalitis, and pancreatitis; the pattern of organ involvement appears to depend on the drug trigger.[7,13] Some of the sequelae from DRESS syndrome are strongly related to herpes virus reactivation.[7] A recurrence of symptoms at the third week is common. Diagnostic criteria have been proposed to include all of the following: maculopapular rash developing more than 3 weeks after drug exposure, prolonged clinical symptoms after drug discontinuation, fever (>38°C [100.4°F]), liver abnormalities or other organ involvement, leukocyte abnormalities (atypical lymphocytosis, leukocytosis, eosinophilia), lymphadenopathy, and human herpesvirus-6 reactivation.[13]
- Pityriasis rosea (PR) is a mysterious eruption of unknown etiology that could easily mimic a maculopapular drug eruption. Look and ask for the herald patch to help make the diagnosis of PR. In PR, look for the collarette scale and observe whether the eruption follows the skin lines (causing a Christmas tree pattern on the back). These features should help positively identify PR because there are no laboratory tests that are specific to PR or most drug eruptions (see Chapter 137, Pityriasis Rosea).
- Syphilis is the great imitator. Any generalized rash without a known etiology may be caused by secondary syphilis. A rapid plasma reagin (RPR) will always be positive in secondary syphilis and is easy to run (see Chapter 181, Syphilis).
- Chronic bullous disease of childhood and pemphigus vulgaris can resemble a bullous drug eruption. Biopsies are the best way to diagnose these bullous diseases. Their clinical pictures are described in detail in Chapters 155, Chronic Bullous Disease of Childhood, and Chapter 156, Pemphigus.

MANAGEMENT

NONPHARMACOLOGIC

- Discontinue the offending medication for all types of drug reactions whenever possible. Older patients with drug eruptions may be on multiple medications and may be very ill; however, efforts should be made to discontinue all nonessential medications.[5] SOR Ⓒ
- Patients with maculopapular reactions may continue to be treated with the offending agent if it is essential for treating a serious underlying condition.[5]
- Maculopapular drug eruptions are not a precursor to severe reactions such as TEN.[5]
- Local wound care, debridement, and skin grafting may need to be performed to repair resultant disfigurement from necrosis.[15]

MEDICATIONS

- Maculopapular- and urticarial/angioedema-type drug reactions are treated with antihistamines. If the angioedema is causing airway compromise, epinephrine (10 mcg/kg intramuscular) and other treatments will be necessary.[5,13] SOR Ⓒ Usually an H_1-blocker is started. In some cases of urticaria/angioedema, an H_2-blocker is added on for broader antihistamine effects (see Chapter 134, Urticaria and Angioedema).
- Diphenhydramine (Benadryl)—Orally every 4 to 6 hours (nonprescription).
- Hydroxyzine (Atarax)—Pediatric dose 0.5 to 1.0 mg/kg per day orally 4 times daily.[5]
- Loratadine (Claritin)—Once daily[5] (nonprescription).
- H_2-blockers can be used by prescription or nonprescription.

- Topical steroids such as triamcinolone or desonide may be used for symptomatic relief of pruritus.[5] SOR Ⓒ
- Oral steroids have been used, but little benefit has been shown in most drug reactions.[5] SOR Ⓒ
- Systemic steroids are recommended for treatment of DRESS syndrome.[13,14] SOR Ⓒ
- FDEs are treated by discontinuing the drug and applying topical corticosteroids to the affected area.[4] SOR Ⓒ

REFERRAL OR HOSPITALIZATION

Patients with SJS, TEN, and DRESS syndrome are usually hospitalized.

- SJS, TEN, DRESS/DIHS—Start with early diagnosis, rapid discontinuing of offending agent, intravenous fluid replacement, and placement in an intensive care unit (ICU) or burn unit (see Chapter 151, Erythema Multiforme, Steven-Johnson Syndrome, and Toxic Epidermal Necrolysis).[4,5] Liver transplant has been used in patients with DRESS.[13]
- Most experts and studies now agree that systemic corticosteroids should not be used except in DRESS syndrome.[4] SOR Ⓑ
- Nutritional support, careful wound care, temperature control, and anticoagulation are recommended.[4] SOR Ⓒ
- Daily skin samples should be sent for bacterial Gram stain and culture to monitor for developing infection.[4] SOR Ⓒ

PREVENTION

- In the future, prevention may occur through screening for HLA associations and drug avoidance.[1]
- Avoid reexposure to the drug.

- Screening for HLA-B*1502 is advised by the US FDA and Health Canada for patients of southeastern Asian ethnicity before carbamazepine therapy.[1]

PROGNOSIS

- Most cutaneous drug reactions resolve with discontinuation of the causative agent.
- Mortality, however, is high at 10 percent for SJS and DRESS and 30 to 50 percent for TEN.[5,15] In a case series of patients with possible or probably DRESS, case fatality rate was 5 percent (9/172).[6]
- Some studies show the occurrence of autoimmune diseases, including type 1 diabetes mellitus, autoimmune thyroid disease, sclerodermoid graft-versus-host disease (GVHD)-like lesions, and lupus erythematosus months to years after resolution of DRESS syndrome.[7] Because of the long symptom-free interval in some patients, this relationship is questioned.

FOLLOW-UP

- Follow-up is most important when the case is severe or the diagnosis is uncertain. Clear-cut mild drug reactions may not need scheduled follow-up.
- Continued surveillance for autoimmune disorders may be warranted in patients following DRESS syndrome.

PATIENT EDUCATION

- Most patients with drug eruptions recover fully without any complications. The patient should be warned that even after the responsible medication is stopped the eruptions may clear slowly or even worsen at first; the patient should be advised that the reaction may not resolve for 1 to 2 weeks.

- The patient should also be counseled that mild desquamation is normal as the exanthematous eruption resolves. Confirming the diagnosis of an FDE, especially lesions presenting on the glans, with a drug challenge may allay the patient anxiety about the venereal origin of the disease.
- The family should be counseled as to the genetic predisposition of some drug-induced eruptions.
- The patient should be advised to enroll in a medic alert program and to wear a bracelet detailing the allergy.

SECTION 13 BULLOUS DISEASE

155 CHRONIC BULLOUS DISEASE OF CHILDHOOD

Holly H. Volz, MD
Richard P. Usatine, MD

PATIENT STORY

An 8 year-old girl presented with a two-day history of blisters on her face, trunk, and extremities (**Figure 155-1**). She complained of moderate discomfort from the blisters, but denied itching, burning, fever, and recent illness. She was not taking any medications. Biopsy demonstrated subepidermal vesicles and a rich neutrophilic infiltrate in the dermal papillary tips. Direct immunofluorescence revealed a linear deposition of IgA along the basement membrane confirming the diagnosis of chronic bullous disease of childhood. The patient was started on systemic therapy with dapsone and her lesions quickly resolved.

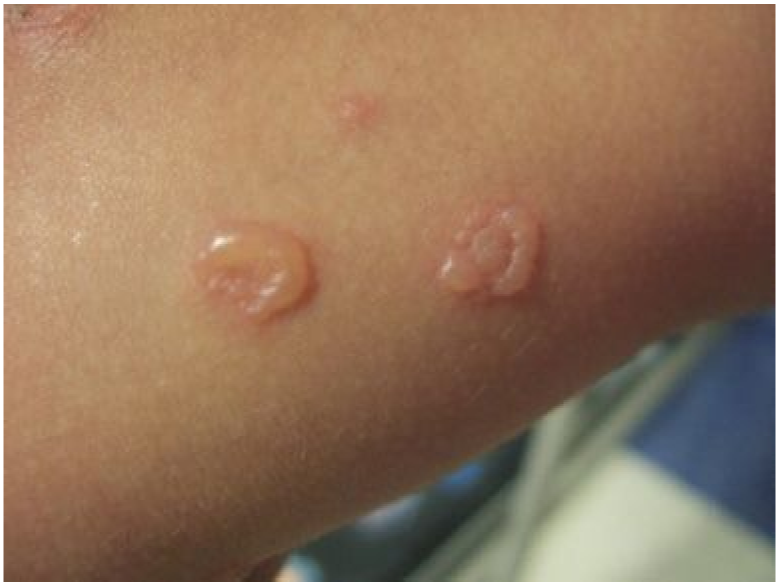

FIGURE 155-1 Chronic bullous disease of childhood in an 8-year-old girl. She had blisters on her face, trunk, and extremities. Note the annular and arcuate patterns of the bullae. (Used with permission from John Browning, MD.)

INTRODUCTION

Chronic bullous disease of childhood (CBDC) is the most common autoimmune bullous disorder in children.[1] This subepidermal vesiculobullous disorder is characterized by linear IgA deposits at the dermal-epidermal junction. It shares the same immunopathologic mechanism with its adult counterpart, adult linear IgA dermatosis. Although there is a great deal of overlap between the adult and childhood forms of linear IgA dermatosis, CBDC classically appears before the age of 5 years old, whereas adult linear IgA disease appears after age 60 years old. CBDC is considered a benign condition because it does not increase mortality; however, it may carry significant morbidity and, therefore, warrants treatment aimed at controlling the disease. Treatment with dapsone or sulfapyridine usually results in rapid resolution of the lesions. No correlation between the severity of blistering and the chronicity of disease exists. Most patients undergo spontaneous remission within months to years of initial presentation.

SYNONYMS

IgA bullous dermatosis of childhood, Linear IgA dermatosis, bullous disease of childhood, or chronic bullous dermatosis of childhood.

EPIDEMIOLOGY

- CBDC is a rare disorder with an incidence of 1:500,000.[2]
- It is the most common autoimmune bullous disorder in children.[1]
- Age of onset generally ranges from 1 to 11 years old with a mean of 3.5 to 4.5 years;[2] however, some case reports have documented neonatal onset of disease.[3,4]
- All races may be affected, although the disease appears to be more common in developing countries.[2]
- Data on the sex predilection of CBDC is heterogeneous and appears to vary with location.[5]Both sexes are affected, and some of the literature notes a slight female predominance.[2,6]

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology and exact pathophysiology of CBDC has not yet been defined, although both humoral and cellular immune responses are implicated in the disease process. The characteristic blister formation occurs as a result of IgA antibody formation against a heterogenous group of antigens located in the basement membrane zone of the epidermis. Over the last few decades, studies have identified a significant number of these targeted antigens, most commonly the 120-kDa and 97-kDa protein fragments of collagen XVII. Collagen XVII, also known as the 180-kDa bullous pemphigoid antigen (BP180), is a hemidesmosomal transmembrane protein that helps maintain the structural integrity of the dermal-epidermal junction.[4]
- Most cases of CBDC are idiopathic, and the inciting event that induces the production of autoantibodies remains unknown; however, a thorough history is imperative as numerous precipitating factors have been identified. These include:
    - Infection—Recent upper respiratory tract infection, gastroenteritis, varicella, and other viral or bacterial infections.[2,7]

    - Drugs—Vancomycin is most commonly associated; others include nonsteroidal antiinflammatory drugs such as diclofenac and naproxen, antibiotics such as amoxicillin, amoxicillin-clavulanate, ampicillin, ceftriaxone-metronidazole, and penicillin, as well as amiodarone, captopril, and phenytoin.[5,6,8]
    - Skin trauma—Local skin injury, burns, UV light exposure[5–7]
- The literature highlights a notable association between the development of CBDC and the presence of certain human leukocyte antigen (HLA) genotypes, including HLA-B8, CW7, DR3, and DQW2.[2,4,9,10] The presence of these haplotypes has been associated with an early onset of disease,[6] particularly in homozygous individuals.[2]

DIAGNOSIS

CLINICAL FEATURES

- A non-specific prodromal illness may precede development of the skin lesions.
- Onset of blisters is abrupt; systemic symptoms such as fever may or may not be present.
- Disease presentation is variable with respect to both the distribution and morphology of the skin lesions.
- Classically, the primary lesions of CBDC are tense, clear or hemorrhagic vesicles or bullae. The vesicobullous lesions may develop on normal-appearing skin or the skin may appear erythematous or urticated. The blister size is variable, and lesions frequently assume annular or arcuate patterns (**Figures 155-2** to **155-4**).

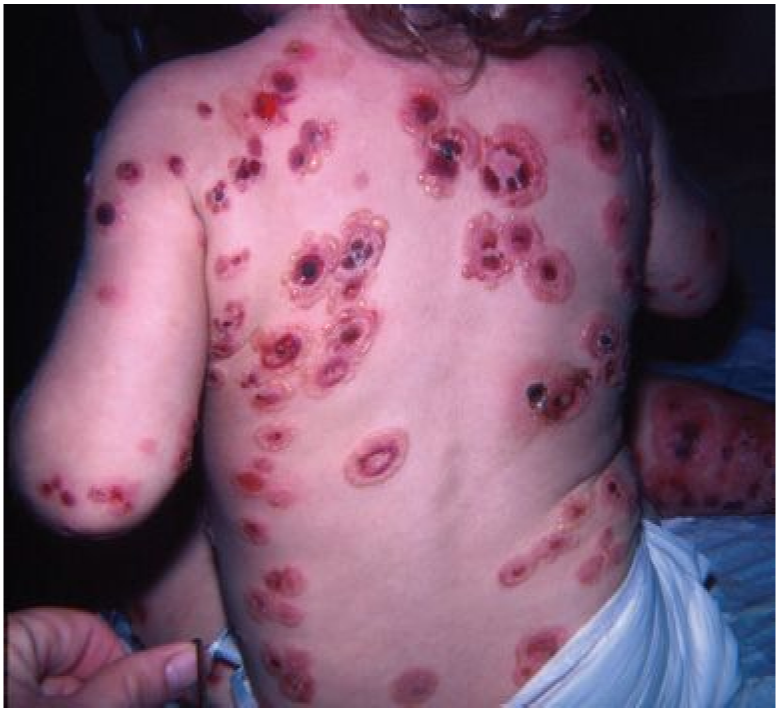

FIGURE 155-2 Bullae in a ring-like pattern in a young girl with chronic bullous disease of childhood. Note the pathognomonic “rosette” or “string of pearls” appearance. (Used with permission from Jack Resneck, Sr., MD.)

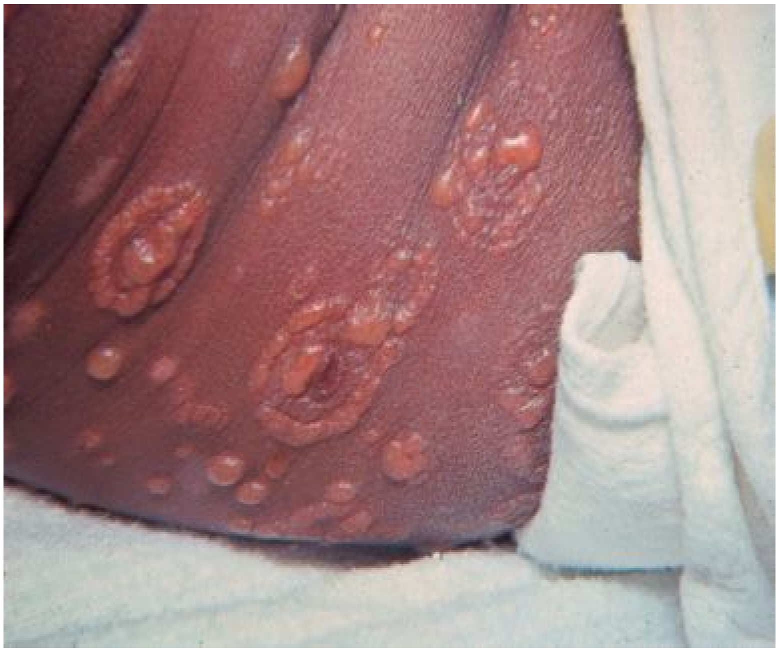

FIGURE 155-3 Chronic bullous disease of childhood with annular lesions and a “string of pearls” appearance. (Used with permission from Weinberg

SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-28, New York, NY: McGraw-Hill, 2008.

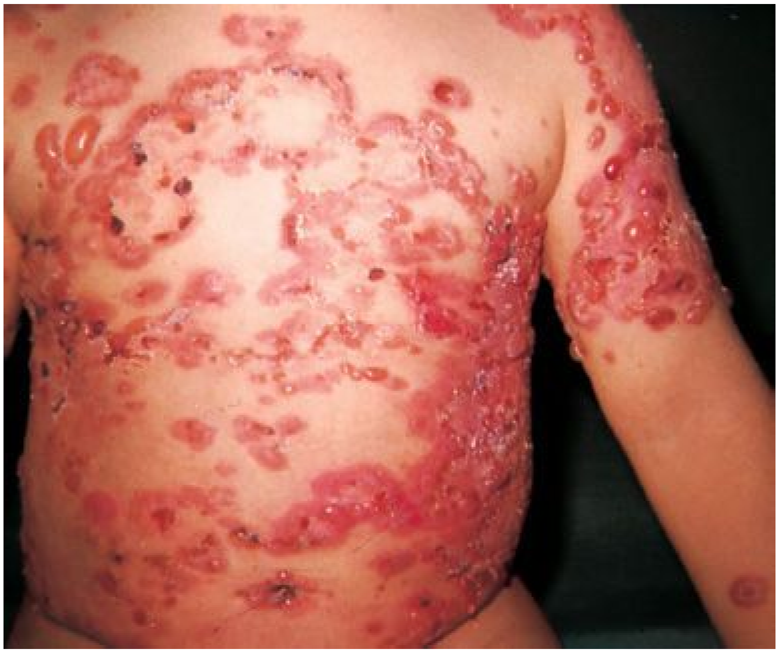

FIGURE 155-4 Chronic bullous disease of childhood with extensive annular lesions on the trunk and arm. Note the ‘string of pearls’ appearance. (Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-30, New York, NY: McGraw-Hill, 2008.)

- The development of new lesions around resolving lesions creates the pathognomonic “string of pearls” or “rosette” appearance of CBDC (**Figures 155-2** to **155-4**).
- Mucous membrane involvement is present in the majority of patients with variable presentation. Possible manifestations include oral ulceration, desquamative gingivitis, erosive cheilitis, nasal congestion, and bleeding. Ocular involvement may present as a conjunctivitis associated with photosensitivity, dryness, and irritation. Importantly, eye involvement can progress to serious sequelae including scarring and blindness.
- Patients may be asymptomatic or may experience a variety of symptoms ranging from mild pruritus to severe pruritus or burning.

- Skin lesions are usually most severe at initial presentation. Subsequent attacks, if they occur, are less severe.
- Healed lesions may cause transient skin hypopigmentation or hyperpigmentation known as "postinflammatory dyspigmentation." Permanent scarring is not typical.

TYPICAL DISTRIBUTION

- Lesions may be localized or widespread.
- The most commonly affected areas include the face, trunk, perineum, external genitalia, and thighs (**Figures 155-4** and **155-5**).

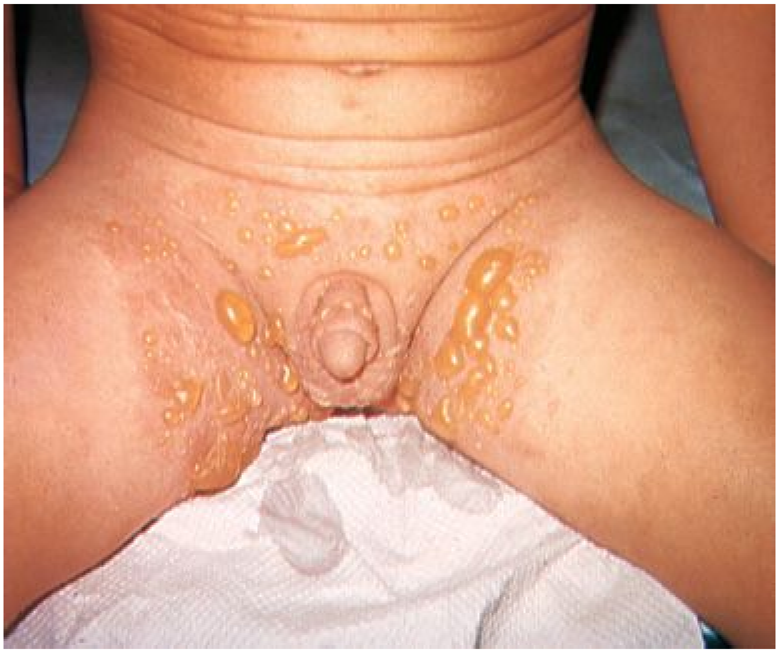

FIGURE 155-5 Chronic bullous disease of childhood involving the penis, groin and upper thighs. (Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-29, New York, NY: McGraw-Hill 2008.

  - Lesions on the face typically occur in a perioral distribution (**Figure 155-6**) or around the eyes, including the eyelids.

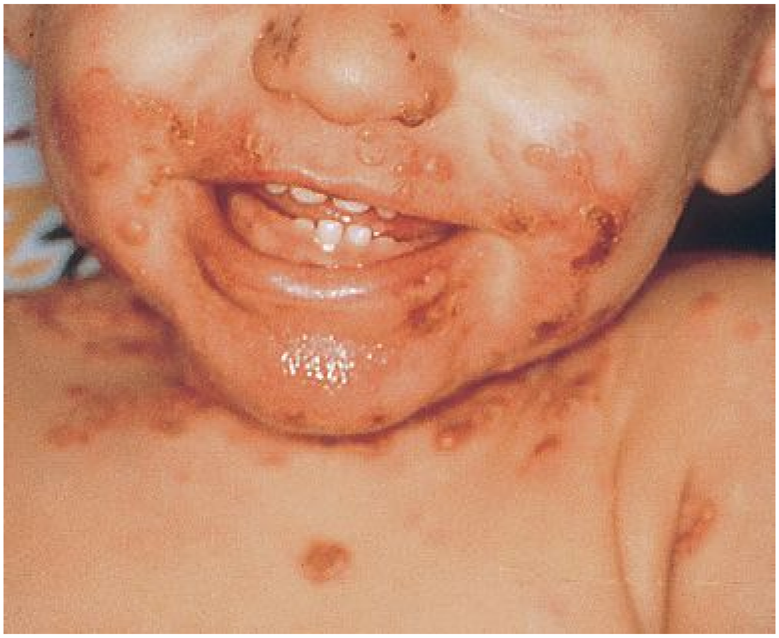

FIGURE 155-6 Chronic bullous diseases of childhood on the face of a 13-month-old infant. (Used with permission from Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 5-4b, 2009, New York: McGraw-Hill.)

  - Eruptions that initially manifest in the perineum have been mistaken for sexual abuse.[4]
- Other sites of involvement include the hands and feet (**Figure 155-7**).

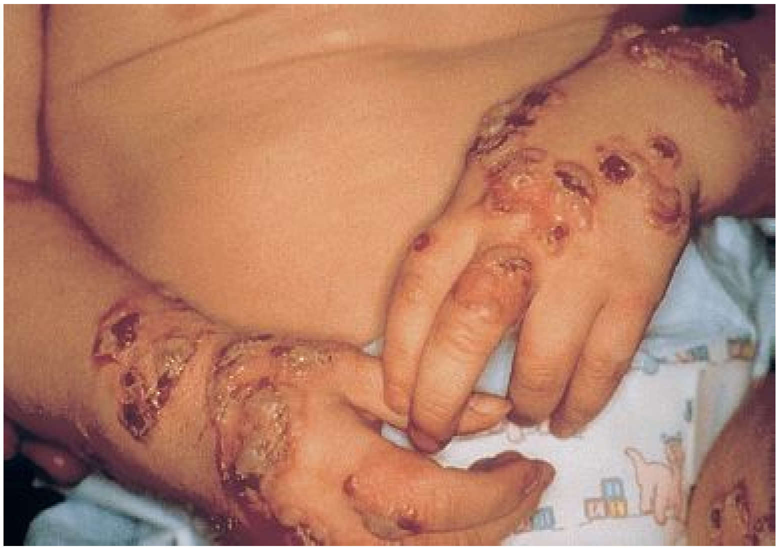

FIGURE 155-7 Chronic bullous disease of childhood on the hands and arms of this 13-month-old infant. Note the rosette appearance of some of the lesions. (Used with permission from Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 5-4c, New York, NY: McGraw-Hill, 2009

- Younger children frequently demonstrate the classic distribution of both facial and perineal lesions. Older children more commonly present with a more generalized distribution.[4]

LABORATORY STUDIES

- If detected, circulating antibodies are of the IgA1 subclass. In general, indirect immunofluorescence has a variable rate of positivity; low titers of autoantibody are detected in greater than 90 percent of patients.[4] Notably, the detection of circulating IgA occurs at a higher frequency in CBDC compared to the adult form of the disease.[6] Detection of circulating antibody is not necessary for diagnosis.
- All patients should be screened for glucose-6-phosphate dehydrogenase deficiency before initiating therapy with dapsone. Individuals with this deficiency are at risk for the development of severe hemolysis. Other initial laboratory tests include a complete blood count with differential, liver function tests, renal function tests, and urinalysis. A CBC should be monitored regularly during the first three months of therapy with dapsone with periodic blood work thereafter.
- If corticosteroids or immunosuppressive agents are required for treatment, a baseline complete blood count and a comprehensive metabolic profile should be obtained to allow for proper surveillance.

BIOPSY

- CBDC is diagnosed by the combination of clinical features along with hematoxylin-eosin–stained biopsy and direct immunofluorescence testing. Although histopathology can support the diagnosis, it does not distinguish CBDC from other important diseases in the differential diagnosis, including bullous pemphigoid and dermatitis herpetiformis; therefore, immunopathologic examination is required. Histologically, CBDC is characterized by subepidermal blisters and a rich inflammatory infiltrate along the basement membrane and in the dermal papillary tips. The gold standard for diagnosis is the immunohistochemical demonstration of linear IgA deposits along the dermal-epidermal junction.

- Direct immunofluorescence (DIF) testing should be performed on perilesional, uninvolved skin. Biopsy the perilesional skin and send the specimen in special Michel media or sterile saline and let the lab know to transfer it to Michel media when it arrives. The easiest way to do this is to take a shave biopsy that includes the bulla and the perilesional skin. Then cut the specimen in half and send the perilesional skin for DIF and the blister for standard pathology. Biopsy from the skin of the forearm appears to be less sensitive,[6] and false-negative results may be seen early in the disease and necessitate repeat biopsy.

DIFFERENTIAL DIAGNOSIS

- Bullous impetigo is the most common bullous disease seen in children. Vesicles and bullae on normal appearing skin secondary to a superficial bacterial skin infection (usually *Staphylococcus aureus*). It commonly occurs on the face and in the intertriginous areas, and surrounding erythema may or may not be present (**Figure 155-8**; see Chapter 99, Impetigo).

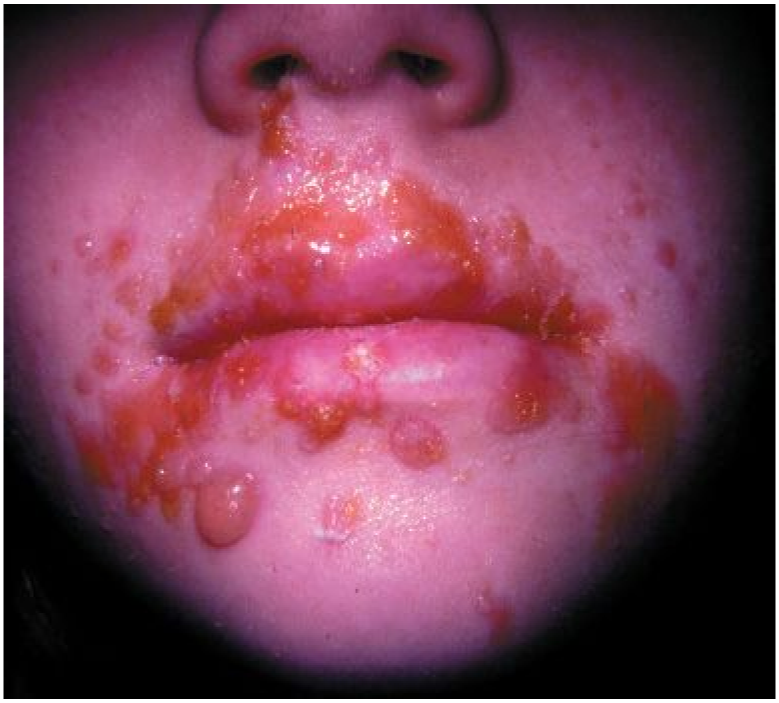

FIGURE 155-8 Bullous impetigo on the face of a child. Note the honey crusts, vesicles and bulla. (Used with permission from Jack Resneck, Sr., MD.)

- Bullous pemphigoid is much more common in older adults than children. Bullae are tense because they occur in the deeper subepidermal layer. In childhood, bullous pemphigoid has a predilection to involve the palms, soles and face but can also be generalized.[11] Biopsy (including DIF) is needed to make the diagnosis.
- Pemphigus is a rare group of autoimmune bullous diseases of skin and mucous membranes characterized by flaccid bulla and erosions. While it is more commonly seen in adults, it can occur in childhood. It often affects the oral mucosa in the form of pemphigus vulgaris. Biopsy (including DIF) is needed to make the diagnosis.
- Dermatitis herpetiformis is rare in children with typical onset in the second to fourth decades of life. Herpes-like lesions in the form of grouped vesicles and erosions occur especially on the elbows and extensor surfaces. It is associated with gluten-induced enteropathy. Blood tests for antigliadin and antiendomysial antibodies can help diagnose the

gluten-induced enteropathy and a skin biopsy is helpful to diagnose the associated skin disease.

- Epidermolysis bullosa is a rare group of inherited bullous diseases in which bullae form in response to even minor mechanical trauma. These diseases can manifest in infancy with most cases being epidermolysis bullosa simplex (**Figure 155-9**).

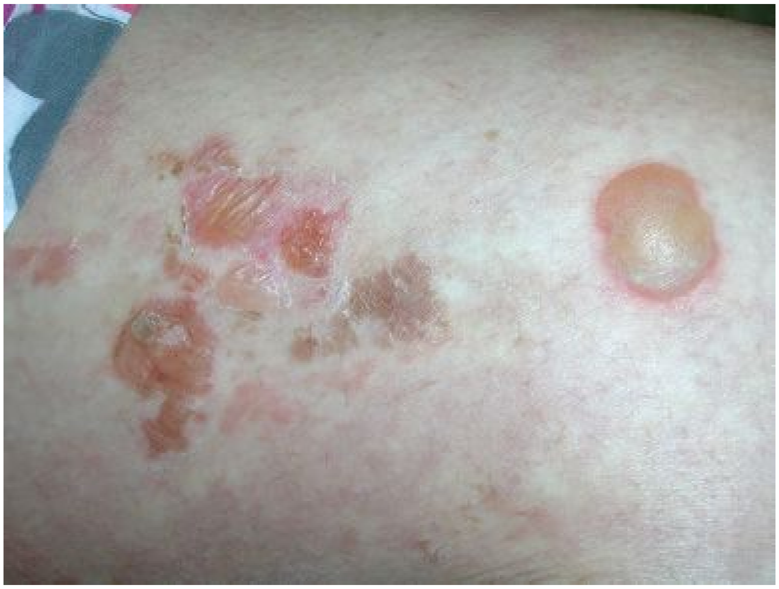

FIGURE 155-9 Epidermolysis bullosa simplex with trauma induced bullae on the leg of 15-year-old girl. (Used with permission from Richard P. Usatine, MD.)

Severe cases can be fatal in infancy. Biopsy (including DIF) is needed to make the diagnosis (see Chapter 157, Other Bullous Diseases).

- Erythema multiforme—Erythematous papular and vesiculobullous lesions that typically involve the extremities and mucous membranes. Most cases are related to herpes simplex virus infection. The typical lesion is targetoid and may have a vesiculobullous component (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).

MANAGEMENT

Treatment of CBDC is directed by the extent of cutaneous and mucosal involvement and may require a multidisciplinary approach. As a rare disease, large, randomized, double-blind, controlled trials on the treatment of CBDC are lacking. In general, referral to a dermatologist is necessary and involvement of an ophthalmologist, otolaryngologist, or gastroenterologist should be considered when appropriate. Treatment is initially aimed at achieving control of the blistering while avoiding side effects. The majority of patients rapidly respond to treatment with sulfones or sulfonamides, anti-inflammatory antibiotics, and topical steroids. If drug-induced CBDC is suspected, discontinuation of the medication may lead to resolution of the disease. Complete clinical remission is expected, and patients should subsequently be tapered from medications. A maintenance dosage of medications may be required and should be scheduled based on clinical judgment.

SYSTEMIC THERAPY

Sulfones: dapsone

Dapsone is considered the first line agent for treatment of CBDC. SOR C It is effective as both an anti-inflammatory and immunomodulatory drug.

- Begin treatment at a low dose and slowly titrate upward until adequate symptom control has been achieved. A good starting point for initial therapy is less than 0.5 mg/kg of body weight per day. Most patients maintain symptom control at doses around 2 mg/kg per day.[12] Unfortunately, mucous membrane involvement may be refractory to monotherapy with dapsone[13] and an additional agent will be required.
- All patients should be screened for glucose-6-phosphate dehydrogenase (G6PD) deficiency before initiating therapy with dapsone. Patients with this deficiency are at an increased risk of hemolytic anemia.
- All patients receiving dapsone will have some hemolysis so it is important to monitor a CBC weekly at first and then less often when the dose and blood count are stable.

- Other adverse effects associated with dapsone therapy include methemoglobinemia, bone marrow suppression including agranulocytosis, hepatitis, peripheral neuropathy, and dapsone hypersensitivity syndrome.[12,13]

Sulfonamide drugs

Sulfonamide drugs, often considered first or second-line therapy in the treatment of CBDC, are an effective alternative treatment option with a side effect profile similar but less severe than that of dapsone. This class of drugs can be used as monotherapy or in combination with dapsone without an increased risk of adverse effects.

- Sulfapyridine and sulfasalazine are the most commonly used drugs in this class; however, the therapeutic dosages in children are not well established.[12] Because sulfapyridine is not readily available in the US, its prodrug, sulfasalazine, is being used in its place.[12] SOR Ⓒ
- Other sulfonamides, such as trimethoprim-sulfamethoxazole, may be effective.[5] SOR Ⓒ
- The potential side effects of sulfonamides include hemolysis, granulocytopenia, aplastic anemia, pancreatitis, and hepatotoxicity.[5]

Corticosteroids and other immunosuppressive agents

Widespread or poorly controlled disease may necessitate the use of systemic corticosteroids. Corticosteroids should also be considered when patients have contraindications to dapsone or sulfonamide drugs such as G6PD deficiency. Ideally, corticosteroids are used for short term control of symptoms, tapered, and then discontinued.

- The recommended dose of corticosteroid is 0.05 to 2.0 mg/kg/day of oral prednisone[5] or 1.0 mg/kg/day of oral prednisolone.[10] SOR Ⓒ Short-term treatment for 1 to 3 weeks followed by a taper over 3 to 6 weeks is recommended in order to avoid the adverse side effects of prolonged steroid use.[10]
- Other immunosuppressive agents have been used with some success. These include colchicine, azathioprine, and cyclosporine.[2,5,12,13] SOR Ⓒ

Antibiotic therapy

Non-sulfa antibiotics are another potential therapeutic option for the treatment of CBDC. The successful use of various antibiotics, including amoxicillin, dicloxacillin, oxacillin, erythromycin, and tetracyclines, have been reported in the literature.[5,8,12–14,16] SOR C Consider these drugs in patients who are not candidates for therapy with dapsone or sulfonamides, patients who cannot comply with regular blood monitoring, or as adjuncts to treatment.

Adjuvant agents

- The use of alternative therapeutic strategies, including intravenous immunoglobulin and immunoadsorption, have been successfully documented in adults with refractory linear IgA disease.[5] The use of these therapies in children has not been thoroughly evaluated; however, there are case reports documenting successful treatment of CBDC with intravenous immunoglobulin.[16] SOR C

LOCAL THERAPY

- Mild cases of CBDC may resolve with treatment with a topical steroid alone.[13] SOR C Higher potency ointments are more likely to be beneficial than low potency creams. SOR C
- Alternatively, topical steroids can be used in combination with systemic therapy.

PROGNOSIS

Most cases of CBDC carry a good prognosis; however, a select number of patients suffer from severe mucosal disease with ocular and pharyngeal involvement that may progress to blindness or dysphagia.[4] In most cases, however, the disease remits after months to years and lesions heal without scarring.[6] Although most cases resolve before puberty, some patients may continue to suffer from the disease into adulthood.[6] Notably, the severity of blistering has not been shown to correlate with disease chronicity.

FOLLOW-UP

Patients should be regularly followed by their physician to allow for assessment of disease severity, medication adjustments, and monitoring of blood work.

PATIENT EDUCATION

- Education is an important aspect of patient care. Patients and family members should be informed regarding the disease, possible complications, prognosis, and therapeutic options.

156 PEMPHIGUS

Richard P. Usatine, MD
Shashi Mittal, MD

PATIENT STORY

A teenage boy presented with painful blisters on his face and mouth (**Figure 156-1**). The patient was referred to dermatology that day. The dermatologist recognized likely pemphigus vulgaris (PV) and did shave biopsies for histopathology and direct immunofluorescence of facial vesicles/bullae to confirm the presumed diagnosis. The patient was started on 60 mg of prednisone daily until the pathology confirmed PV. Steroid-sparing therapy was then discussed and started in 2 weeks from presentation.

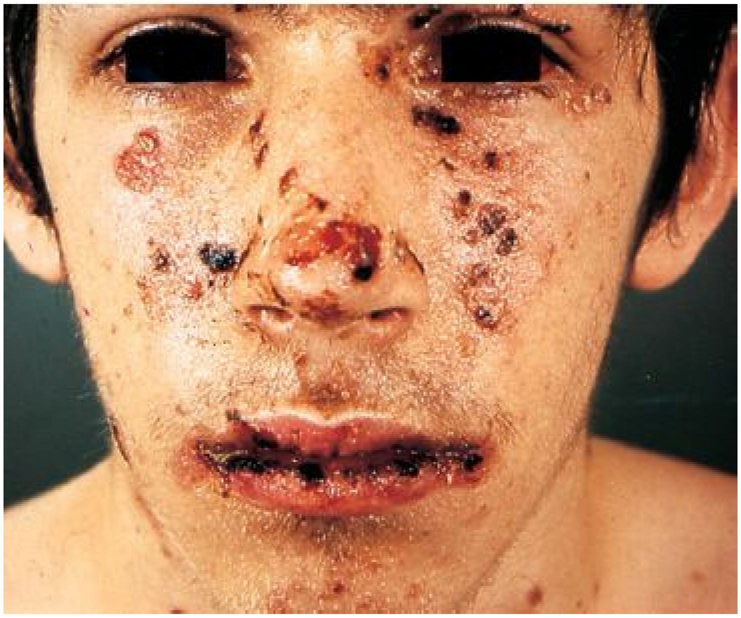

FIGURE 156-1 Pemphigus vulgaris on the face of a teenage boy with mouth involvement. Note the crusting that appears when the bullae erode. (Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-2, New York, NY: McGraw-Hill, 2008.)

INTRODUCTION

Pemphigus is a rare group of autoimmune bullous diseases of skin and mucous membranes characterized by flaccid bulla and erosions. The three main types of pemphigus are PV (with the pemphigus vegetans variant), pemphigus foliaceous (with the pemphigus erythematosus variant), and paraneoplastic pemphigus. All types of pemphigus cause significant morbidity and mortality. Although pemphigus is not curable, it can be controlled with systemic steroids and immunosuppressive medications. These medications can be lifesaving, but also place pemphigus patients at risk for a number of complications. The word *pemphigus* is derived from the Greek word *pemphix*, which means bubble or blister.

EPIDEMIOLOGY

Epidemiology of the three major types of pemphigus:

- PV (**Figures 156-1** to **156-4**):

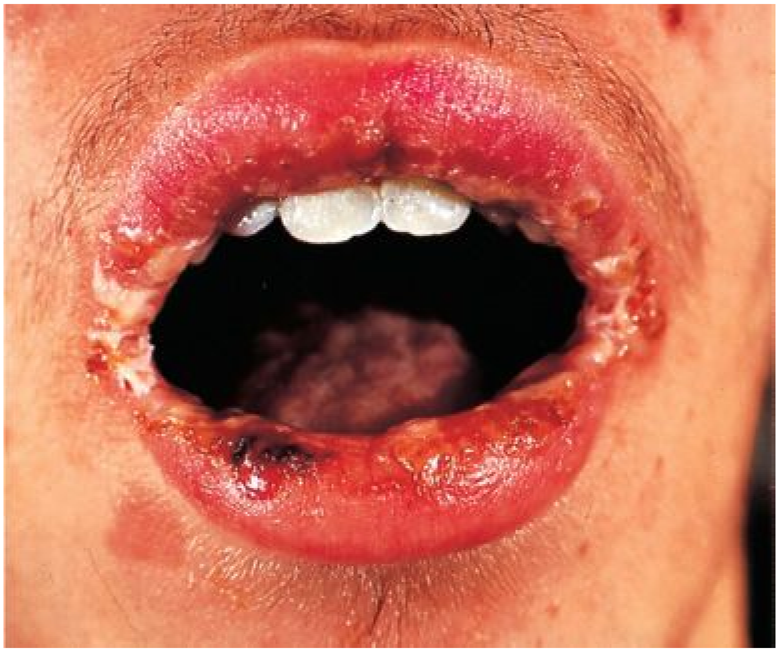

FIGURE 156-2 Pemphigus vulgaris with erosions of the lips and tongue. There are also erosions of the gums and palate that are not visible. This patient was in severe pain when attempting to eat or drink fluids. (Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-1, New York, NY: McGraw-Hill 2008.)

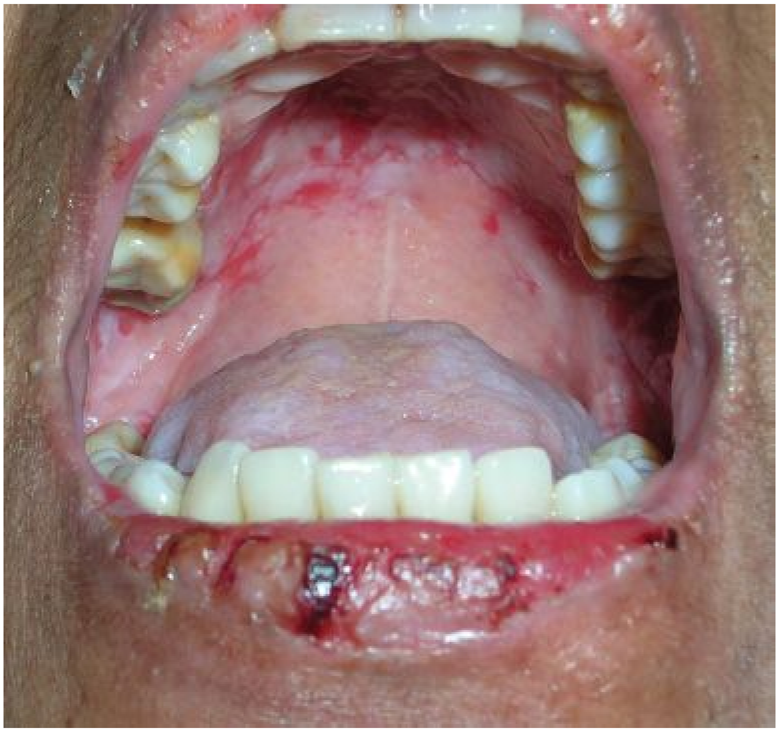

FIGURE 156-3 Pemphigus vulgaris involving the lips and palate. This is severely painful, making it difficult to eat or drink. (Used with permission from Dan Shaked, MD.)

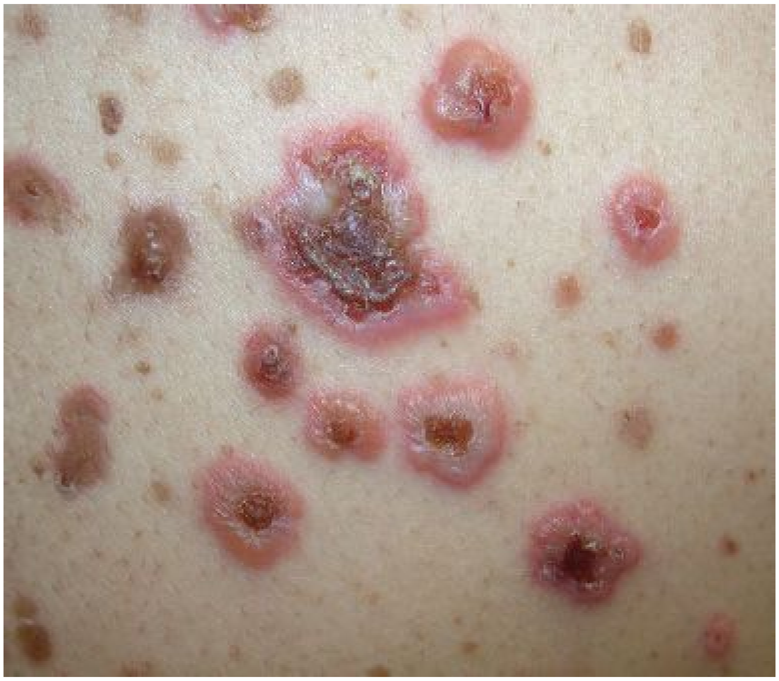

FIGURE 156-4 Pemphigus vulgaris on the back with crusted and intact bullae. (Used with permission from of Eric Kraus, MD.)

- Most common form of pemphigus is in the US.
- Annual incidence is 0.75 to 5 cases per 1 million population.[1]
- Usually occurs between 30 and 50 years of age, but can occur in childhood.[2]
- Increased incidence in Ashkenazi Jews and persons of Mediterranean origin.[2]
- Pemphigus vegetans is a variant form of PV (**Figures 156-5** and **156-6**).

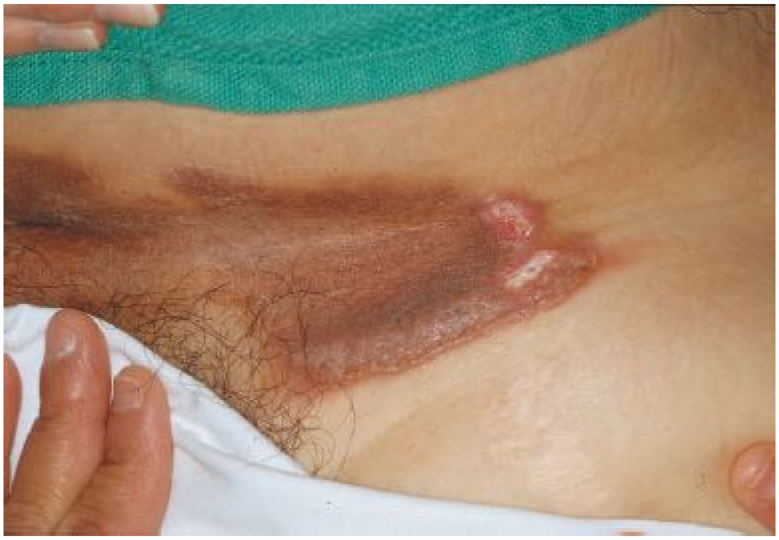

FIGURE 156-5 Pemphigus vegetans in the groin. (Used with permission from Eric Kraus, MD.)

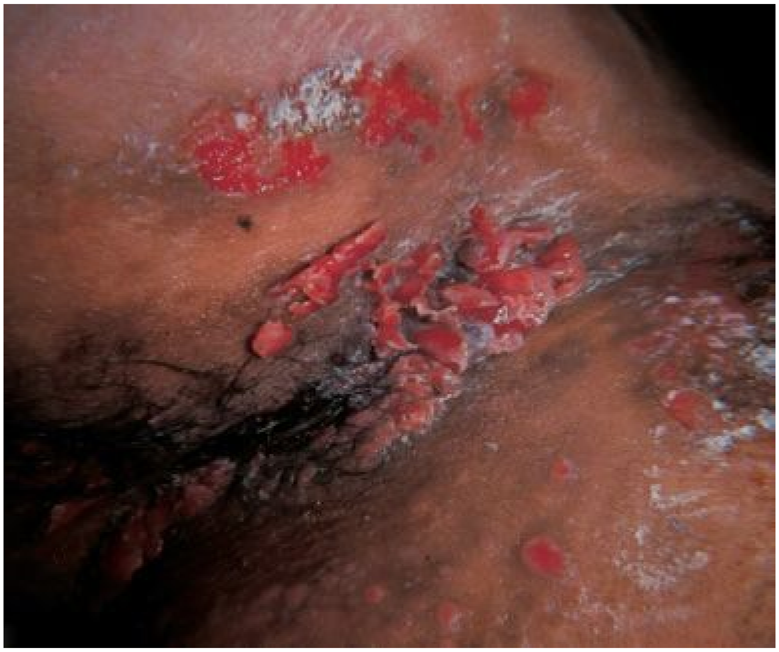

FIGURE 156-6 Pemphigus vegetans in the groin with boggy inflammation and tumid granulation. (Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-4, New York, NY: McGraw-Hill, 2008.)

- Pemphigus foliaceus (PF): Superficial form of pemphigus (**Figure 156-7**).

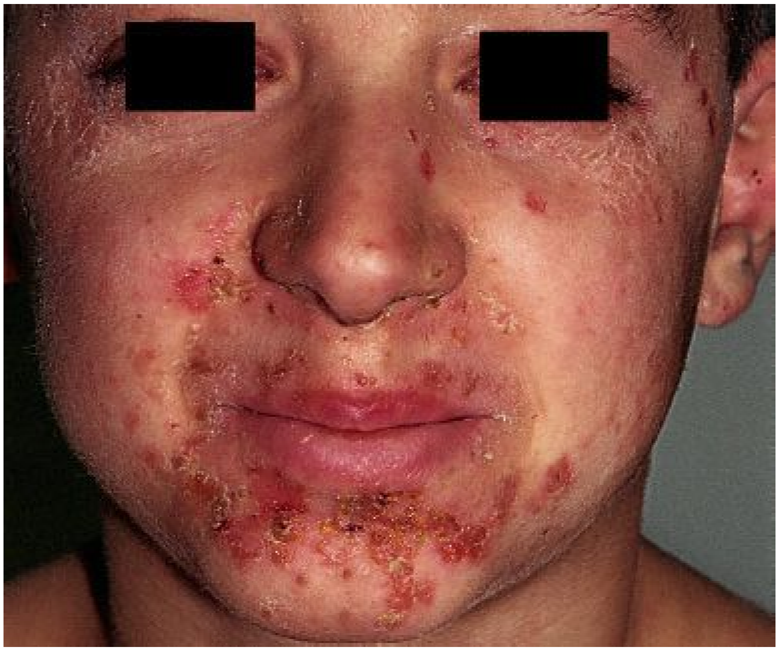

FIGURE 156-7 Pemphigus foliaceous in the perioral area without oral mucosal involvement. This can be mistaken for impetigo as impetigo is much more common than pemphigus. (Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-8, New York, NY: McGraw-Hill, 2008.)

  - Variant forms include pemphigus erythematosus (resembles the malar rash of lupus erythematosus) and fogo selvagem.
  - Fogo selvagem is an endemic form of PF seen in Brazil and affects teenagers and individuals in their 20.[1]
- Paraneoplastic pemphigus (PNP):
  - Onset at age 60 years and older.
  - Associated with occult neoplasms commonly lymphoreticular.

ETIOLOGY AND PATHOPHYSIOLOGY

- The basic abnormality in all three types of pemphigus is acantholysis, a process of separating keratinocytes from one another. This occurs as a result of autoantibody formation against desmoglein (the adhesive molecule that holds epidermal cells together). Separation of epidermal cells leads to formation of intraepidermal clefts, which enlarge to form bullae.[1]

- The mechanism that induces the production of these autoantibodies in most individuals is unknown. Yet PF may be triggered by drugs, most commonly thiol compounds like penicillamine, captopril, piroxicam, and others, like penicillin and imiquimod.[3] An environmental trigger in the presence of susceptible human leukocyte antigen (HLA) gene is suggested to induce autoantibodies in fogo selvagum.[1]
- The autoantibodies in pemphigus are usually directed against desmoglein 1 and 3 molecules (Dsg1 and Dsg3). Dsg1 is present predominantly in the superficial layers of the epidermis, whereas Dsg3 is expressed in deeper epidermal layers and in mucous membranes. As a result, clinical presentation depends on the antibody profile. In PV, a limited mucosal disease occurs when only anti-Dsg3 antibody is present, but extensive mucosal and cutaneous disease occurs when both anti-Dsg1 and Dsg3 antibodies are present. In PF, mucosal lesions are absent and the cutaneous lesions are superficial because of isolated anti-Dsg1 antibody.
- Patients with PNP demonstrate both anti-Dsg1 and Dsg3 antibodies. However, unlike PV, autoantibodies against plakin proteins (another adhesive molecule) are also observed in patients with PNP and these autoantibodies form a reliable marker for this type of pemphigus.

DIAGNOSIS

CLINICAL FEATURES

- Pemphigus vulgaris (**Figures 156-1** to **156-4**)—Classical lesions are flaccid bullae that rupture easily, creating erosions. Since bullae are short-lived, erosions are the more common presenting physical finding (**Figure 156-4**). Lesions are typically tender and heal with postinflammatory hyperpigmentation that resolves without scarring. A positive Asboe-

Hansen or Nikolsky sign may be present, but neither sign is diagnostic. A positive Asboe-Hansen sign occurs when a bulla extends to surrounding skin while pressure is applied directly to the bulla. The Nikolsky sign is positive when skin shears off while lateral pressure is applied to unblistered skin during active disease. Sometimes the Asboe-Hansen sign is also attributed to Nikolsky and called a Nikolsky sign, too.

- Pemphigus vegetans is a variant of PV where healing is associated with vegetating proliferation of the epidermis (**Figures 156-5** and **156-6**). Tumid granulation occurs with boggy inflammation (**Figure 156-6**).
- Pemphigus foliaceous: Multiple red, scaling, crusted, and pruritic lesions described as “corn flakes” are seen. Shallow erosions arise when crusts are removed, but intact blisters are rare as the disease is superficial (**Figures 156-7** to **156-10**).

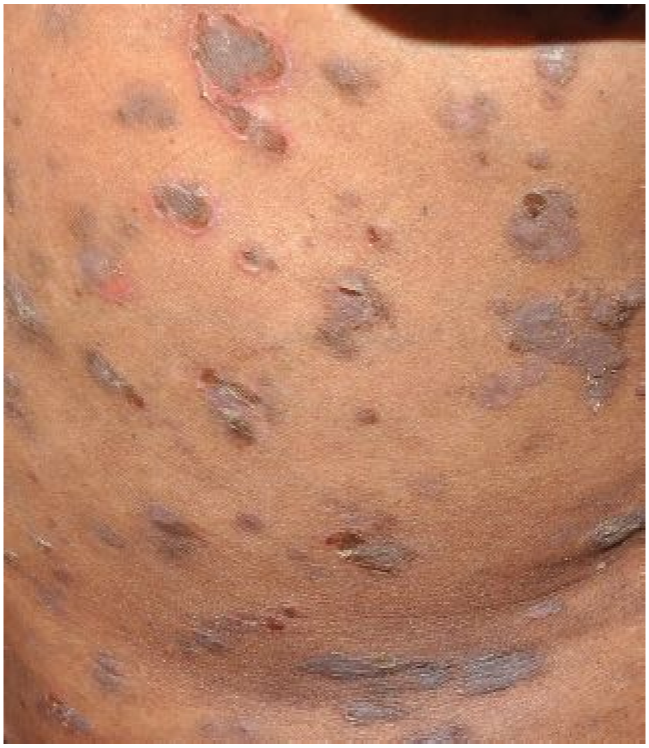

FIGURE 156-8 Pemphigus foliaceous on the back with superficial blisters and erosions. (Used with permission from Richard P. Usatine, MD.)

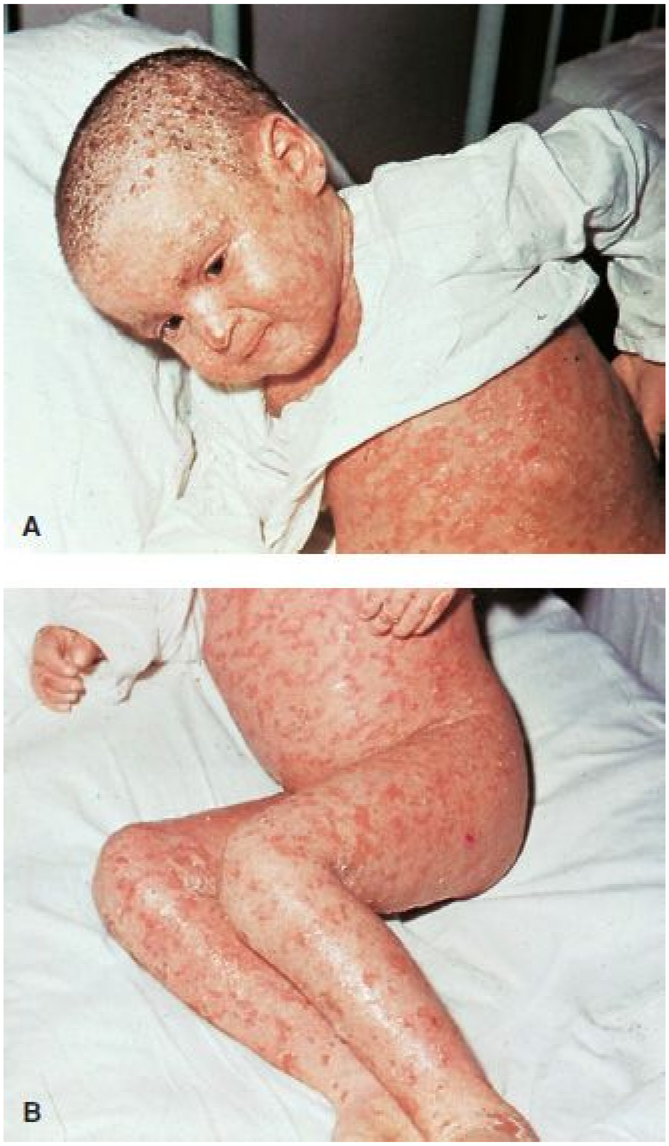

FIGURE 156-9 A and B. Pemphigus foliaceous from head to toe in this young child. The blister formation occurs high in the epidermis and is not unusual to only see “corn flake” crusting of the skin with no intact blisters. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-6 (for part A), Figure 14-7 (for part B), New York, NY: McGraw-Hill, 2008.*)

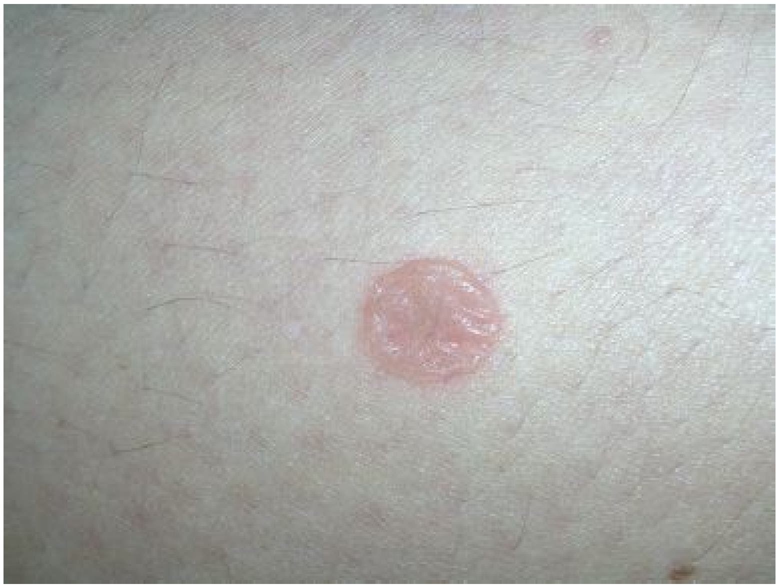

FIGURE 156-10 An intact flacid bullae that just appeared on the leg of a person with pemphigus foliaceous. (Used with permission from Richard P. Usatine, MD.)

TYPICAL DISTRIBUTION

- PV—Common mucosal site is oral mucosa, although any stratified squamous epithelium may be involved. Mucosal lesions may be followed by skin lesions after weeks to months usually on scalp, face, and upper torso. PV should be suspected if an oral ulcer persists beyond a month (**Figures 156-2** and **156-3**).
- Pemphigus vegetans—Usually seen in intertriginous areas like the axilla, groin, and genital region (**Figures 156-5** and **156-6**).
- PF—Initially affects face and scalp, though may progress to involve chest and back (**Figures 156-7** to **156-10**). When the facial involvement in PF is in a lupus-like pattern, this is called pemphigus erythematosus (**Figure 156-11**).

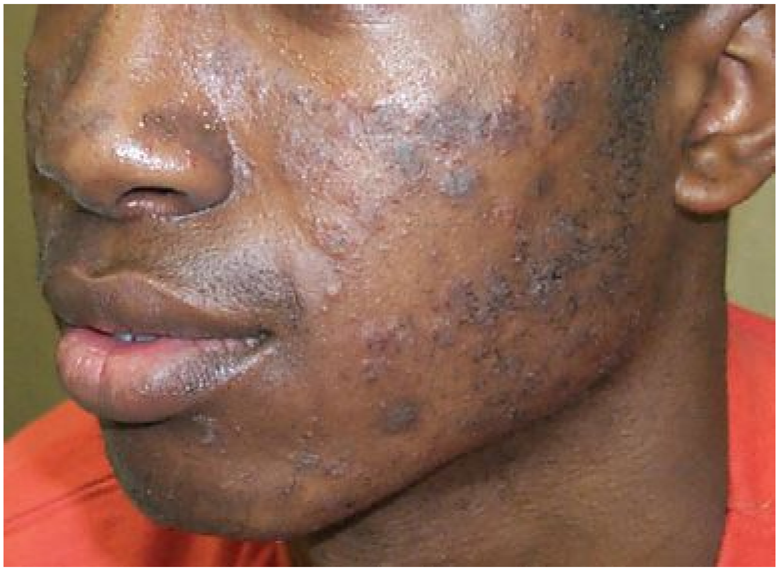

FIGURE 156-11 Pemphigus foliaceous (erythematosus) on the face. Note how the lesions have a butterfly pattern on the cheek. (Used with permission from Jack Resneck, Sr., MD.)

LABORATORY STUDIES

- Circulating desmoglein antibodies levels may be measured in the blood using indirect immunofluorescence. This is usually not necessary unless the diagnosis is in question and further data are needed.
- Complete blood count and a comprehensive metabolic profile including liver function tests, creatinine, and glucose will be needed as a baseline, as all the systemic therapies have significant toxicities.
- Patients at risk for steroid-induced osteoporosis should have a dual-energy x-ray absorptiometry (DEXA) scan performed.

BIOPSY

- Skin biopsy is essential for accurate diagnosis. The depth of acantholysis and site of deposition of antibody complexes help differentiate pemphigus from other bullous diseases. Two specimens should be sent. Perform a shave of the edge of the bulla to include the surrounding normal appearing epidermis. This biopsy should be of the freshest lesion with an intact bulla, if possible. Cut the specimen in half and send the portion with the bulla in formalin for routine histopathology. The second half should be perilesional adjacent normal skin. This is sent on a gauze pad soaked in normal saline or Michel solution for direct immunofluorescence (DIF). Routine histopathology demonstrates suprabasal acantholysis and DIF shows antibody deposition in the intercellular spaces of the epidermis. The pattern of the DIF fluorescence is described as chicken wire (**Figure 156-12**).

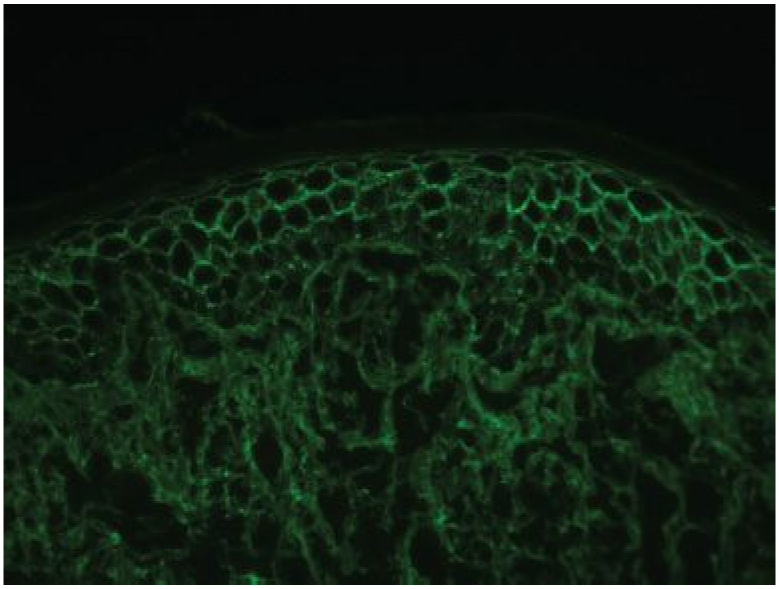

FIGURE 156-12 Direct immunofluorescence against immunoglobulin (Ig) G antibodies surrounding cells of the epidermis in a patient with pemphigus vulgaris. Note the chicken-wire appearance. (Used with permission from Martin Fernandez, MD, and Richard P. Usatine, MD.)

DIFFERENTIAL DIAGNOSIS

- Chronic bullous disease of childhood (CBDC) is the most common autoimmune bullous disorder in children. This subepidermal vesiculobullous disorder is characterized by linear IgA deposits at the dermal-epidermal junction. Typical lesions are described as “string of pearls,” which is an urticarial plaque surrounded by vesicles and bullae (see Chapter 155, Chronic Bullous Disease of Childhood).

- Hailey-Hailey disease (benign familial pemphigus)—A genodermatosis with crusted erosions and flaccid vesicles distributed in the intertriginous areas (**Figure 156-13**). It most closely resembles pemphigus vegetans clinically but has a completely different pathophysiology than true pemphigus. It is called benign because it is not life-threatening. A 4-mm punch biopsy is adequate to make this diagnosis as the histology is different than pemphigus.

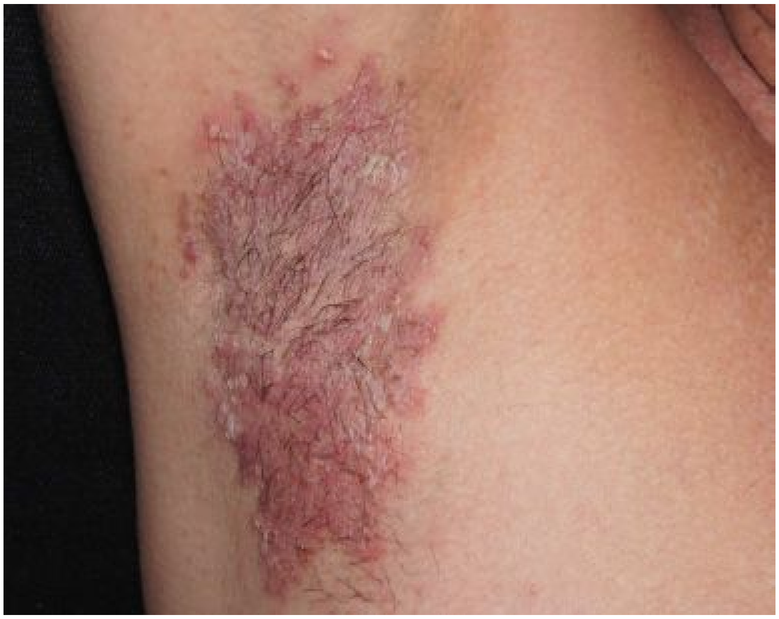

FIGURE 156-13 Hailey-Hailey disease (benign familial pemphigus) with erythema and pustules in the axilla. This is not true pemphigus but resembles pemphigus vegetans. (Used with permission from Jonathan B. Karnes, MD.)

- Bullous pemphigoid—Bullae are tense because they occur in the deeper subepidermal layer. Mucous membrane involvement is rare. Biopsy illustrates subepidermal acantholysis and immunoglobulin deposition along the basement membrane.[3]
- Dermatitis herpetiformis—Herpes-like lesions in the form of grouped vesicles and erosions occur especially on the elbows and extensor surfaces. It is associated with gluten-induced enteropathy. Biopsy reveals

neutrophilic microabscesses at the tips of dermal papillae with deposition of immunoglobulin (Ig) A antibody complexes. Blood tests for antigliadin and antiendomysial antibodies can help diagnose the gluten-induced enteropathy (Chapter 157, Other Bullous Diseases).

MANAGEMENT

Treatment of pemphigus should be undertaken in consultation with a dermatologist. Treatment is directed initially at disease control and remission followed by disease suppression. The goal is to eventually discontinue all medications and achieve complete remission. Unfortunately, this goal is hard to achieve. Most studies of the treatment of pemphigus have been performed in adults so the following recommendations are based on a combination of adult studies and pediatric case reports and expert reviews.

SYSTEMIC THERAPY

Corticosteroids

Oral steroids with a steroid-sparing adjuvant agent is the most effective treatment for all forms of pemphigus (two randomized controlled trials [RCTs]).[4,5] SOR Ⓑ

- Treatment should begin with the corticosteroid.[4–6] SOR Ⓑ Mild disease may be controlled with prednisone (or prednisolone) 1 mg/kg/day but for rapidly progressive and extensive disease, a higher dose prednisone 2 mg/kg/day may be initiated. SOR Ⓒ In most cases, the prednisone daily will need to be continued for at least 1 month. Once remission is induced, the dose is tapered by 25 percent every 1 to 2 weeks to the lowest dose needed to suppress recurrence of new lesions.[1]
- High-dose and prolonged treatment with steroids can have serious side effects. Consequently, it is advisable to start adjuvant steroid-sparing therapy within 2 to 4 weeks of treatment. Adjuvant agents have a lag

period of 4 to 6 weeks before they become effective, so starting them sooner allows for earlier steroid taper. They may be used alone to maintain remission after steroid withdrawal.

Adjuvant agents

- Adjuvant agents include azathioprine, methotrexate, mycophenolate, cyclophosphamide, dapsone, and intravenous immunoglobulin.[6–10] The efficacy of steroids have been shown to be enhanced when combined with a cytotoxic drug.[5]
- In one RCT open-label trial of four treatment regimens for adult PV, the most efficacious cytotoxic drug to reduce steroid was found to be azathioprine, followed by cyclophosphamide (IV pulse therapy), and mycophenolate mofetil.[5] SOR Ⓑ
- Azathioprine and methotrexate are often the preferred adjuvants for childhood pemphigus.[10] SOR Ⓒ
- Dapsone is an alternative adjuvant for pemphigus.[6] SOR Ⓒ In one small study of adults with pemphigus vulgaris, 8 (73%) of 11 patients receiving dapsone versus 3 (30%) of 10 receiving placebo reached the primary outcome of a prednisone dosage of 7.5 mg/day or less. This was not statistically significant and only showed a trend to efficacy of dapsone as a steroid-sparing drug in maintenance-phase PV.[11]
- Intravenous immunoglobulin (IVIG) may be used as adjuvant therapy in refractory cases of pemphigus.[6,12–14] SOR Ⓑ In one RCT of adult patients, it was used as a 5-day cycle to treat pemphigus that was relatively resistant to systemic steroids. In this multicenter study of 61 adult patients with PV or foliaceous, there was a decrease in disease activity subsequent to the cycle of IVIG.[14] SOR Ⓑ
- Rituximab is a chimeric monoclonal antibody against CD20 on B lymphocytes. It leads to depletion of pathogenic B cells for up to 12 months, resulting in a reduction of plasma cells secreting pathogenic autoantibodies. Rituximab is infused weekly for 4 consecutive weeks in addition to the standard immunosuppressive treatment. It has shown promise in several case reports and cohort studies in the treatment of refractory cases of PV and foliaceus.[15–18] SOR Ⓑ

▶ Treating and preventing complications of therapy

- Growth retardation has been reported in 50 percent of patients receiving oral corticosteroids.[19]
- Obesity and steroid-induced diabetes may also occur. Good diet, exercise, and monitoring of blood sugars and hemoglobin A_{1c} can be helpful.

LOCAL THERAPY

- Solitary lesions may be treated with topical high-potency steroids, such as clobetasol, or with intralesional steroid injections; for example, 20 mg/mL triamcinolone acetonide. Isolated oral lesions may be treated with steroid paste, sprays, or lozenges.
- Normal saline compresses or bacteriostatic solutions such as potassium permanganate are useful in keeping lesions clean. Oral hygiene is crucial. Mouthwashes such as chlorhexidine 0.2 percent or 1:4 hydrogen peroxide may be used. Topical anesthetics may be used for pain.[6]

PROGNOSIS

Pemphigus is a chronic group of diseases that are potentially life-threatening. There is no cure and the long-term use of steroids and immunosuppressive drugs places the patients at risk for a number of complications including infections, sepsis, steroid-induced diabetes, and steroid-induced osteoporosis. Some patients will be lucky and go into remission while others will need systemic therapy for life. Complications of treatment have become the greatest source of morbidity and mortality in pemphigus.

FOLLOW-UP

Prolonged follow-up is needed for medication adjustment and to monitor disease activity and drug side effects.

PATIENT EDUCATION

- Educate patients regarding disease, complications, and side effects of medications.
- Advise patients on avoiding trauma to skin such as with contact sports. Similarly, oral lesions may be aggravated by nuts, spicy foods, chips, and dental plates and bridges.
- Instruct patients on wound care to prevent infections and relieve local discomfort.
- Provide information on support groups such as the International Pemphigus Pemphigoid Foundation.

157 OTHER BULLOUS DISEASES

Jimmy H. Hara, MD
Richard P. Usatine, MD

INTRODUCTION

There are a number of bullous diseases other than pemphigus and bullous pemphigoid that are important to recognize. Epidermolysis bullosa belongs to a family of inherited diseases where blister formation can be caused by even minor skin trauma. PLEVA (pityriasis lichenoides et varioliformis acuta) is a minor cutaneous lymphoid dyscrasia that can appear suddenly and persist for weeks to months. Dermatitis herpetiformis is a recurrent eruption that is usually associated with gluten and diet-related enteropathies. These diseases will be discussed in succession.

EPIDERMOLYSIS BULLOSA

PATIENT STORY

A 12-year-old girl with the Dowling-Meara type of epidermolysis bullosa (EB) simplex presents to her pediatrician for a URI. While examining her respiratory tract, the pediatrician notes the extensive, severe blistering over many areas of the body including, the (A) trunk, (B) extremities, and (C) the hands (**Figure 157-1**). She has been followed by a dermatologist since early childhood when the EB simplex was first diagnosed. It turns out that she only has a viral URI so no antibiotics are needed and standard treatment with fluids and analgesics is recommended. Her mom states that the girl has an appointment with her dermatologist next month.

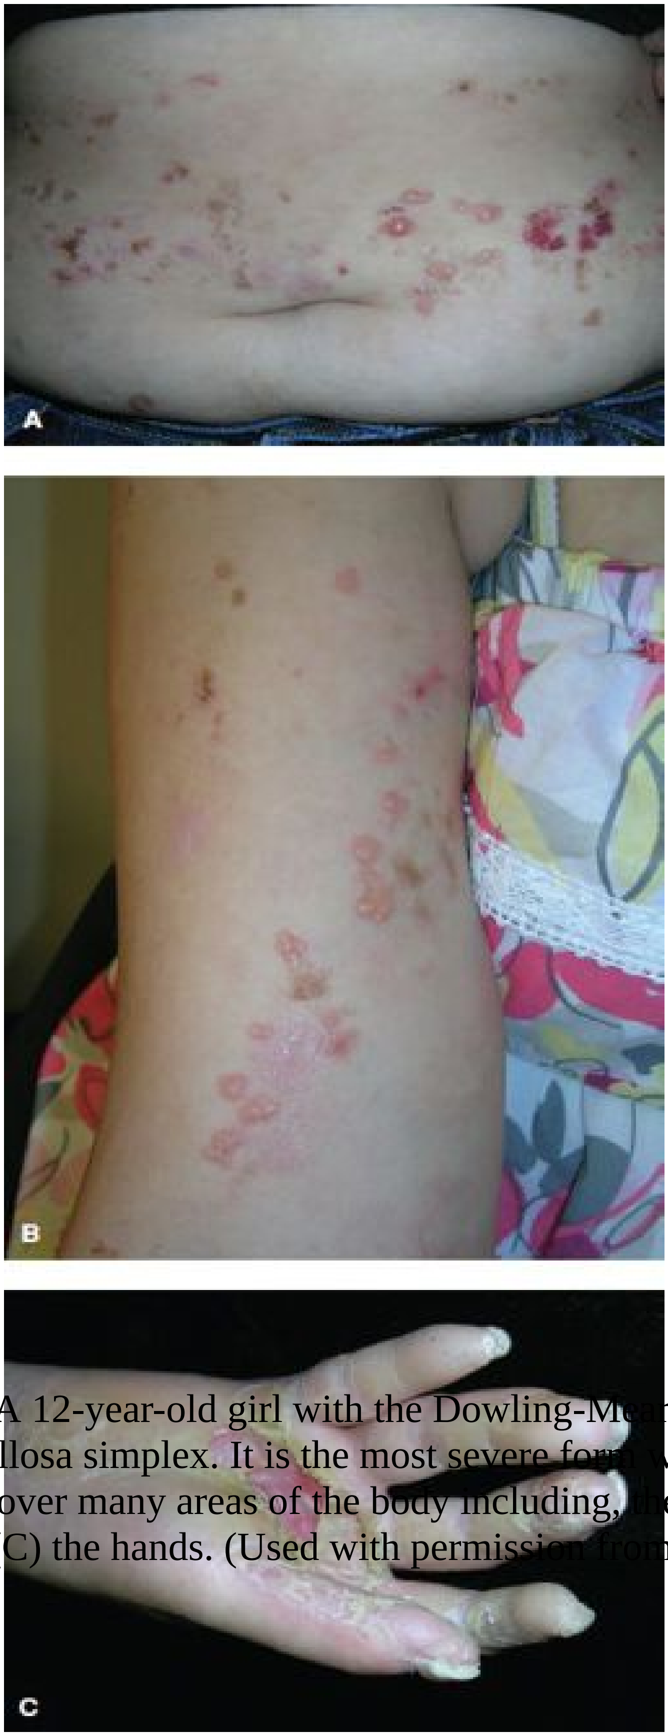

FIGURE 157-1 A 12-year-old girl with the Dowling-Meara type of epidermolysis bullosa simplex. It is the most severe form with extensive, severe blistering over many areas of the body including, the (A) trunk, (B) extremities, and (C) the hands. (Used with permission from Richard P, Usatine, MD.)

EPIDEMIOLOGY

- Epidermolysis bullosa (EB) is a family of inherited diseases characterized by skin fragility and blister formation caused by minor skin trauma.[1]
- There are autosomal recessive and autosomal dominant types; the severity of this disease may vary widely.
- Onset is in childhood and in later years severe dystrophic deformities of hands and feet are characteristic (**Figure 157-2**).

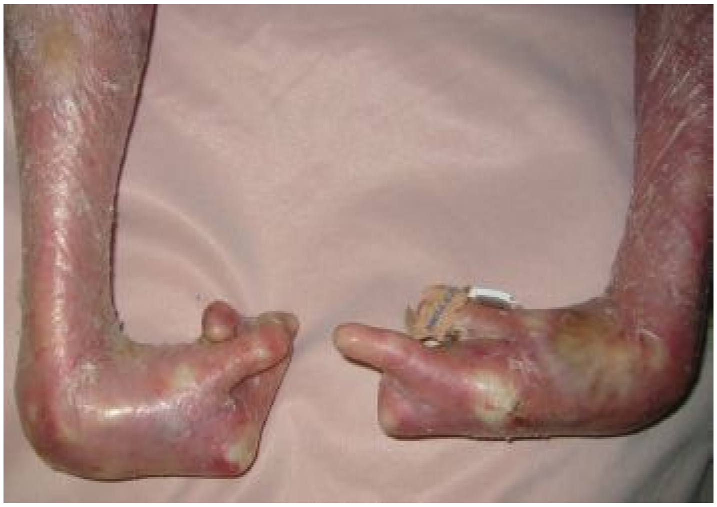

FIGURE 157-2 Recessive dystrophic epidermolysis bullosa in an adolescent with a mitten deformity and flexion contractures at the wrists. (Used with permission from Kane KS, Lio PA, Stratigos AJ, Johnson RA. Color Atlas & Synopsis of Pediatric Dermatology, 2nd edition, Figure 5-3b, New York, NY: McGraw-Hill, 2009.)

ETIOLOGY AND PATHOPHYSIOLOGY

Blistering occurs at different levels for these 3 types of EB:

1. Epidermolysis bullosa simplex (**Figure 157-1**) blisters within the epidermis (most superficial).[2,3]

2. Dystrophic epidermolysis bullosa (dominant and recessive) has vesiculobullous skin separation occurring at the sub-basal lamina level of the dermis (deepest layer of all 3 types; **Figures 157-2** to **157-4**).

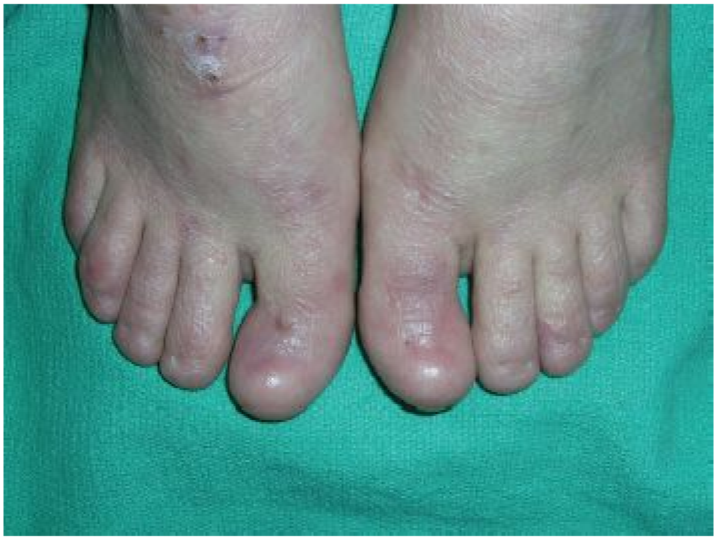

FIGURE 157-3 Recessive dystrophic epidermolysis bullosa with loss of all her toenails starting as a young child. (Used with permission from Richard P. Usatine, MD.)

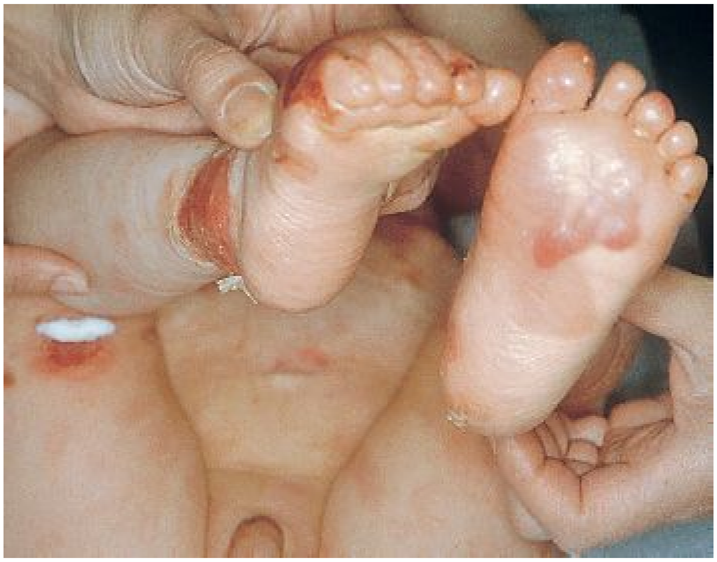

FIGURE 157-4 Recessive dystrophic epidermolysis bullosa in a newborn. Bullae occur at areas of minimal trauma at or near birth. (Used with permission from Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas

and Synopsis of Pediatric Dermatology, 2nd edition, Figure 5-3a, New York, NY: McGraw-Hill, 2009.)

3. Junctional epidermolysis bullosa blisters at the dermal-epidermal junction (**Figure 157-5**).

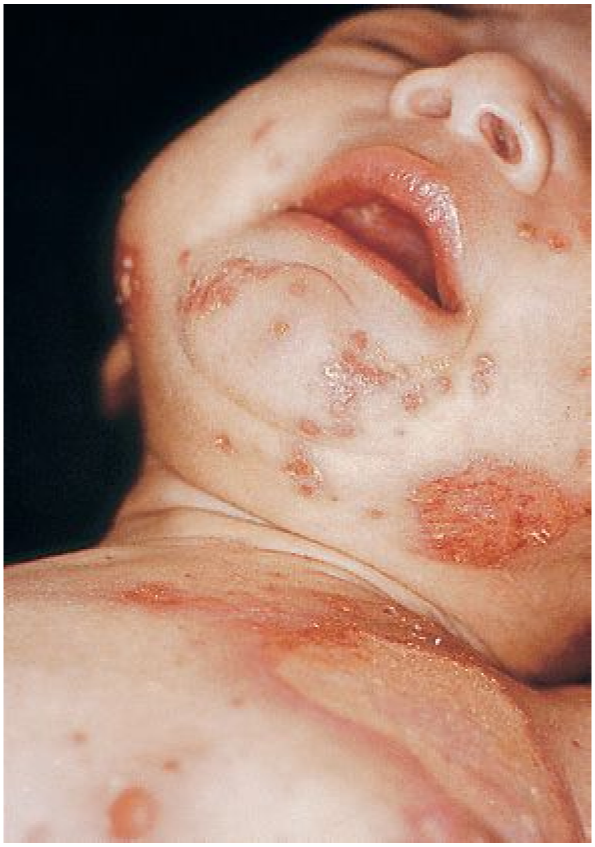

FIGURE 157-5 Junctional epidermolysis bullosa in a newborn with severe perioral, oral and GI involvement. This infant was subsequently hospitalized and despite burn unit supportive measures eventually passed away because of sepsis. (Used with permission from Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 5-2c, New York, NY: McGraw-Hill, 2009.)

DIAGNOSIS

CLINICAL FEATURES

Acral skin fragility and blistering are the hallmark in childhood. Minor trauma can induce severe blistering. As the disease progresses initially, painful and ultimately debilitating dystrophic deformities are typical. Repeated blistering of the hands can lead to fusion of the fingers and the “mitten” deformity (**Figure 157-2**).

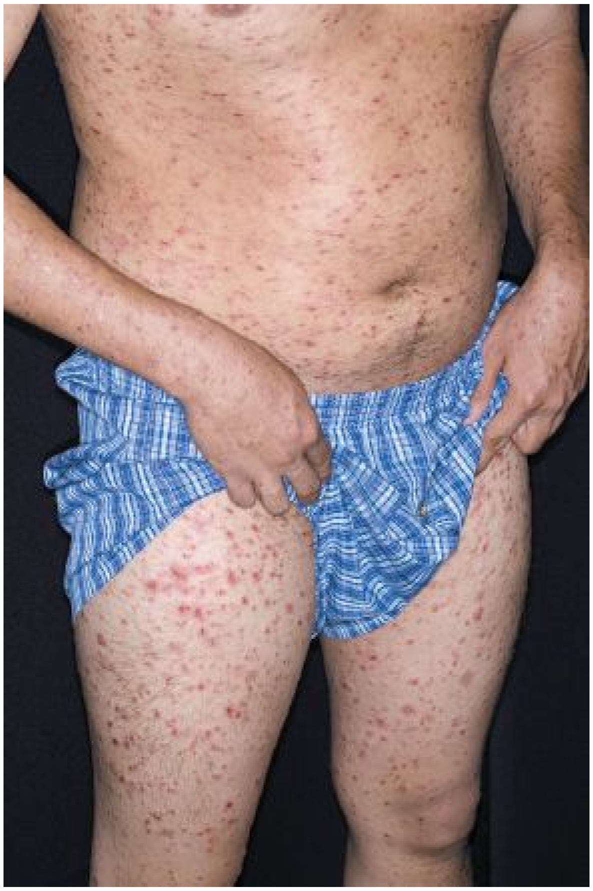

FIGURE 157-6 A college student with pityriasis lichenoides et varioliformis acuta. His skin lesions cleared with oral doxycycline. (Used with permission from Richard P, Usatine, MD.)

TYPICAL DISTRIBUTION

The typical distribution is acral (hands and feet), although blistering may extend proximally secondary to trauma.

LABORATORY STUDIES AND BIOPSY

There are no laboratory tests to confirm the diagnosis. A punch biopsy can provide adequate tissue for the dermatopathologist to differentiate between the different forms of epidermolysis bullosa: simplex, junctional, and dystrophic.

DIFFERENTIAL DIAGNOSIS

- Erythema multiforme bullosum may have a similar appearance, but the distribution is less apt to be limited to the distal extremities.
- The first appearance of the condition may be confused, with staphylococcal scalded skin syndrome (see Chapter 105, Staphylococcal Scalded Skin Syndrome).[4]

MANAGEMENT

Management is primarily prevention of trauma, careful wound care, and treatment of complicating infections. Other supportive measures such as pain management and nutritional support are often necessary. Screening the skin for squamous cell carcinoma is important in adulthood for the dystrophic form.[2]

FOLLOW-UP

Periodic skin examinations should be done to help manage symptoms and screen for malignancy.

PATIENT EDUCATION

Avoid trauma and come in early if there are any signs of infection or malignancy.

PITYRIASIS LICHENOIDES ET VARIOLIFORMIS ACUTA

PATIENT STORY

A young man presented with a varicelliform eruption that he has had for 6 weeks (**Figure 157-6**). Initially, he was diagnosed with varicella and given a course of acyclovir. Then he was misdiagnosed with scabies and treated with permethrin. A correct diagnosis of PLEVA was made by clinical appearance and confirmed with biopsy. His skin lesions cleared with oral doxycycline.

EPIDEMIOLOGY

- PLEVA or Mucha-Habermann disease and pityriasis lichenoides chronica are maculopapular erythematous eruptions that can occur in crops of vesicles that can become hemorrhagic over a course of weeks to months (**Figures 157-7**).[5]

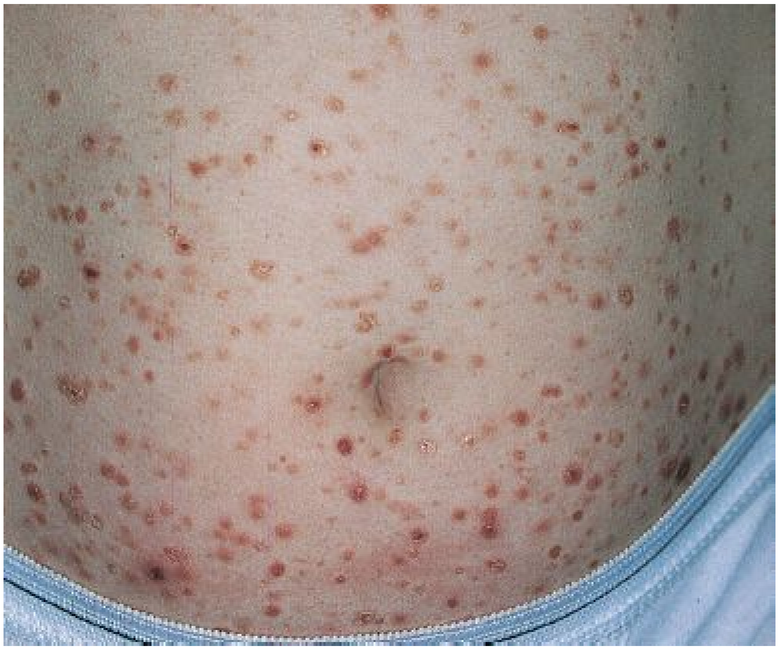

FIGURE 157-7 A teenager with pityriasis lichenoides et varioliformis acuta (PLEVA, Mucha-Habermann disease). (Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 9-35, New York, NY: McGraw-Hill, 2008.)

- There is a predilection for males in the second and third decades.
- PLEVA occurs in preschool and preadolescent children as well.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

- PLEVA has traditionally been classified as a benign papulosquamous disease. However, there is increasing evidence that suggests that PLEVA should be considered a form of cutaneous lymphoid dyscrasia.[7] It may even represent an indolent form of mycosis fungoides.

DIAGNOSIS

CLINICAL FEATURES

PLEVA occurs with crops of maculopapular and papulosquamous lesions that can vesiculate and form hemorrhagic vesicles (**Figures 157-6** and **157-7**). Although it resembles varicella, new crops of lesions continue to appear over weeks and months. It can be thought of as “chickenpox that lasts for weeks to months.”

TYPICAL DISTRIBUTION

Lesions typically occur over the anterior trunk and flexural aspects of the proximal extremities. The face is spared.

LABORATORY STUDIES

There are no specific laboratory tests for PLEVA except biopsy.

BIOPSY

A punch biopsy is helpful in making the diagnosis. It may be necessary to differentiate PLEVA from lymphomatoid papulosis (see the following section “Differential Diagnosis”).

DIFFERENTIAL DIAGNOSIS

- Varicella—A varicella direct fluorescent antibody test can confirm acute varicella. If no viral testing was done and what appeared to be varicella persists, PLEVA should be considered (Chapter 108, Chickenpox).
- Pityriasis lichenoides chronica is the chronic form of PLEVA and can be distinguished from PLEVA by length of time and biopsy (**Figure 157-8**). It has a more low-grade clinical course than PLEVA and the lesions appear over a longer course of time.

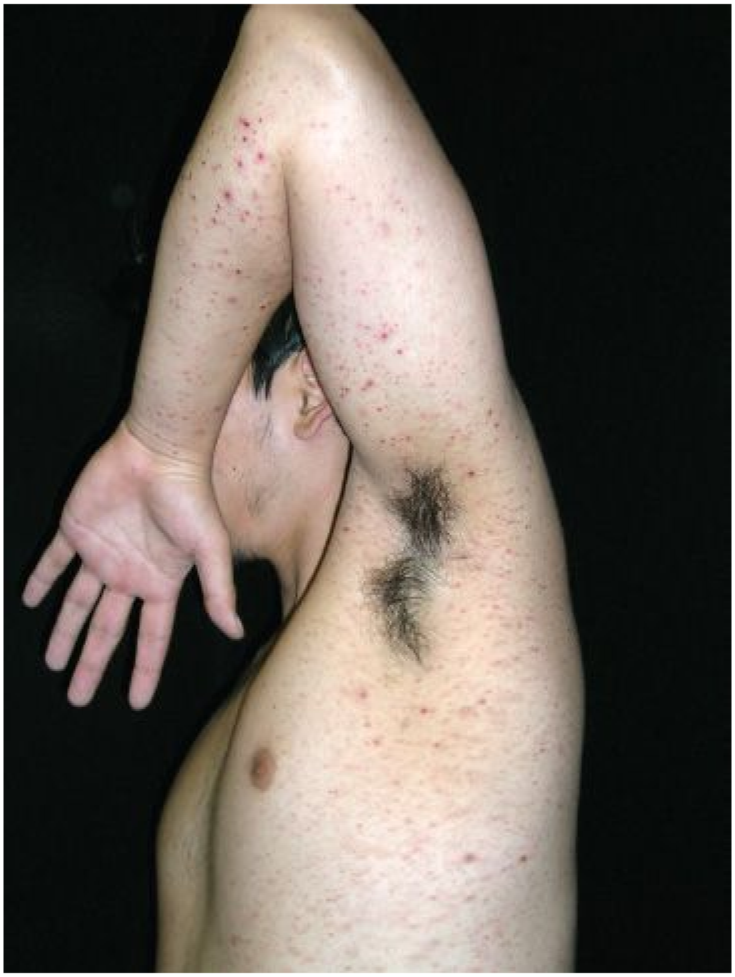

FIGURE 157-8 Pityriasis lichenoides chronica is the chronic form of pityriasis lichenoides et varioliformis acuta that may persist for months to years. (Used with permission from Richard P. Usatine, MD.)

- Erythema multiforme is a hypersensitivity syndrome in which target lesions are seen. The target lesions have epidermal disruption in the center with vesicles and/or erosions. Look for the target lesions to help differentiate this from PLEVA (see Section 12, Hypersensitivity Syndromes and Drug Reactions).
- Lymphomatoid papulosis presents in a manner similar to PLEVA with recurrent crops of pruritic papules at different stages of development that appear on the trunk and extremities. Although it has histologic features that suggest lymphoma, lymphomatoid papulosis alone is not fatal. It is important to differentiate this from PLEVA because these patients need to

be worked up for coexisting malignancy. These patients tend to be older and a punch biopsy can make the diagnosis.

- Gianotti-Crosti syndrome (papular acrodermatitis of childhood) may resemble PLEVA but the lesions are usually acral in distribution (**Figure 157-9**).[3] The erythematous papules and vesicles are found on the extremities and sometimes on the face. It is a benign syndrome associated with many childhood viruses that may last 2 to 8 weeks.

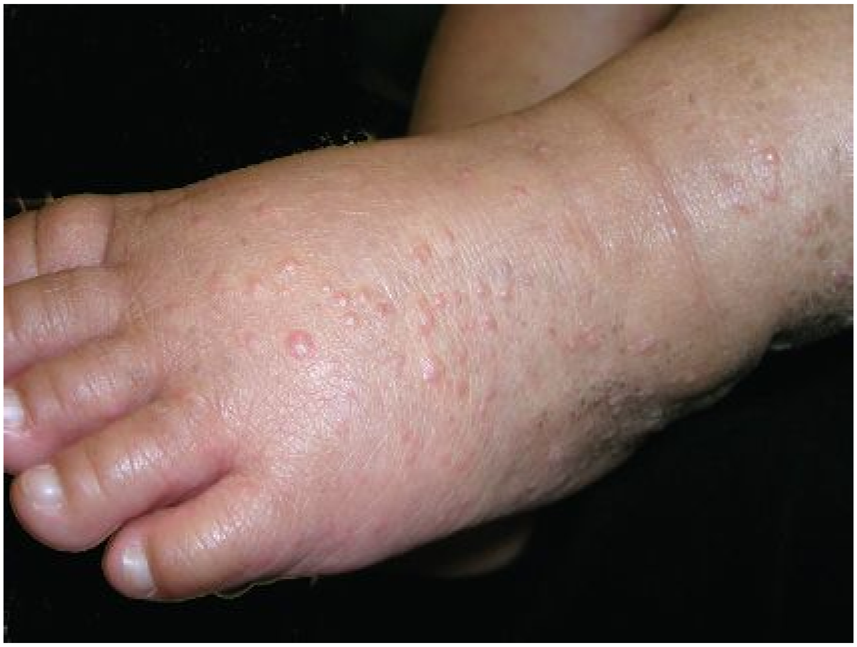

FIGURE 157-9 Gianotti-Crosti syndrome, “papular acrodermatitis of childhood,” in a 7-month-old child. The acral eruption started just after a viral upper respiratory infection and involved the feet, lower legs, and buttocks. (Used with permission from Richard P. Usatine, MD.)

MANAGEMENT

- UV A1 phototherapy has been deployed with some success.[8] Various reports suggest the efficacy of macrolides and tetracyclines, probably more for their antiinflammatory properties than for their antibacterial effects.

FOLLOW-UP

Needed only if the disease does not resolve.

PATIENT EDUCATION

This is usually a temporary disease but if it becomes chronic there are treatments that could help such as oral macrolides or doxycycline.

DERMATITIS HERPETIFORMIS

PATIENT STORY

A young man with a past history of diarrhea and malabsorption carries a past diagnosis of gluten-induced enteropathy. Despite a gluten-free diet he continues to have a pruritic eruption on his shoulders, back, extremities and buttocks (**Figures 157-10** and **157-11**). While the most likely diagnosis is dermatitis herpetiformis, a punch biopsy was performed to confirm this before starting the patient on oral dapsone.

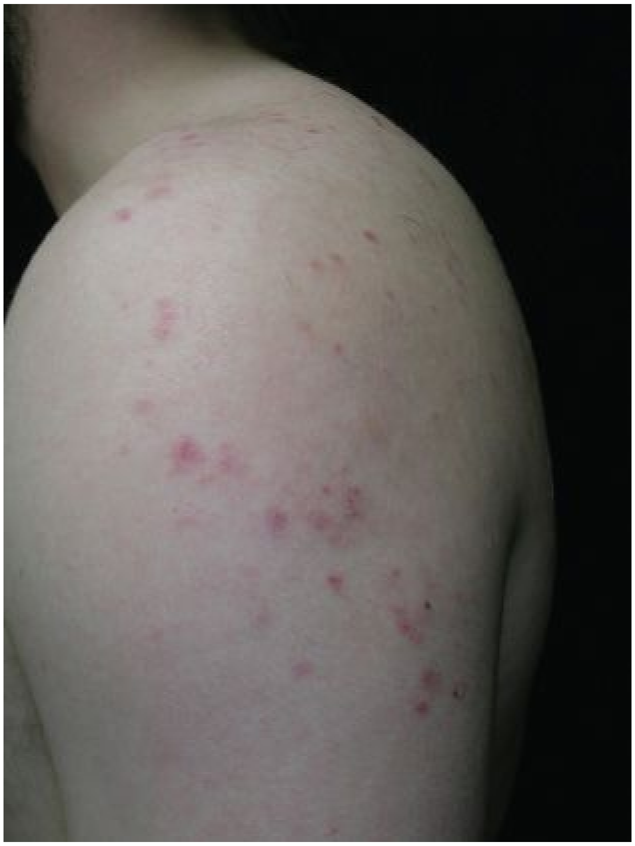

FIGURE 157-10 A young man with dermatitis herpetiformis and gluten-induced enteropathy. The daily vesicles that form are fragile and rapidly become small erosions. (Used with permission from Richard P. Usatine, MD.)

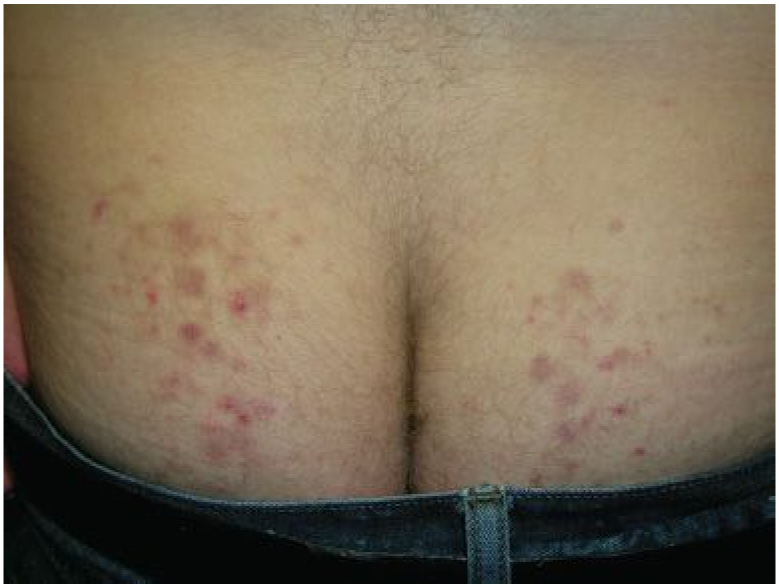

FIGURE 157-11 Dermatitis herpetiformis that has persisted even though he is on a strict gluten-free diet. The buttocks is a commonly involved area. His gastrointestinal symptoms have resolved on the gluten-free diet but his eruption has only diminished. His skin lesions resolved with oral dapsone. (Used with permission from Richard P. Usatine, MD.

EPIDEMIOLOGY

- Dermatitis herpetiformis is a chronic recurrent symmetric vesicular eruption that is usually associated with diet-related enteropathy.[9] It most commonly occurs in the 20 to 40 years of age group. Men are affected more often than women.

ETIOLOGY AND PATHOPHYSIOLOGY

- The disease is related to gluten and other diet-related antigens that cause the development of circulating immune complexes and their subsequent deposition in the skin. The term *herpetiformis* refers to the grouped vesicles that appear on extensor aspects of the extremities and trunk and is not a viral infection or related to the herpes viruses. The disease is characterized by the deposition of immunoglobulin (Ig) A along the tips of the dermal papillae. The majority of patients will also have blunting and flattening of jejunal villi, which leads to diarrhea even to the point of steatorrhea and malabsorption.

DIAGNOSIS

CLINICAL FEATURES

The clinical eruption is characterized by severe itching, burning, or stinging in the characteristic extensor distribution. Herpetiform vesicles and urticarial plaques may be seen. Because of the intense pruritus, characteristic lesions may be excoriated beyond recognition (**Figures 157-10** to **157-12**).

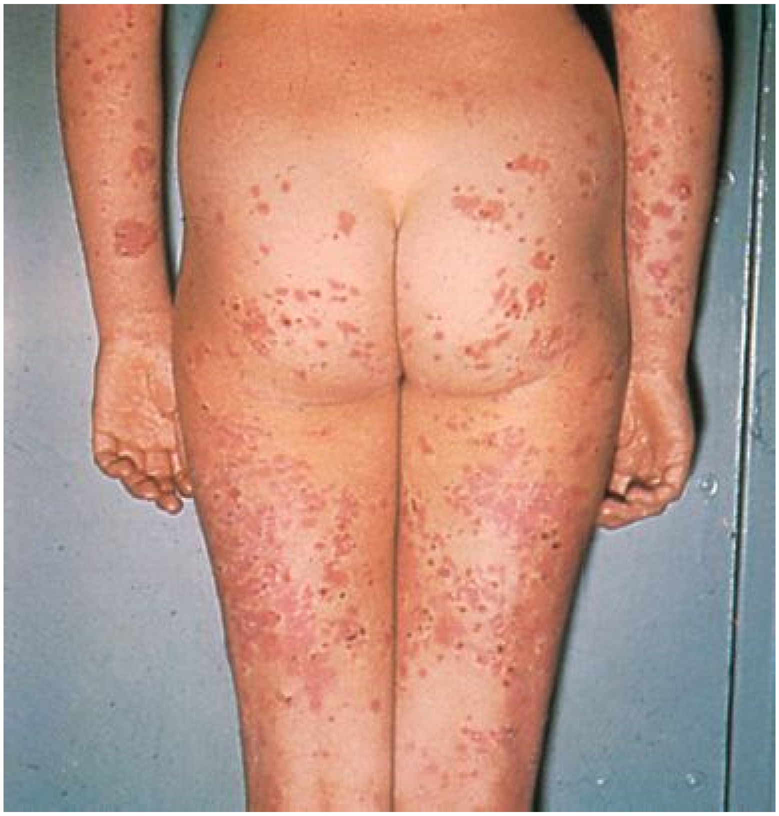

FIGURE 157-12 Dermatitis herpetiformis showing erosions from vesicles and bullae on the buttocks, legs and arms in a young girl with gluten-induced enteropathy. (Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 14-32, New York, NY: McGraw-Hill, 2008.

TYPICAL DISTRIBUTION

Classically, the lesions (or excoriations) are seen in the extensor aspects of the extremities, shoulders (**Figure 157-10**), lower back, and buttocks (**Figures 157-11** and **157-12**).

LABORATORY STUDIES

If the patient has gluten-induced enteropathy, antigliadin and antiendomysial antibodies may be present. A blood test for antigliadin antibody is a sensitive test for gluten-induced enteropathy.

BIOPSY

Diagnosis is confirmed by a punch biopsy. It is best to biopsy new crops of lesions. A standard histologic examination will show eosinophils and microabscesses of neutrophils in the dermal papillae and subepidermal vesicles. Direct immunofluorescence reveals deposits of IgA and complement within the dermal papillae.

DIFFERENTIAL DIAGNOSIS

- Scabies may have a similar appearance with pruritus, papules, and vesicles. If the lesions and distribution suggest scabies, it should be ruled out with skin scraping looking for the mite, feces, and eggs. If the scraping is negative, but the clinical appearance suggests scabies, empiric treatment with permethrin should be considered as well. If the lesions persist, consider a punch biopsy to look for dermatitis herpetiformis (Chapter 128, Scabies).
- Nummular and dyshidrotic eczema may also be diagnostic considerations, but response to steroids in eczema may be helpful in differentiation (Chapter 130, Atopic Dermatitis).

MANAGEMENT

- With a gluten-free diet, 80 percent of patients will show improvement in the skin lesions. The degree of benefit is dependent upon the strictness of the diet.[9]

- A gluten-free diet may help the enteropathy and decrease the subsequent development of small bowel lymphoma.
- Dapsone may be necessary indefinitely.[10]

FOLLOW-UP

Follow-up is needed to control the disease and monitor nutritional status.

PATIENT EDUCATION

Nutritional counseling is important for all patients with gluten-induced enteropathy. Persons with dermatitis herpetiformis and gluten-induced, enteropathy should not eat wheat and barley but can eat rice, oats, and corn.

SECTION 14 HAIR AND NAIL CONDITIONS

158 ALOPECIA AREATA

Richard P. Usatine, MD

PATIENT STORY

An 8-year-old Hispanic girl was brought to her physician by her mother, who noticed two bald spots on the back of her daughter's scalp while brushing her hair. The child had no itching or pain. The mother was more worried that her beautiful girl would become bald. The girl was pleased that the bald spots could be completely covered with her long hair, as she did not want anyone to see them. The child was otherwise healthy. When the mother lifted the hair in the back, two round areas of hair loss were evident (**Figure 158-1**). On close inspection, there was no scaling or scarring. The mother and child were reassured that alopecia areata (AA) is a condition in which the hair is likely to regrow without treatment. Neither of them wanted intralesional injections or topical therapies. During a well-child examination 1 year later, it was noted that the girl's hair had fully regrown.[1]

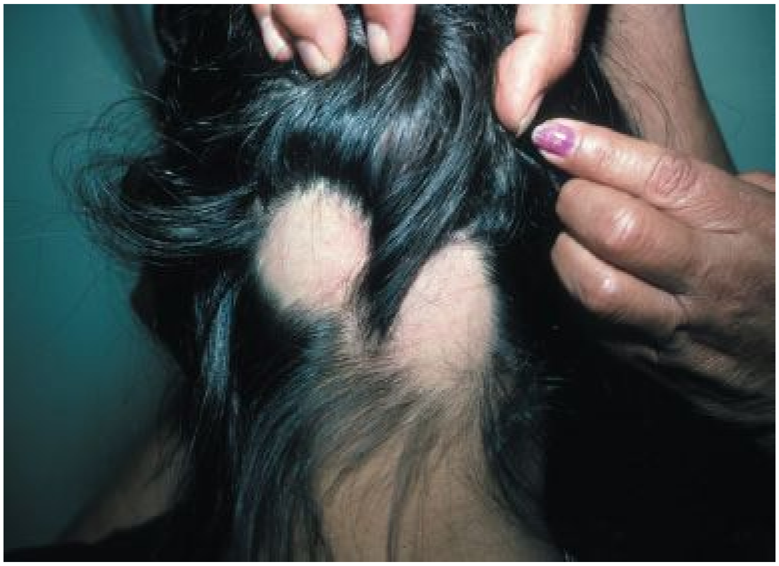

FIGURE 158-1 Alopecia areata in an 8-year-old girl. (From Usatine R. Bald spots on a young girl. J Fam Pract. 2004;53(1):33-36. Reproduced with permission from Frontline Medical Communications.)

INTRODUCTION

AA is a common disorder that causes patches of hair loss without inflammation or scarring. The areas of hair loss are often round and the scalp is often very smooth at the site of hair loss.

SYNONYMS

Alopecia totalis involves the whole scalp. Alopecia universalis (AU) involves the whole scalp, head, and body (**Figure 158-2**). Limited alopecia areata on the scalp is called “patchy” alopecia areata or patch AA.

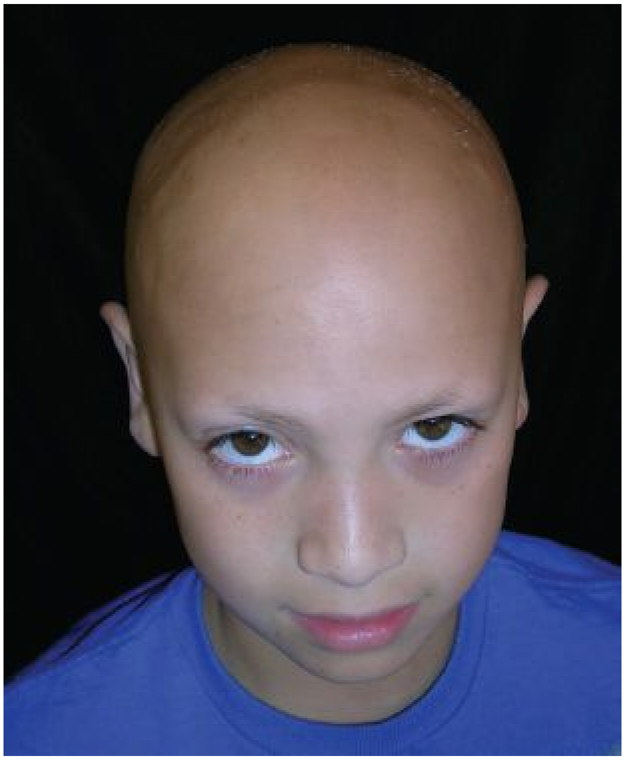

FIGURE 158-2 Alopecia universalis in a 10-year-old boy that started when he was 3 years old. The hyperpigmentation and peeling on his scalp is from repeated sun burns. He does have eyelashes and the medial sides of his eyebrows. Many children with alopecia universalis lose their eyebrows and eyelashes along with all their body hair. (Used with permission from Richard P. Usatine, MD.)

EPIDEMIOLOGY

- Alopecia areata affects approximately 0.2 percent of the population at any given time with approximately 1.7 percent of the population experiencing an episode during their lifetime.[2,3]
- Males and females are equally affected.
- Patients with alopecia totalis and/or universalis were younger at the age of onset than those with patchy AA, were more likely to have atopic dermatitis, thyroid disease, and had a greater number of relatives affected by AA.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology is unknown but experts presume that the AA spectrum of disorders is secondary to an autoimmune phenomenon involving antibodies, T cells, and cytokines.

RISK FACTORS

- Previous episode of AA.

- Family history of AA—In one study, the estimated lifetime risks were 7.1 percent in siblings, 7.8 percent in parents, and 5.7 percent in offspring of patients with AA.[5]

DIAGNOSIS

CLINICAL FEATURES

- Sudden onset of 1 or more 1- to 4-cm areas of hair loss on the scalp (**Figures 158-1** and **158-3**). This can occur in the eyebrows or other areas of hair (**Figure 158-4**).

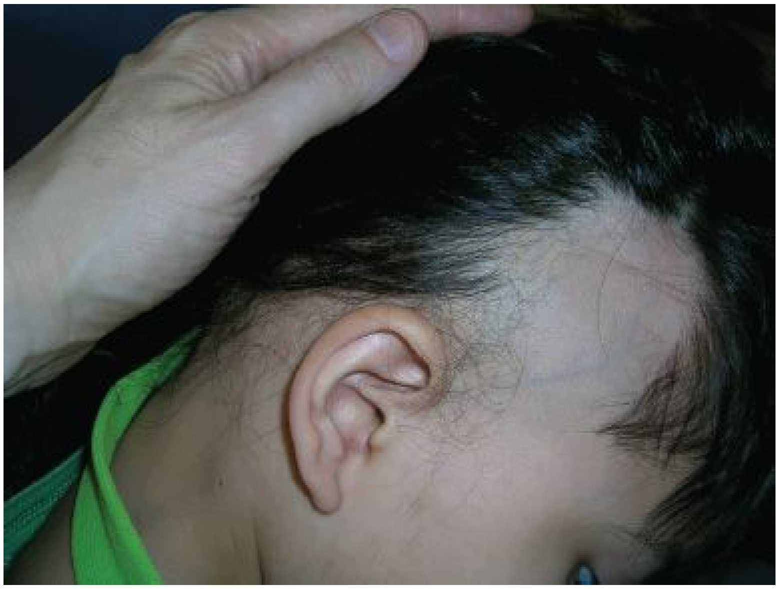

FIGURE 158-3 Alopecia areata for 2 years in a young girl. (Used with permission from Richard P. Usatine, MD.)

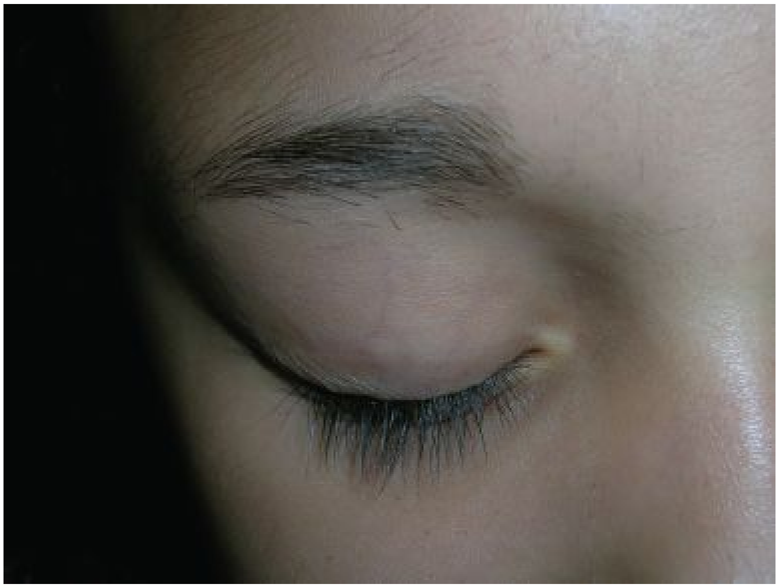

FIGURE 158-4 Alopecia areata in the medial eyebrow a 7-year-old girl. (Used with permission from Richard P. Usatine, MD.)

- The affected skin is smooth and may have short stubble hair growth.
- "Exclamation point" hairs are often noted (**Figure 158-5**). These hairs are characterized by proximal thinning while the distal portion remains of normal caliber.

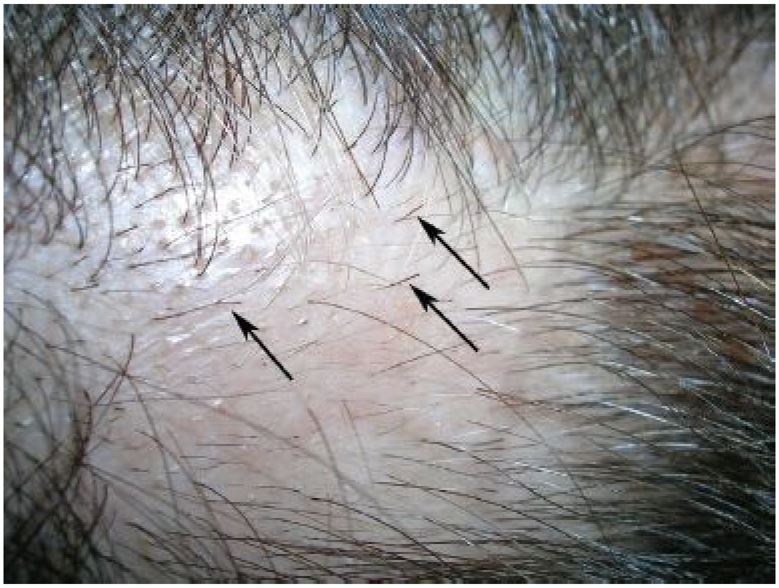

FIGURE 158-5 Exclamation point hairs (arrows) can be seen in this case of alopecia areata. The hair is narrow at the base, short and wide at the end.

(Used with permission from Richard P. Usatine, MD.)

- When hair begins to regrow, it often comes in as fine white hair (**Figure 158-6**).

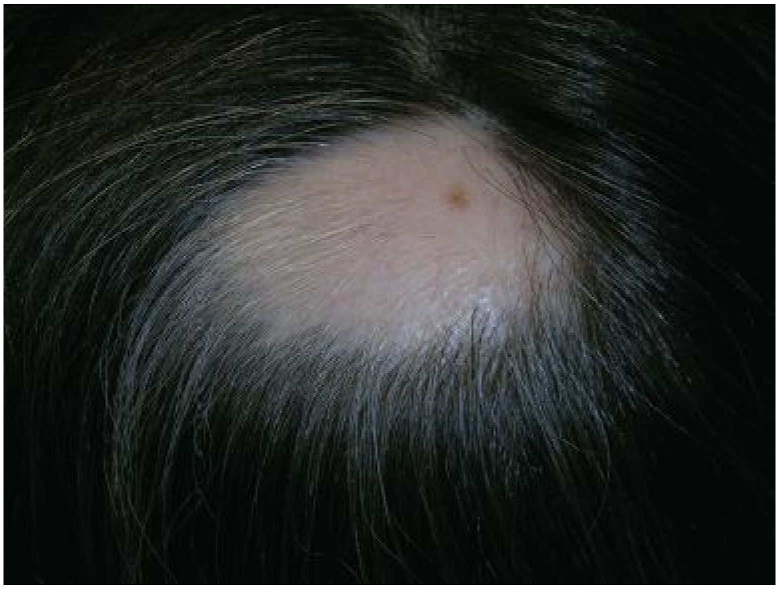

FIGURE 158-6 New growth of white hair after 7 months of alopecia areata. (Used with permission from Richard P. Usatine, MD.)

- Nail dystrophy can occur and might suggest a worse prognosis for hair regrowth.

TYPICAL DISTRIBUTION

- Scalp and eyebrows but can involve any area with hair.
- Ophiasis is the term used to describe the distribution of alopecia areata when the hair loss follows a serpent-like distribution on the scalp (**Figures 158-7** and **158-8**). It is said to have a worse prognosis but studies to prove this are lacking. This pattern can also be seen with traction alopecia so hair care practices should be queried.

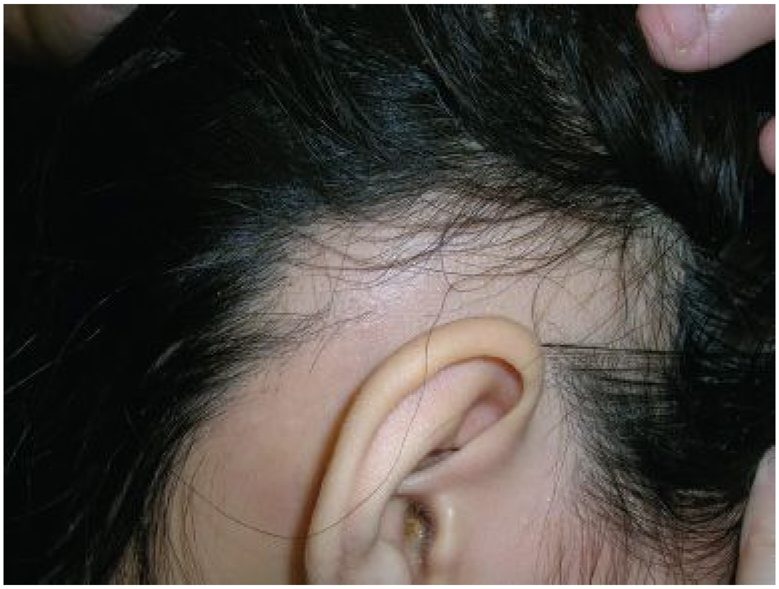

FIGURE 158-7 Ophiasis pattern of alopecia areata in a 12-year-old girl with atopic dermatitis. Ophiasis means “serpent-like.” (Used with permission from Richard P. Usatine, MD.)

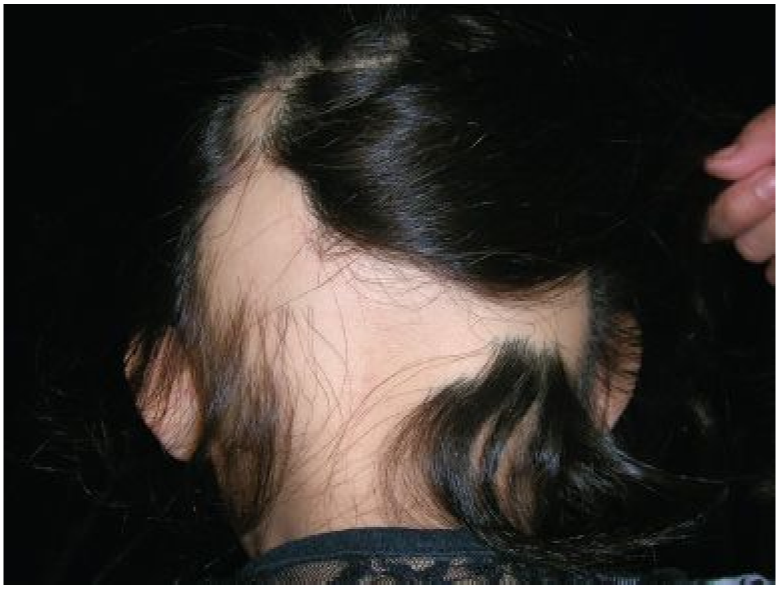

FIGURE 158-8 Ophiasis pattern of extensive alopecia areata in a 6-year-old girl. (Used with permission from Richard P. Usatine, MD.)

LABORATORY STUDIES

- Typically, the diagnosis can be made with history and physical examination alone (**Figure 158-9**).

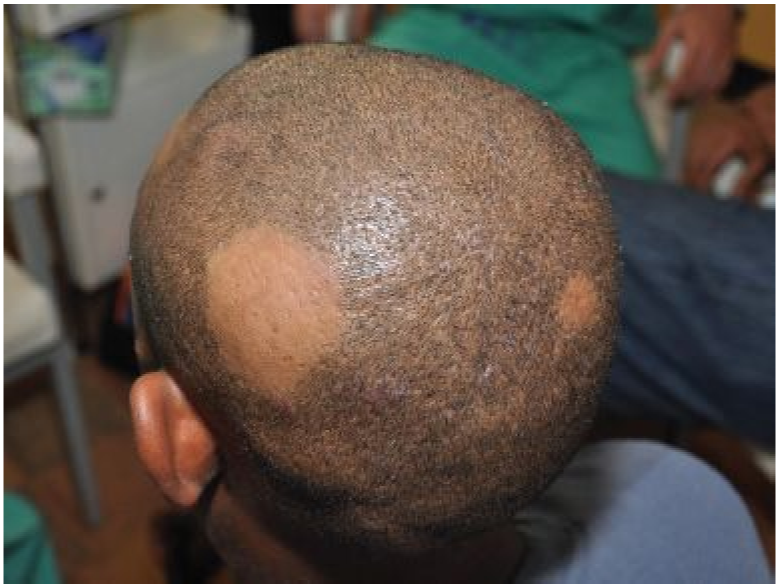

FIGURE 158-9 Alopecia areata with multiple round areas of hair loss in this young African boy. Note how the skin of the affected area appears smooth and there is no scale. (Used with permission from Richard P. Usatine, MD.)

- Thyroid abnormalities, vitiligo, and pernicious anemia often accompany AA. Consequently, screening laboratory tests (e.g., thyroid-stimulating hormone, complete blood count [CBC]) may be helpful to look for thyroid disorders and anemia.

BIOPSY

Not needed unless the diagnosis is uncertain. Histology examination shows peribulbar lymphocytic infiltration, frequently including eosinophils and the previously mentioned (see “Clinical Features”) “exclamation point” hairs.

DIFFERENTIAL DIAGNOSIS

- Trichotillomania—History of hair pulling; short, “broken” hairs are seen (see Chapter 159, Traction Alopecia and Trichotillomania).
- Telogen effluvium—Even distribution of hair loss; may be drug-induced (e.g., warfarin, b blockers, or lithium) or occur after pregnancy.
- Anagen effluvium—History of drug use (e.g., chemotherapy); even distribution of hair loss.
- Tinea capitis—Skin scaling and inflammation; KOH prep or fungal culture, if necessary (see Chapter 122, Tinea Capitis).
- Secondary syphilis—“Moth-eaten” appearance in beard or scalp; risk factors and rapid plasma reagin (RPR) will help distinguish (see Chapter 181, Syphilis).
- Lupus erythematosus—Skin scarring; antinuclear antibody (ANA) if clinical presentation compatible with this diagnosis (see Chapter 173, Lupus: Systemic and Cutaneous).

MANAGEMENT

- Alopecia areata can lead to significant psychological distress for the child and family. Counseling the child and parents about the nature and course of the condition as well as the available treatments is critical to management.[6]
- Treatment for AA includes immune-modulating agents (e.g., corticosteroids or anthralin), and biologic response modifiers (e.g., minoxidil).[6,7] SOR Ⓒ
    - A commonly used treatment in patients older than 10 years of age with less than 50 percent scalp involvement is intralesional steroids (**Figure 158-10**). SOR Ⓑ

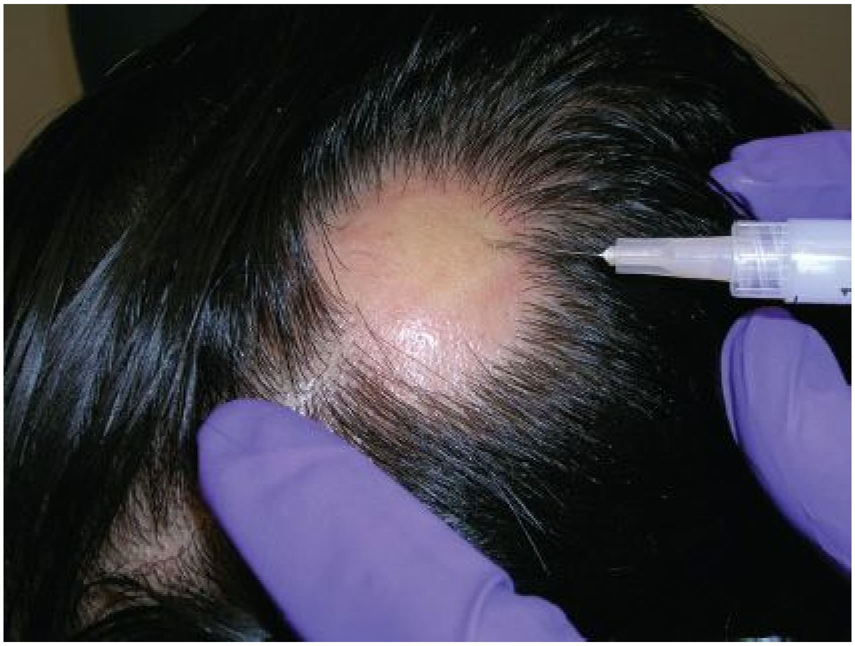

FIGURE 158-10 Injecting alopecia areata with triamcinolone acetonide 5 mg/mL. (Used with permission from Richard P. Usatine, MD.)

- In one randomized controlled trial (RCT), intralesional triamcinolone acetonide (10 mg/mL every 3 weeks) was better than betamethasone valerate foam and topical tacrolimus in the management of localized AA.[8] There was no satisfactory hair regrowth in the tacrolimus group.[8] Although 10 mg/mL triamcinolone is often used as treatment, there is a higher rate of scalp atrophy than with 5 mg/mL. Start with 5 mg/mL and consider 10 mg/mL in subsequent injections if there is acceptance of a higher risk of scalp atrophy.
- Triamcinolone acetonide (Kenalog)—Dilute with sterile saline to 5 mg/mL. Inject with a 3-mL or 5-mL syringe and a 27- or 30-gauge needle. Inject into the dermis of the involved areas but not to exceed 4 mL per visit. Use 2.5 mg/mL for involved areas of the eyebrows or beard. SOR Ⓒ
- Skin atrophy can be reduced by injecting intradermally and limiting both the volume per site and the frequency of injections (4 to 6 weeks between injections). Do not reinject areas that show atrophy and in most cases, the atrophy will resolve spontaneously. SOR Ⓒ
- Spontaneous regrowth may still occur, so steroid injections should be discontinued after 6 months.

  - For patients younger than age 10 years, a mid-potency topical steroid such as triamcinolone 0.1 percent cream applied twice daily is one option. SOR Ⓒ

A Cochrane review in 2008 concluded that most trials have been reported poorly and are so small that any important clinical benefits are inconclusive.[9] They stated that considering the possibility of spontaneous remission (especially for those in the early stages of the disease) the options of not treating or wearing a wig are reasonable alternatives.[9]

- Hairpieces and hair transplantation may be used for those patients with unresponsive, recalcitrant disease.

COMPLEMENTARY/ALTERNATIVE THERAPY

- One RCT showed aromatherapy with topical essential oils to be a safe and effective treatment for AA.[10] The active group massaged essential oils (thyme, rosemary, lavender, and cedarwood) in a mixture of carrier oils (jojoba and grapeseed) into their scalp daily. This is a good option for families that want to do something but want to avoid the use of steroids. SOR Ⓑ

PATIENT EDUCATION AND PROGNOSIS

- Although spontaneous recovery usually occurs, the course of AA is unpredictable and often characterized by recurrent periods of hair loss and regrowth.
- Spontaneous long-term regrowth in alopecia totalis and AU is poor.
- Prognosis is worse if the alopecia persists longer than 1 year.
- Alopecia areata, totalis and universalis can actually resolve spontaneously at any time as the hair follicle retains its ability to regrow even years after the initial loss of hair.

- Patients with a family history of AA, younger age at onset, coexisting immune disorders, nail dystrophy, atopy, and widespread hair loss have a poorer prognosis.[5]

FOLLOW-UP

- Spontaneous recovery usually occurs within 6 to 12 months and the prognosis for total permanent regrowth with limited involvement (AA) is excellent.
- The regrown hair is usually of the same texture and color but may be fine and white at first (**Figure 158-5**).
- Ten percent of patients never regrow hair and advance to chronic disease. Clinicians should provide contact information to the National Alopecia Areata Foundation and offer follow-up in the office as necessary.

159 TRACTION ALOPECIA AND TRICHOTILLOMANIA

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 17-year-old Hispanic girl is brought to the office by her mother who is worried about the hair loss that has been going on for the past 3 months. The physician recognized the pattern of trichotillomania (**Figure 159-1**) and asked the girl if she was pulling on her hair. She told the doctor that this has been a very stressful year for her as she is currently taking four Advanced-Placement courses simultaneously. She admitted to playing with her hair while studying and sometimes that involved pulling on the hairs. The physician explained to the girl and her mother that this was a case of trichotillomania. He asked if the girl would be willing to stop pulling on her hairs and if she would like further counseling. She promised the doctor and her mother that she would stop pulling her hair and preferred to not enter counseling at this time. A follow-up appointment for one month was set.

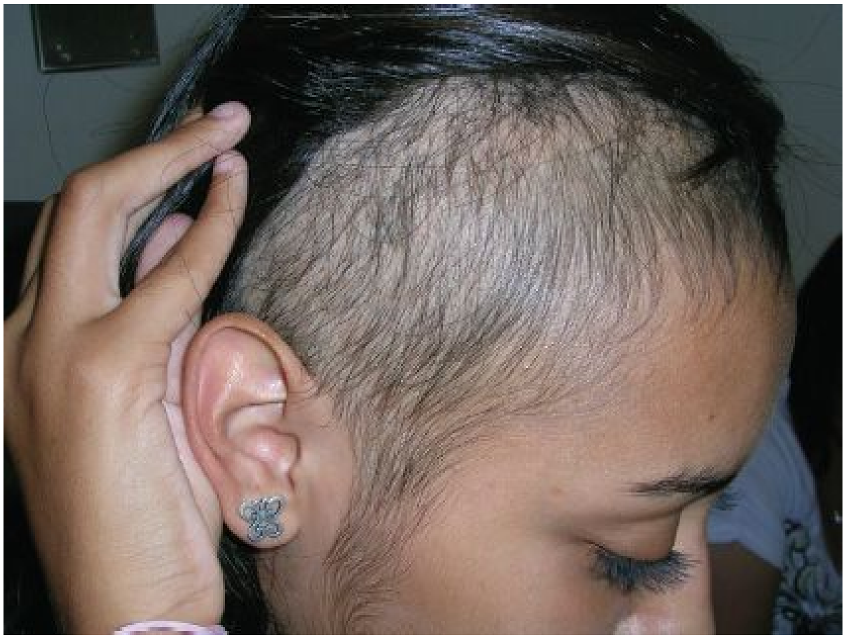

FIGURE 159-1 Trichotillomania in his 17-year-old honors student who is currently taking four Advanced Placement courses simultaneously. (Used with permission from Richard P. Usatine, MD.)

INTRODUCTION

Traction alopecia is hair loss caused by damage to the dermal papilla and hair follicle by constant pulling or tension over a long period. It often occurs in persons who wear tight braids, especially “cornrows” that lead to high tension, pulling, and breakage of hair. Trichotillomania (Greek for “hair-pulling madness”) is a traction alopecia related to a compulsive disorder caused when patients pull on and pluck hairs, often creating bizarre patterns of hair loss.

EPIDEMIOLOGY

- The prevalence of traction alopecia (**Figures 159-1** and **159-2**) is unknown and varies by cultural hairstyle practices. It is most commonly seen in females and children.[1]

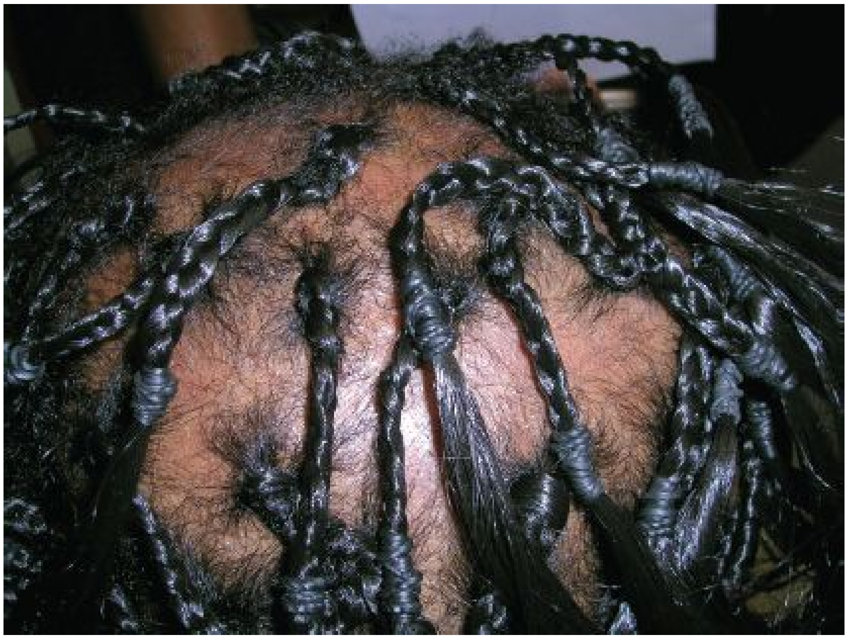

FIGURE 159-2 Traction alopecia in a young African American girl whose mom braids her hair tightly. (Used with permission from Richard P. Usatine, MD.)

- The prevalence of trichotillomania (**Figures 159-3** to **159-6**) is also difficult to determine, but is estimated to be approximately 1.5 percent of males and 3.4 percent of females in the US. The mean age of onset of trichotillomania is 8 years in boys and 12 years in girls, and it is the most common cause of childhood alopecia.[2]

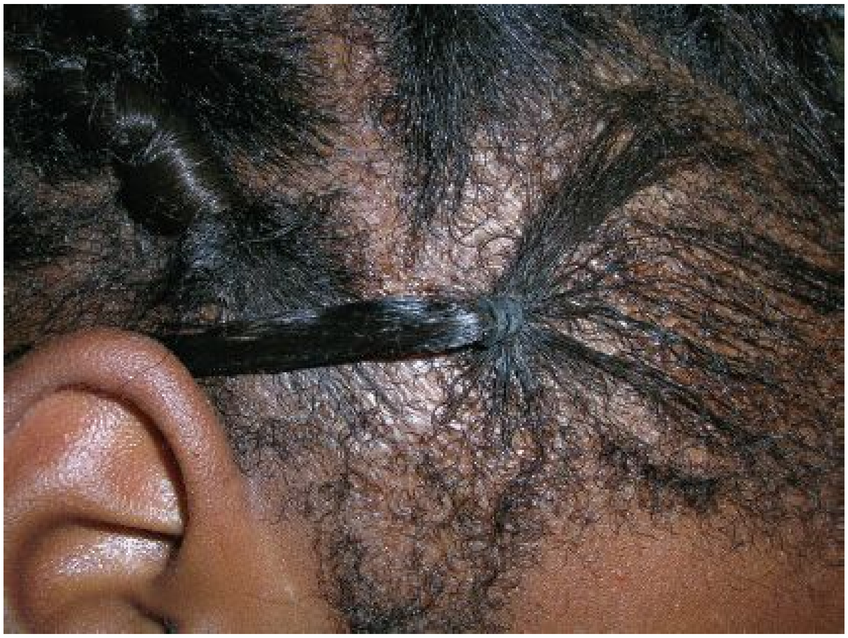

FIGURE 159-3 Traction alopecia on the lateral aspect of the scalp of a young girl due to pulling the hair tightly with rubber bands. (Used with permission from Richard P. Usatine, MD.)

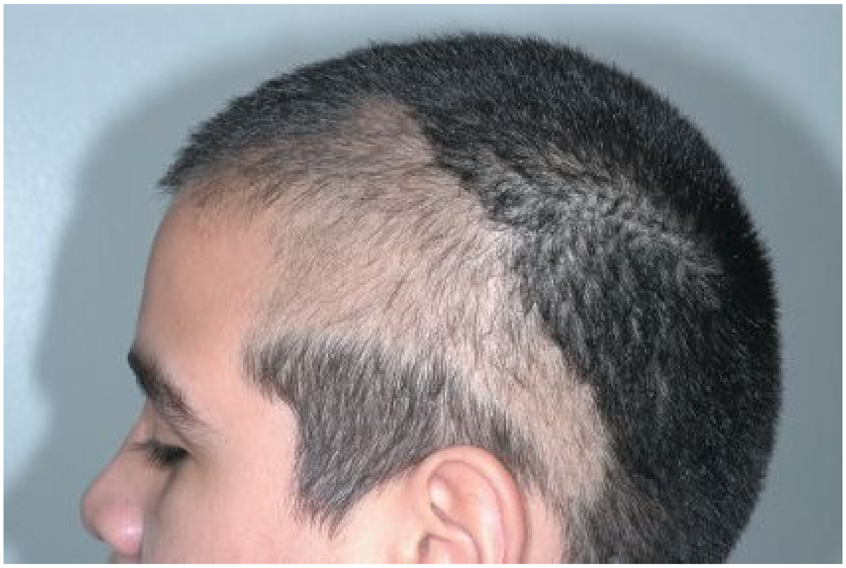

FIGURE 159-4 Trichotillomania in an 11-year-old boy. Note the incomplete hair loss and unusual geometric pattern. He was receiving help and the hair is now growing in. (Used with permission from Richard P. Usatine, MD.)

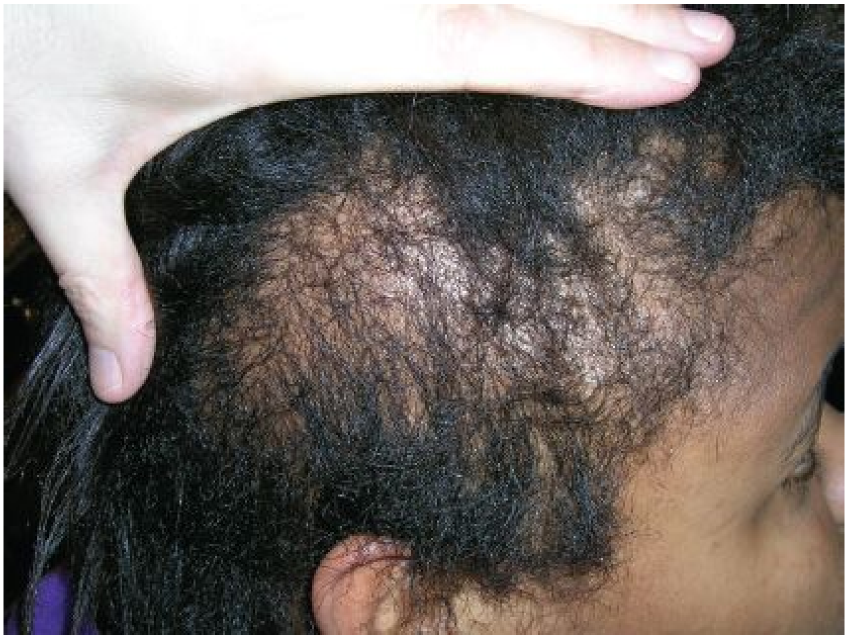

FIGURE 159-5 Trichotillomania in a 12-year-old black girl. The lateral right scalp was most involved. (Used with permission from Richard P. Usatine, MD.)

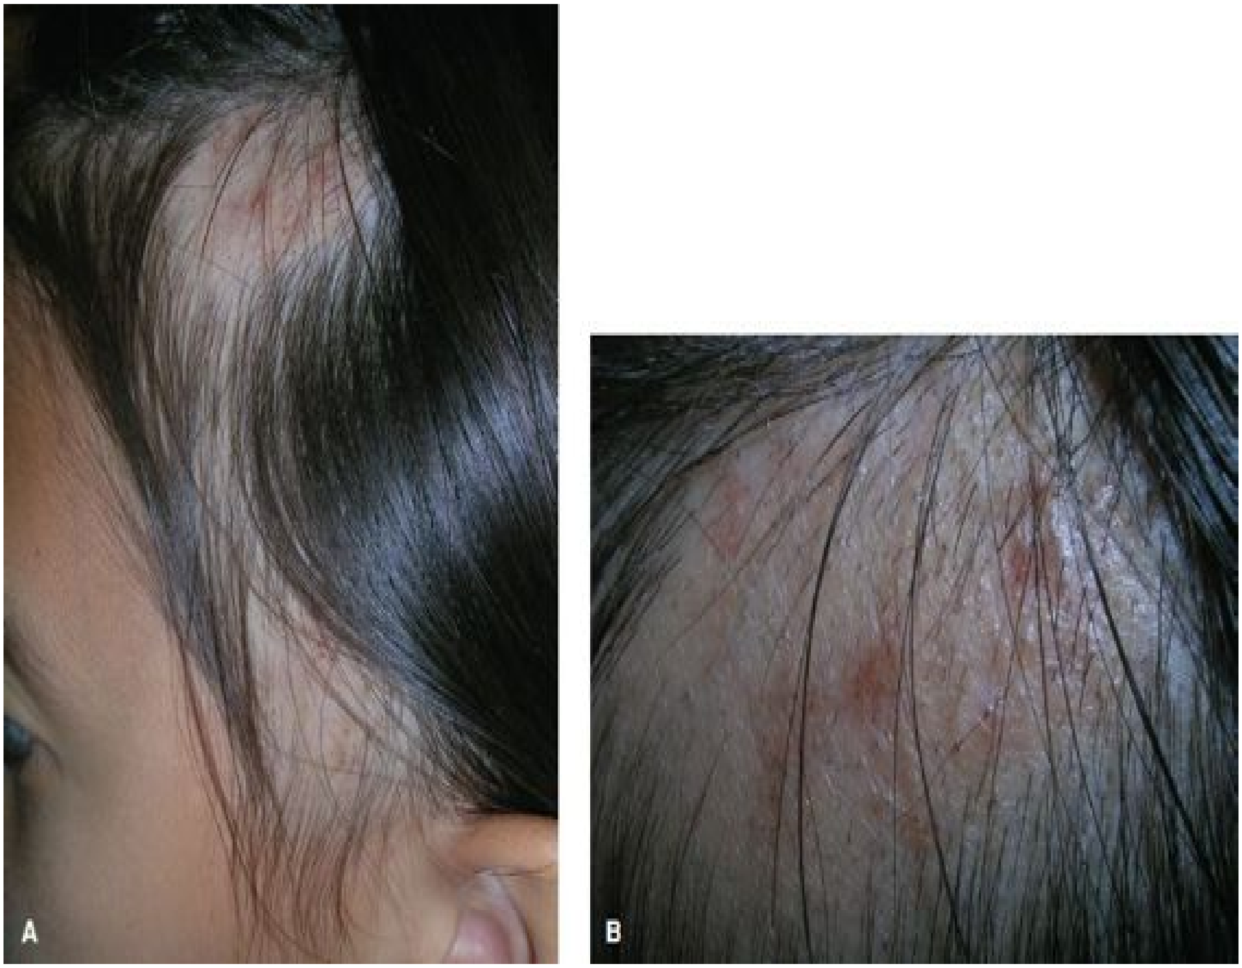

FIGURE 159-6 A. Trichotillomania in a 12-year-old girl undergoing much stress because of conflict in her family. B. Close-up of trichotillomania showing broken hairs, black dots, and excoriations. (Used with permission from Richard P. Usatine, MD.)

ETIOLOGY AND PATHOPHYSIOLOGY

- Traction alopecia is seen in individuals who place chronic tension on the hair shafts with tight braids, heavy natural hair, use of hair prostheses, or chronic pulling (**Figures 159-1** and **159-2**).[1] It also occurs commonly in female athletes who pull their hair into tight ponytails.
- Chronic tension on the hair shaft seems to create inflammation within the hair follicle that eventually leads to cessation of hair growth. Because hair

loss from traction alopecia may become permanent, prevention and early treatment are important.

- It is seen most frequently in black women who tightly braid or pull the hair into a hairstyle during youth and on into adulthood. May also be seen in individuals who wear hair prostheses or extensions for a prolonged period of time. It is also seen in Sikh men of India and Japanese women whose traditional hairstyles may pull and damage hair.
- Trichotillomania is a subtype of traction alopecia manifested by chronic hair pulling (**Figures 159-3** to **159-6**) and sometimes hair eating (trichophagy), which can lead to a trichobezoar. It is classified as a psychiatric impulse-control disorder.[3]
- Trichotillomania may be a manifestation of the inability to cope with stress rather than more severe mental disorders.
- Children who exhibit trichotillomania may discontinue the hair pulling with parental support and maturity. Adults who exhibit trichotillomania, even though they are aware of the problem, may require psychiatric intervention to limit the behavior. The hair loss is initially reversible but may become permanent if the habits persist.

DIAGNOSIS

CLINICAL FEATURES

In patients with traction alopecia, there are decreased follicular ostia in the affected area coupled with decreased hair density. The hair loss usually occurs in the frontal and temporal areas but depends on the precipitating hairstyle (**Figures 159-1** and **159-2**). No scalp inflammation or scaling is typically visible. No pain or other discomfort is associated with the condition. Patients with trichotillomania often demonstrate short, broken hairs (**Figure 159-6**) without the presence of inflammation or skin scale early in the disease. The affected areas are not bald, but rather possess hairs of varying length. There may be telltale stubble of hairs too short to pull. The hair loss often follows bizarre patterns with incomplete areas of clearing. The scalp may appear normal or have areas of erythema and pustule formation. With chronic pulling, the hair loss becomes permanent (**Figure 159-4**). The patient may be observed pulling or twisting the hair by friends or family members.

TYPICAL DISTRIBUTION

Trichotillomania most commonly occurs on the scalp and can involve any area of the body that can be reached by the patient.[1] Traction alopecia can occur anywhere on the scalp, but is most commonly seen at the anterior hairline. This is the site where the hair is pulled back from the face into braids or a bun.

LABORATORY STUDIES

Laboratory tests are not needed to make the diagnosis. A hand lens can be used to examine the affected scalp for decreased follicular ostia, if desired. A scalp biopsy (4-mm punch biopsy) may be necessary to make the diagnosis and rule out other etiologies, especially in trichotillomania, because patients may not acknowledge the habit.

Hypothyroidism or hyperthyroidism may be associated with telogen effluvium or alopecia areata. It may be worth ordering a thyroid-stimulating hormone (TSH) if the history and physical exam are not completely convincing for self-induced hair loss.

DIFFERENTIAL DIAGNOSIS[1]

- Alopecia areata is characterized by the total absence of hair in an area and the presence of exclamation point hairs. These hairs are thinner in diameter closer to the scalp and thicker in diameter away from the scalp, creating the appearance of an exclamation point. Hairs are often white when they start to regrow (see Chapter 158, Alopecia Areata).

- Tinea capitis exhibits hairs broken off at the skin surface and the presence of scale and/or inflammation. Some varieties fluoresce when examined with a Wood light (UV light). Microscopy of a KOH preparation may detect the dermatophyte. Sometimes it is necessary to culture some hairs and scale to make this diagnosis (see Chapter 122, Tinea Capitis).

MANAGEMENT

NONPHARMACOLOGIC

- Stop hairstyling practices that led to the traction alopecia. No tight braiding or buns should be worn.[1] SOR C
- For trichotillomania, open discussions with the patient, and the family, if appropriate, are important to understand the reason for the behavior. Many times there are secondary social or emotional issues that must be resolved before the trichotillomania ceases.
    - Cognitive behavioral treatment is the most effective treatment for trichotillomania.[1,3] SOR B
    - Cognitive-behavioral therapy usually is successful if the patient is recalcitrant to simple education.[5] SOR C

MEDICATIONS

- Topical corticosteroids can be used to decrease scalp inflammation if erythema or itching is present. SOR C
- Topical minoxidil is sometimes used to speed hair regrowth in the area. SOR C
- Fluoxetine hydrochloride (Prozac) 20 to 40 mg/day in adults or clomipramine (Anafranil) 25 to 250 mg/day in adults or a maximum of 3 mg/kg per day in children has had some success for alleviating compulsive hair pulling.[4–6] SOR B

- Olanzapine (Zyprexa) has been studied for the treatment of trichotillomania in a 12-week, randomized, double-blind, placebo-controlled trial. A dose of 10 mg/day showed a significant decrease in the CGI-Severity of Illness scale in 85 percent of subjects.[7] SOR B
- Methylphenidate also has showed limited efficacy in trichotillomania patients with comorbid attention deficit hyperactivity disorder (ADHD) in a 12-week study.[8] SOR B

FOLLOW-UP

Specific follow-up is not required for traction alopecia but psychiatric/behavioral counseling follow-up is indicated for trichotillomania.

PATIENT EDUCATION

Explain that in traction alopecia, current grooming practices are responsible for the hair loss and a new hairstyle must be selected. It is important to tell the patient that some of the hair loss may be permanent and no guarantee can be given regarding the amount of expected hair regrowth. Similar hair grooming practices should be avoided in the patient’s children to prevent traction alopecia from occurring. Prevention is definitely the best treatment.

Explain that trichotillomania is a self-induced disease that can often resolve if the hair pulling or twisting is discontinued. Patients may exhibit hair pulling or twisting unconsciously when stressed or use it as a calming activity when relaxing or going to sleep. The underlying reasons for the behavior should be explored and discussed. Sometimes trichotillomania can be substituted with another behavior, such as playing with beads or rubbing a stone.

160 NORMAL NAIL VARIANTS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 14-year-old boy was brought into the office for a well-child visit and his mother pointed out white streaks in his fingernail (**Figure 160-1**). He has had them for about a year and his mother is concerned that he may have a vitamin deficiency. They were reassured that this is a normal nail finding often associated with minor trauma.

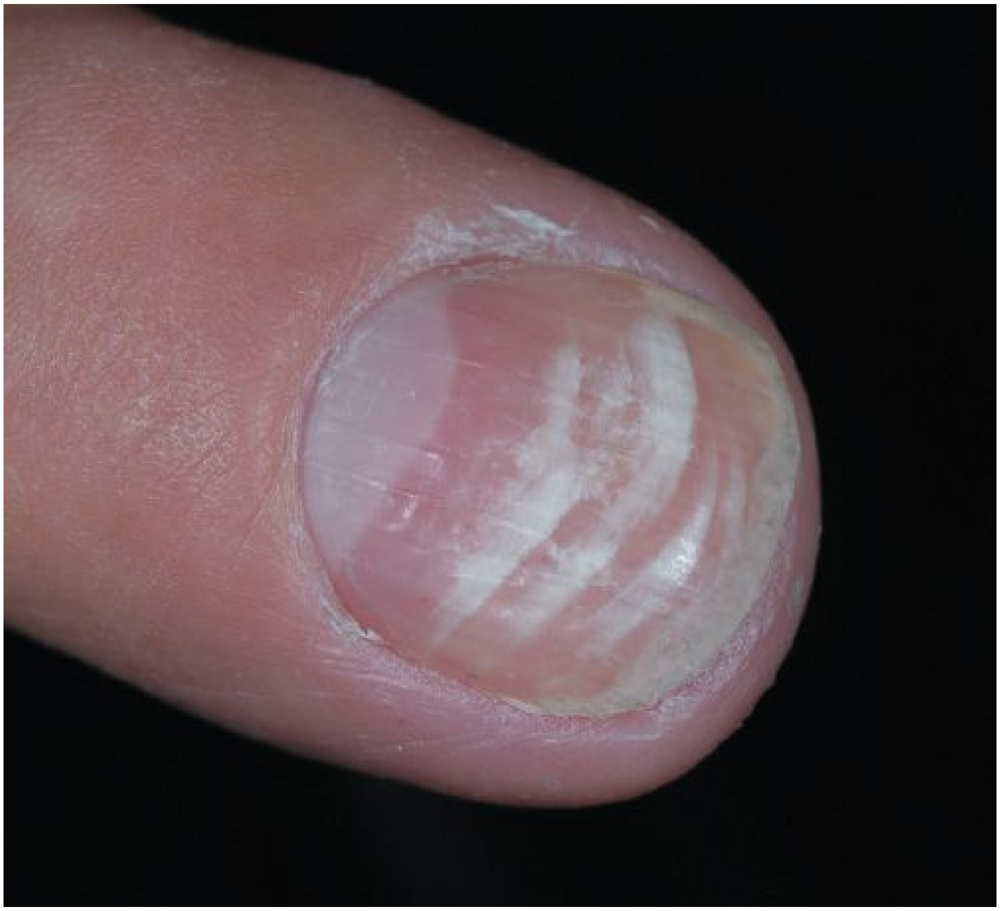

FIGURE 160-1 Transverse striate leukonychia (transverse white streaks) in a healthy patient. Note that the lines do not extend all of the way to the lateral folds, which indicates a probable benign process. (Used with permission from Richard P. Usatine, MD.)

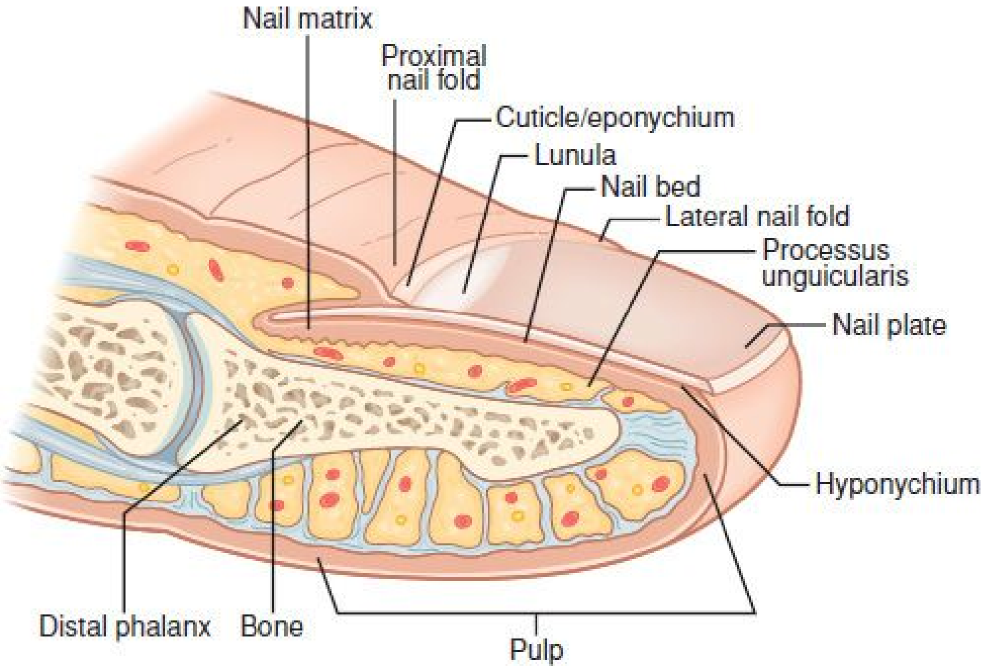
INTRODUCTION

The anatomy of the nail unit is shown in **Figure 160-2**. The nail unit includes the nail matrix, nail plate, nail bed, cuticle, proximal and lateral folds, and fibrocollagenous supportive tissues. The proximal matrix produces the superficial aspects of the plate, and the distal matrix the deeper portions. The nail plate is composed of hard and soft keratins, is formed via onychokeratinization, which is similar to hair sheath keratinization.[1] Most normal nail variants occur as a result of accentuation or disruption of normal nail formation.



Nail matrix
Proximal nail fold
Cuticle/eponychium
Lunula
Nail bed
Lateral nail fold
Processus unguicularis
Nail plate
Hyponychium
Distal phalanx
Bone
Pulp

FIGURE 160-2 The anatomy of the nail unit. (Used with permission from Usatine R, Pfenninger J, Stulberg D, Small R. Dermatologic and Cosmetic Procedures in Office Practice. Elsevier, Inc., Philadelphia. 2012.)

SYNONYMS

- Leukonychia.
  - Transverse striate leukonychia.
  - Leukonychia punctata.
  - White nails.
- Longitudinal melanonychia (LM).
  - Racial melanonychia in African Americans.
- Nail hypertrophy.
  - Oyster-like deformity.
  - Lateral nail hypertrophy.
  - Thickened toenail.

EPIDEMIOLOGY

Melanonychia often involves several nails and is a more common occurrence in those patients with darker skin types. Among African Americans, benign melanonychia affects up to 77 percent of young adults and nearly 100 percent of those age 50 years or older. In the Japanese, LM affects 10 to 20 percent of adults.[1] Nail matrix nevi have been reported to represent approximately 12 percent of LM in adults and 48 percent in children.[2] The incidences of most other benign nail findings are not well established.

ETIOLOGY AND PATHOPHYSIOLOGY

- *Leukonychia* represents benign, single or multiple, white spots or lines in the nails. Patchy patterns of partial, transverse white streaks (transverse striate leukonychia, **Figure 160-1**) or spots (leukonychia punctata, **Figure**

160-3) are the most common patterns of leukonychia.[3] Leukonychia is common in children and becomes less frequent with age. Parents may fear that it represents a dietary deficiency, in particular a lack of calcium, but this concern is almost always unfounded.

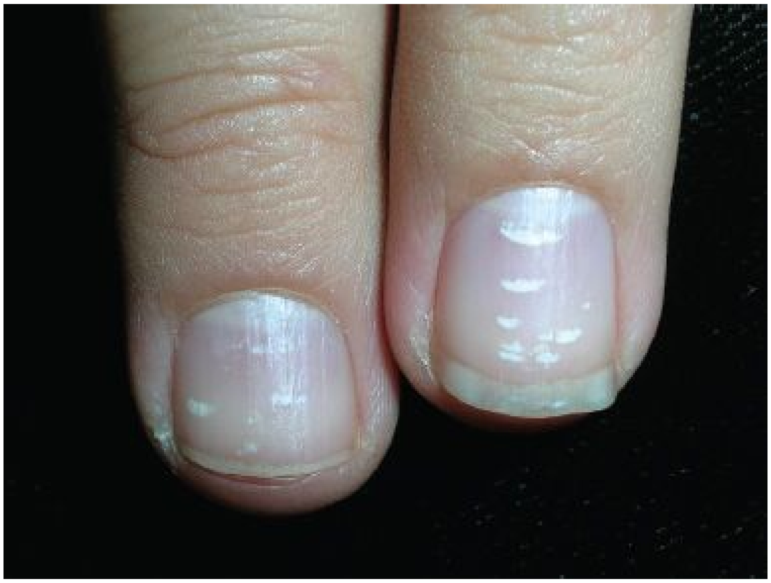


FIGURE 160-3 Leukonychia punctata showing distinct punctate white spots and lines on the fingernails. (Used with permission from Richard P. Usatine, MD.)

- Most commonly, no specific cause for leukonychia can be found. It is usually the result of minor trauma to the nail cuticle or matrix and is the most commonly found nail condition in children.[4] When the lesions are caused by overly aggressive manicuring or nervous habit, behavior modification often is helpful. Leukonychia can also be an indirect manifestation of autoimmunity, including alopecia areata or thyroid disease. Histologically, the nail plate contains a greater number of nucleated cells that are associated with lack of cohesion between the corneocytes, producing reflective properties of the nail.
- Longitudinal melanonychia (**Figure 160-4**) represents a longitudinal pigmented band in the nail plate. Melanonychia is ultimately caused by melanocyte activation. Causes of nongenetic nail matrix melanocyte activation include drugs, inflammatory processes, trauma, mycosis, systemic diseases, and neoplasms (melanomas).[1] LM is often caused by lentigines, benign melanocytic hyperplasia, or nevus of the nail matrix.

However, it must be differentiated from subungual melanoma (see Chapter 161, Pigmented Nail Disorders). Benign causes of LM produce melanocytic activation with bands that usually measure 3 to 5 mm or less in width, whereas melanoma tends to produce wider bands. Most lentigines and nevi display a band with a tan-to-brown hue. A benign nail band is generally relatively homogeneous with respect to color and color intensity and if it expands, tends to expand slowly.[1]

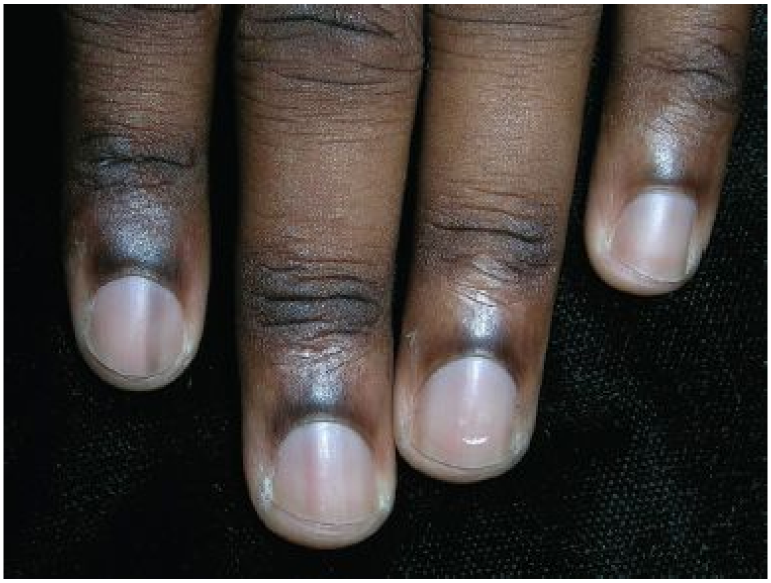

FIGURE 160-4 Longitudinal melanonychia in multiple fingers. These bands of translucent nail pigmentation in multiple fingers are typical of racial longitudinal melanonychia and not suspicious for melanoma. Note the dark pigment on the proximal nail folds represents a pseudo-Hutchinson sign. (Used with permission from Richard P. Usatine, MD.)

- *Nail hypertrophy* (**Figure 160-5**) is the development of opaque thickened nails with exaggerated upward, or lateral growth. It may be associated with age, fungal infections and trauma. It can cause pain with pressure.

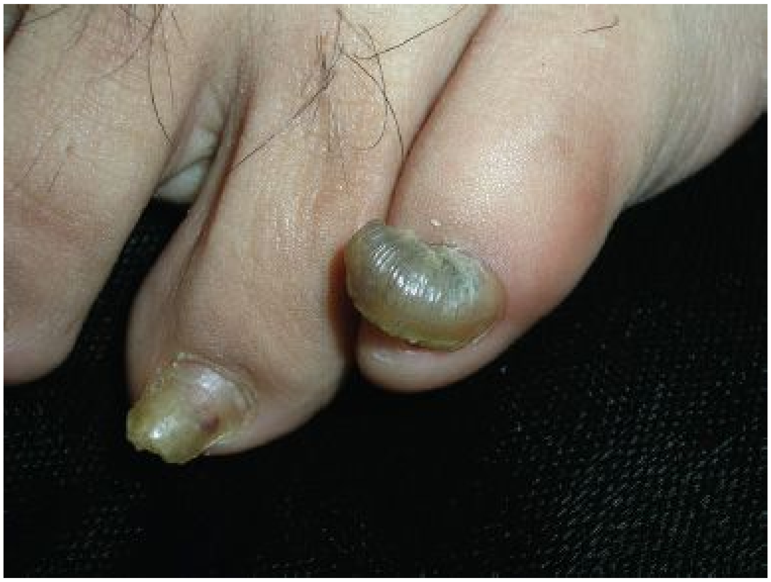

FIGURE 160-5 Onychogryphosis (ram's horn nail) is a type of lateral nail hypertrophy most frequently found in the toenails and often associated with onychomycosis. (Used with permission from Richard P. Usatine, MD.)

- *Habit-tic deformity* (**Figures 160-6** and **160-7**) is caused by habitual picking of the proximal nail fold. The resulting inflammation induces the nail plate to be wavy and ridged, while its substance remains intact and hard.

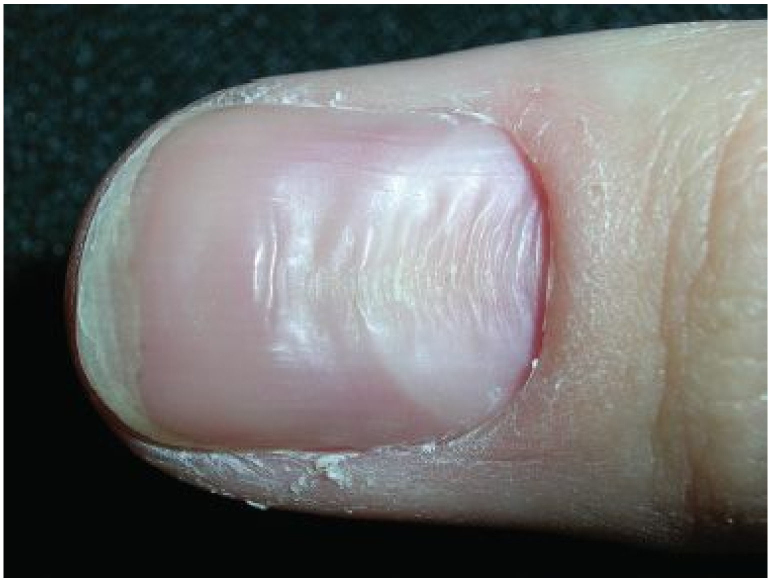

FIGURE 160-6 Habit-tic deformity of the thumbnail caused by a conscious or unconscious rubbing or picking of the proximal nails and nail folds.

Horizontal grooves are formed proximally and move distally with fingernail growth. The thumbnails are most often affected. This was found in a high-school girl. (Used with permission from Richard P. Usatine, MD.)

- *Beau lines* are transverse linear depressions in the nail plate (**Figures 160-8** and **160-9**). They are thought to result from suppressed nail growth secondary to local trauma or severe illness.[5] They most commonly appear symmetrically in several or all nails and may have associated white lines. They usually grow out over several months. One may estimate the time since onset of systemic illness by measuring the distance from the Beau line to the proximal nail fold and applying the conversion factor of 6 to 10 days per millimeter of growth.[4]

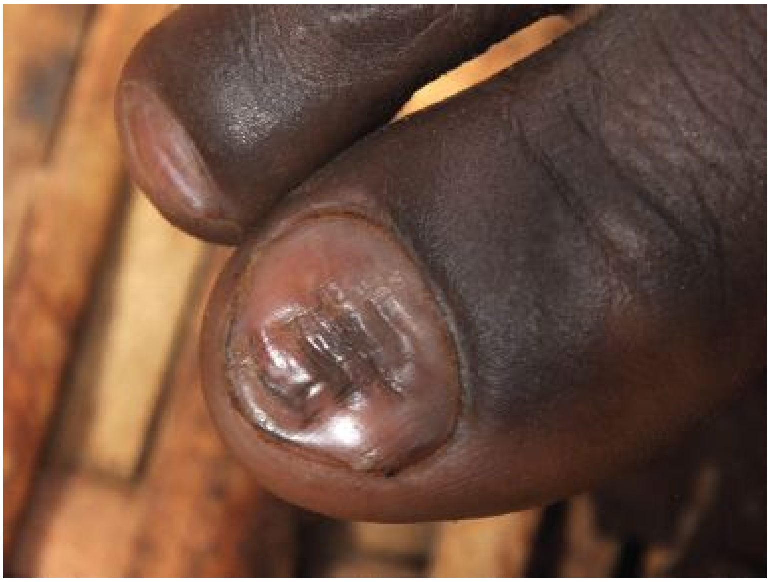

FIGURE 160-7 Habit-tic deformity of the large toenail in a teen that walks barefoot often. He acknowledged that he picks at the nail and cuticle. (Used with permission from Richard P. Usatine, MD.)

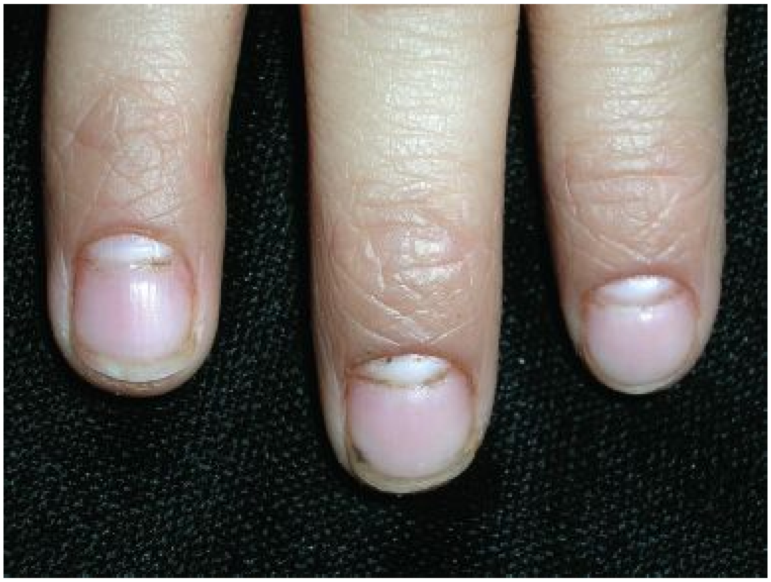

FIGURE 160-8 Beau lines in the fingernails of a young boy that had erythema multiforme and exfoliation approximately 2 months prior to this visit. (Used with permission from Richard P. Usatine, MD.)

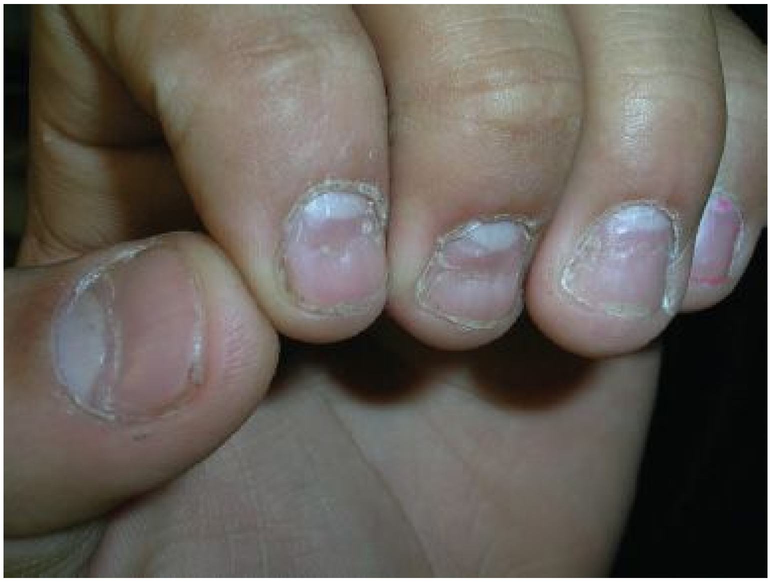

FIGURE 160-9 Beau lines in the fingernails of a young girl who was hospitalized with pneumonia 4 months prior to this visit. (Used with permission from Richard P. Usatine, MD.)

RISK FACTORS

- Leukonychia.
  - Use of nail enamels, nail hardeners, or artificial nails as a result of trauma and allergic reactions.
  - Repetitive trauma from work, sports, or leisure activities.
- LM.
  - Race.
  - Age.
- Nail hypertrophy and onychogryphosis.
  - Age.
  - Fungal Infection.
- Habit-tic deformity.
  - Psychological dysfunctions.
- Beau lines.
  - Severe illness.
  - High fever.

DIAGNOSIS

CLINICAL FEATURES

- All diagnoses of nail disorders should begin with a focused history and physical exam. It is especially important to ask about trauma and recent illnesses.

LABORATORY TESTING

- If renal disease is suspected, order a urinalysis and a serum creatinine.

IMAGING

- The use of nail plate or matrix dermoscopy has been proposed as a way to further define areas to biopsy in LM, but their accuracy in the diagnosis of subungual melanoma has not been established.[2] SOR C

BIOPSY

- Definitive diagnosis of a nail discoloration may be made with a biopsy of the nail or matrix. Patients with darker skin tones and multiple digits with translucent LM often need only be observed. A new dark line in a single nail should be biopsied. A 3-mm punch biopsy can be performed at the origin of the darkest part of a dark band. This usually involves reflecting the skin of the proximal nail fold back while performing a punch biopsy of the distal matrix. Histologic diagnosis of atypical melanocytic hyperplasia necessitates the complete removal of the lesion.[1] SOR C

DIFFERENTIAL DIAGNOSIS

- Pigmented lesions in the nail bed do not cause LM, only nail matrix lesions do. Nail bed lesions make spots under the nails but do not grow out as stripes. These are viewed through the nail as a grayish to brown or black spot.[6]
- The diagnosis of subungual melanoma must always be considered in patients with LM. A biopsy should be performed in an adult if the cause of LM is not apparent. Extension of pigmentation to the skin adjacent to the nail plate involving the nail folds or the fingertip is called Hutchinson sign, which is an important indicator of nail melanoma (see Chapter 147, Pediatric Melanoma).
- Hematoma may be confused with LM, but the color grows out with the nail plate, exhibiting a proximal border that reproduces the shape of the lunula. A hole punched in the nail plate allows for the visualization of the

underlying nail bed and confirmation of the nature of the coloration (see Chapter 166, Subungual Hematoma).

- Mees and Muehrcke lines may be confused with leukonychia or Beau lines. Mees lines are multiple white transverse lines that begin in the nail matrix and extend completely across the nail plate (**Figure 160-10**). They are caused by heavy-metal poisoning or severe systemic insults. Muehrcke lines are white transverse lines that represent an abnormality of the nail vascular bed and may occur with chronic hypoalbuminemia or renal disease (**Figure 160-11**). In contrast to Beau lines, they are not grooved and they do not move with nail growth. **Table 160-1** lists the clinical signs that help differentiate local trauma-induced lesions from those associated with systemic disease.

TABLE 160-1 Signs that Help Differentiate Local Trauma-Induced Nail Changes from Those Associated with Systemic Disease

Characteristic	Mees Lines (Figure 160-10)	Muehrcke Lines (Figure 160-11)	Beau lines (Figures 160-8 and 160-9)	Leukonychia (Figures 160-1 and 160-3)
Number of Nails involved	Tend to be single but may occur on several nails at once	Tend to occur on several nails at once	Appear symmetrically in several or all nails	Usually on one or two nails
Nail coverage	Spread transversely across the entire breadth of the nail	Spread across the entire breadth of the nail bed or plate, often disappear with nail plate pressure	Spread transversely across the entire breadth of the nail	Often do not span the entire breadth of the nail plate
Line shape	Tend to have contour similar to the distal lunula, with a rounded distal edge	White transverse lines that have contour similar to the distal lunula, with a rounded distal edge	Tend to have contour similar to the distal lunula, with a rounded distal edge	More linear and resemble the contour of the proximal nail fold
Nail surface changes	Absent	Absent	Usually depressed	Absent
Etiology	Fragmented nail plate structure as a result of a compromised nail matrix	Abnormality of the nail vascular bed	Suppressed nail growth	Disruption of nail plate formation
Associated conditions	History of a systemic insult correlated with the onset of the lines such as chemotherapy, heart failure, and heavy-metal poisoning	Chronic hypoalbuminemia (hepatic and renal disease)	History of a physiologic stressor such as surgery or a severe illness	History of physical trauma (often not identified)

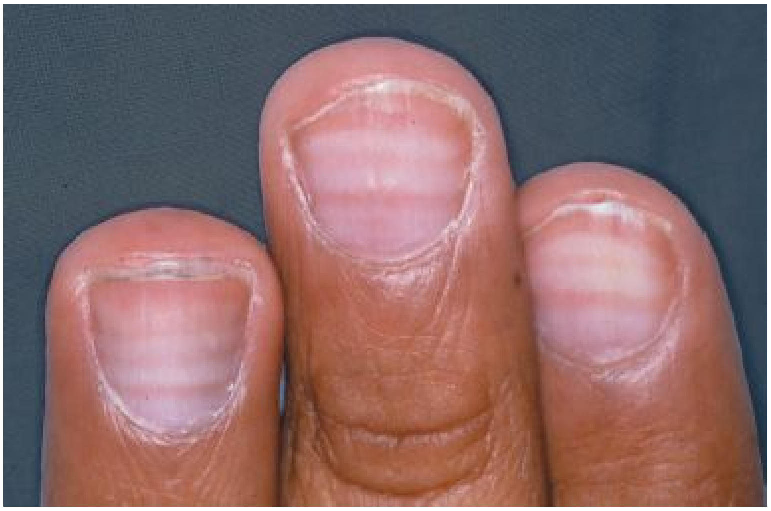

FIGURE 160-10 Mee lines that spread transversely across the entire breadth of the nail and are somewhat rounded with a contour similar to the distal lunula. (Used with permission from Jeffrey Meffert, MD.)

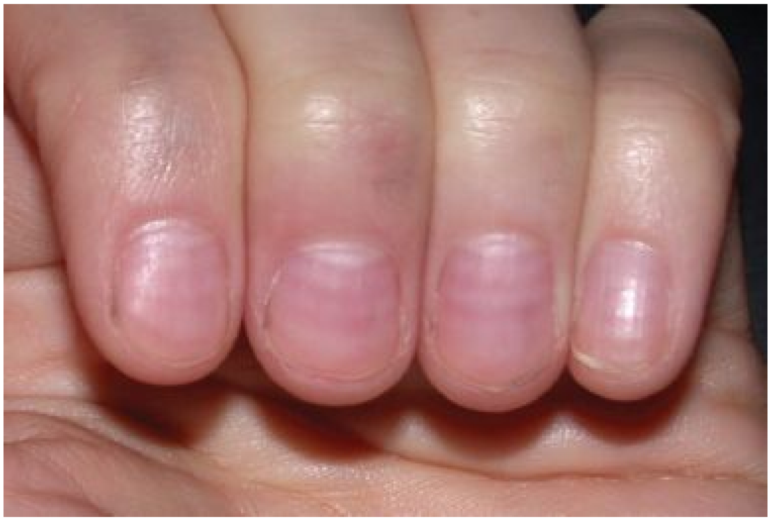

FIGURE 160-11 Muehrcke lines in a patient with chronic hypoalbuminemia from nephrotic syndrome. The white transverse lines extend across the full nail bed and represent an abnormality of the nail vascular bed.

- Leukonychia must also be differentiated from localized white onychomycosis, half-and-half nails, which are white proximal nails and pink or brown distal nails seen in renal failure (**Figure 160-12**), and Terry nails, which are white proximal nails and reddened distal nails that are seen in liver cirrhosis.

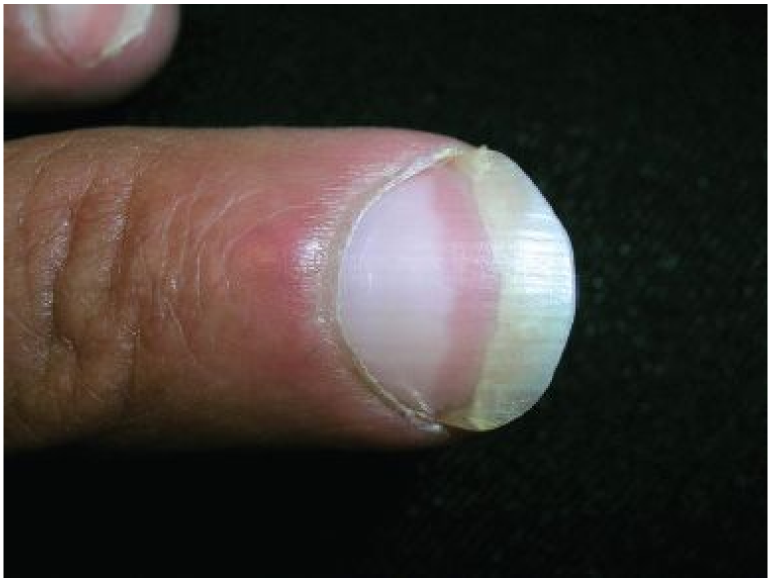

FIGURE 160-12 Half-and-half nail ("Lindsay nails") with the proximal portion of the nail being white and the distal portion pink. Note the sharp line of demarcation between the two halves. This patient has cirrhosis. (Used with permission from Richard P. Usatine, MD.)

- The differential diagnosis of habit-tic deformity includes several nail dystrophies. In median nail, dystrophy produces a distinctive longitudinal split in the center of the nail plate with several cracks projecting laterally. Chronic paronychia is a *Candida* induced inflammation of the proximal nail folds that may induce ripples that can mimic the habit-tic deformity. Chronic eczematous inflammation may produce similar changes. Onychomycosis, Beau lines, and psoriatic nail lesions may also appear similar to habit-tic deformity.[7]
- Twenty-nail dystrophy (**Figure 160-13**) is an idiopathic nail dystrophy that starts in childhood and resolves slowly with age. The nails lose their luster and develop longitudinal striations. It often starts with the fingernails and then affects the toenails.

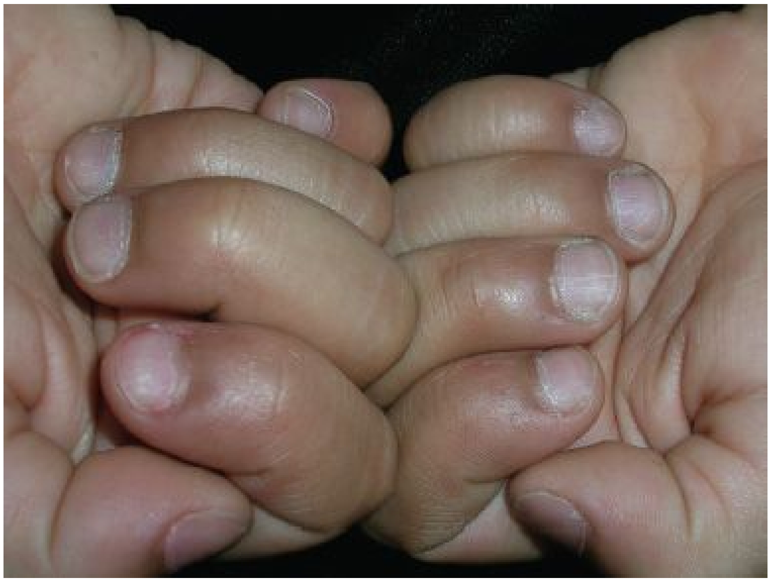

FIGURE 160-13 Twenty-nail dystrophy in a healthy 8-year-old girl. Note how all the fingernails are uniformly affected with longitudinal striations and loss of nail luster. Her skin is otherwise normal. (Used with permission from Richard P. Usatine, MD.)

MANAGEMENT

NONPHARMACOLOGIC

Most normal variants do not require treatment. Cosmetic concerns may often be addressed with nail buffing, polish, or false nail application.

MEDICATIONS

- Fluoxetine has been reported as being helpful in the treatment of habit-tic deformity.[8] SOR C

161 PIGMENTED NAIL DISORDERS

E.J. Mayeaux, Jr., MD
Richard P. Usatine, MD

PATIENT STORY

A four-year-old boy presents with a newly pigmented line on his right thumb for 6 months. He already had one pigmented line on that same thumb since age one. His parents want to know if this pigmentation is dangerous. The child is otherwise healthy. On examination there are two longitudinal pigmented lines easily visible on the right thumbnail (**Figure 161-1A**). The boy is referred to a pediatric dermatologist. Examination with a dermatoscope shows the details of the many lines and confirms his concern for melanoma (**Figure 161-1B**). The concerns are expressed to the parents and the child is set up for a nail matrix biopsy with sedation. The differential diagnosis also includes a congenital melanocytic nevus that is growing.

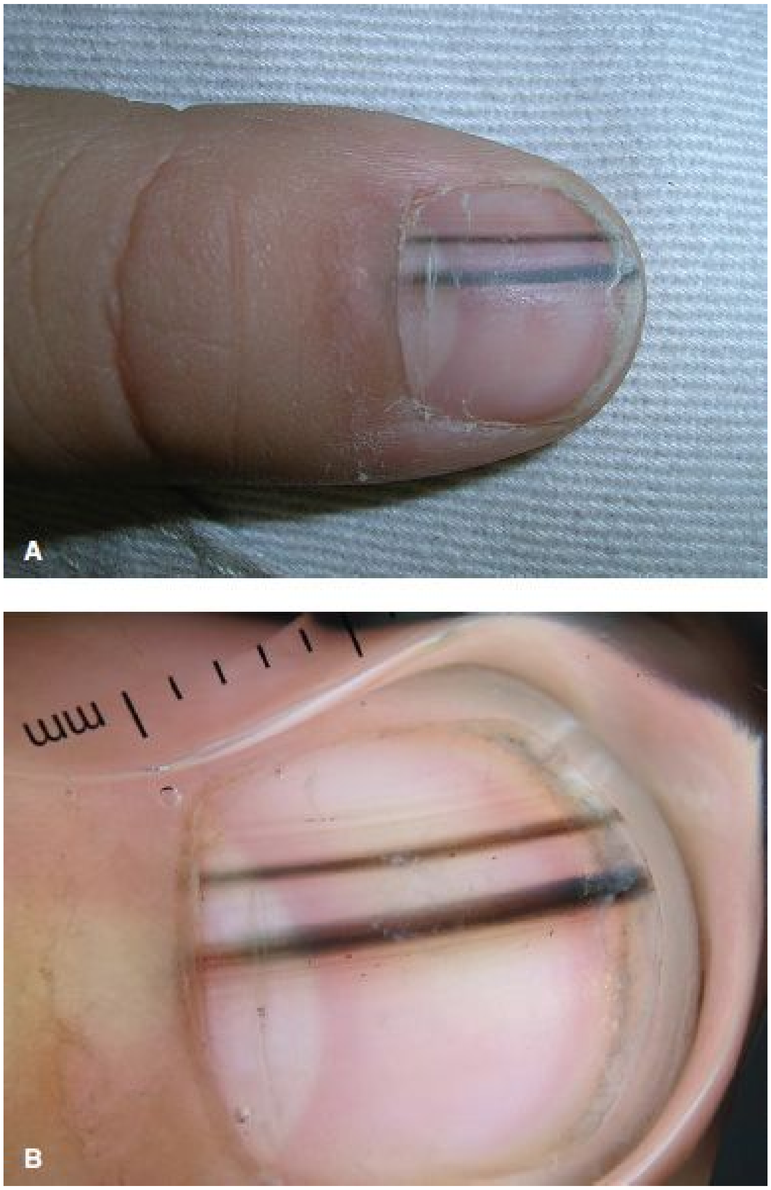

FIGURE 161-1 A. Longitudinal melanonychia on the right thumb of four-year-old boy with two prominent pigmented lines. One of the two lines is new. B. Dermoscopic examination of the nail shows the complex pigment pattern with many lines and melanocytic dots. This is suspicious for melanoma but could also be a congenital nevus that is growing. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Atypical pigmentation of the nail plate may result from many nonmalignant causes, such as fungal infections, benign melanocytic hyperplasia, nevi and medications. It may also result from development of subungual melanoma. The challenge for the clinician is separating the malignant from the nonmalignant sources.

Longitudinal melanonychia (LM) is a clinically descriptive term that represents a longitudinal pigmented band in the nail plate (**Figures 161-1** to **161-3**). It may be caused by any of the conditions listed above but is often due to normal ethnic hyperpigmentation (**Figure 161-3**). It may involve 1 or several digits, vary in color from light brown to black, vary in width (most range from 2 to 4 mm), and have sharp or blurred borders.

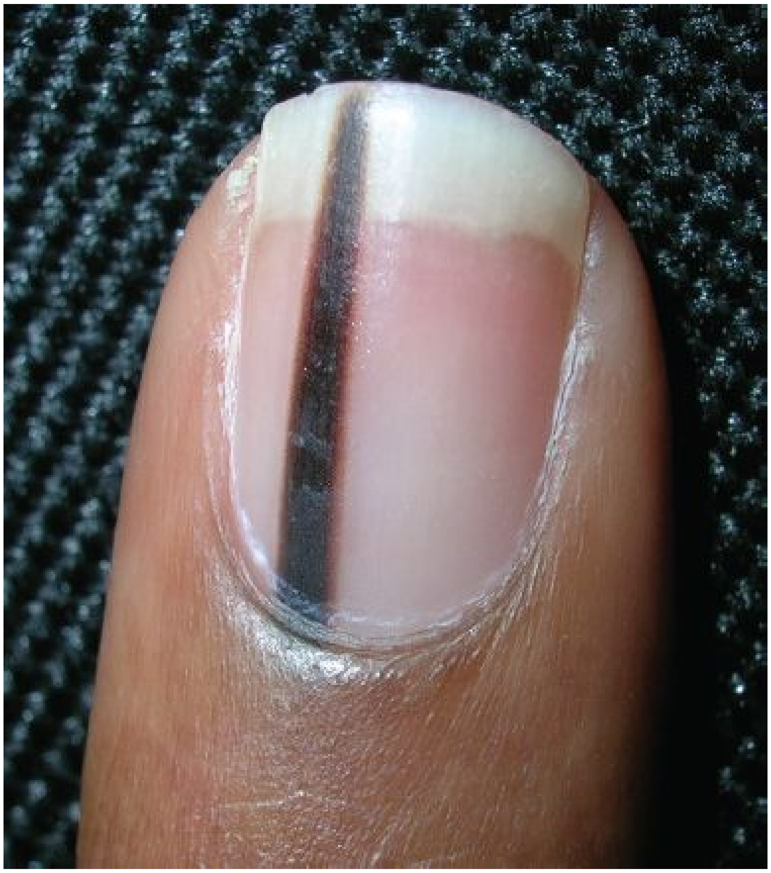

FIGURE 161-2 Longitudinal melanonychia–a single dark band of nail pigment appearing in the matrix region and extended to the tip of the nail. This is concerning for melanoma. The widening of the band in the proximal nail shows that the melanocytic lesion in the matrix is growing. A biopsy showed this to be a benign nevus. (*Used with permission from Richard P. Usatine, MD.*)

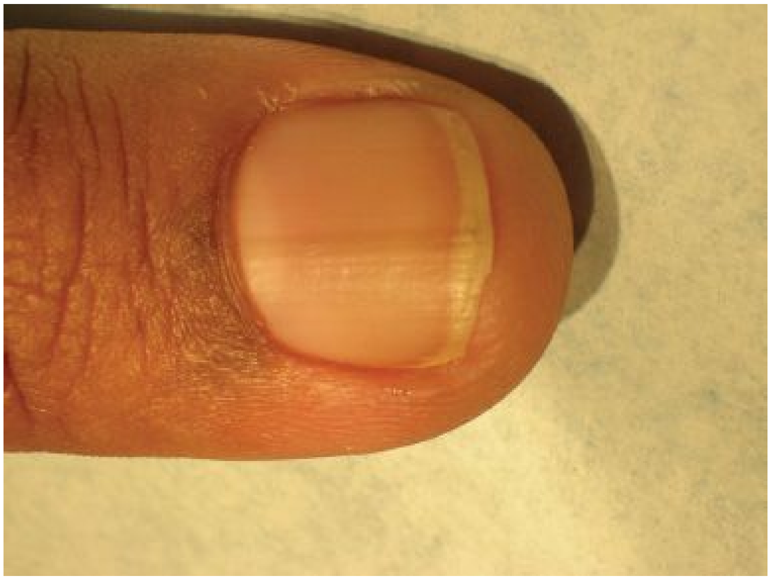

FIGURE 161-3 During a routine sports physical for a black adolescent boy, a translucent darker stipe was discovered in the nail plate of one of his thumbs. The line was faint and uniform in width. He was reassured it was most likely benign but the lesion was noted in his medical record so it could be rechecked in the future and he was instructed to return to clinic if it rapidly changed. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

SYNONYMS

Acrolentiginous melanoma = acral lentiginous melanoma, subungual melanoma is one type of acral lentiginous melanoma involving the nail unit.

EPIDEMIOLOGY

- LM is more common in more darkly pigmented persons. It occurs in 77 percent of African Americans older than age 20 years and in almost 100 percent of those older than age 50 years.[1,2] It also occurs in 10 to 20 percent of persons of Japanese descent. LM is common in Hispanic and other dark-skinned groups. LM is unusual in whites, occurring in only approximately 1 percent of the population.[1]

- Melanoma is the seventh most common cause of cancer in patients in the US. Subungual melanoma is a relatively rare tumor with reported incidences between 0.7 percent and 3.5 percent of all melanoma cases in the general population.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- LM originates in the nail matrix and results from increased deposition of melanin within the nail plate. This deposition may result from greater melanin synthesis or from an increase in the total number of melanocytes (**Figure 161-4**). Pigment clinically localized within the dorsal half of the nail plate indicates a proximal matrix origin, and pigment localized within the ventral nail plate indicates a distal matrix origin. Look at the distal edge of the nail in a cross-sectional view to see whether the pigment is dorsal or ventral (a dermatoscope may help).

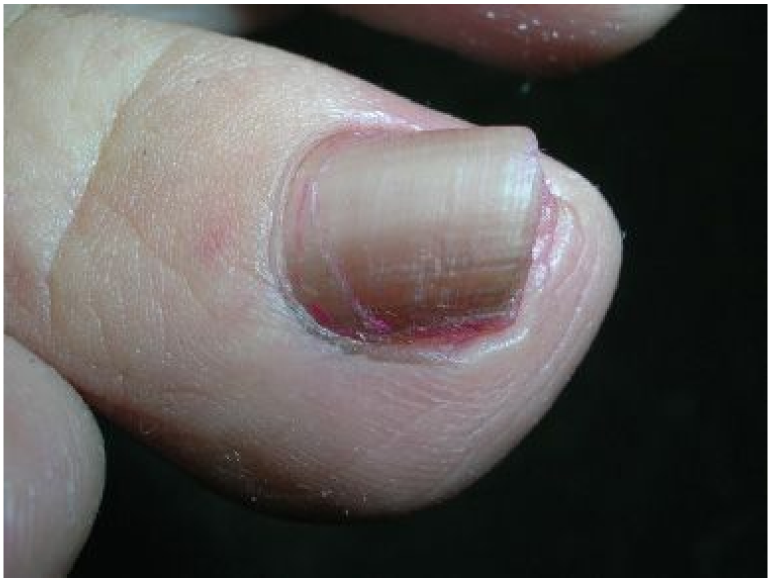

FIGURE 161-4 Longitudinal melanonychia of the toenail of a young person. Biopsy demonstrated benign melanocytosis. (*Used with permission from Richard P. Usatine, MD*.)

- LM may also be caused by chronic trauma, especially in the great toes.
- Inflammatory changes accompanying skin diseases located in the nail unit, such as psoriasis, lichen planus, amyloidosis, and localized scleroderma, rarely may result in LM.
- Benign melanocytic hyperplasia (lentigo) is observed in 30 percent of the pediatric cases of single-biopsied LM.[4]
- Nevi represent almost 50 percent of cases in children. A brown-black coloration is observed in two thirds of the cases and periungual pigmentation (benign pseudo-Hutchinson sign) in 1/3.
- Certain drugs may also cause LM, especially chemotherapeutic agents, and antimalarial drugs (mepacrine, amodiaquine, and chloroquine).
- Endocrine disorders, such as Addison disease, Cushing syndrome, hyperthyroidism, and acromegaly, can be responsible for LM.
- The diagnosis of subungual melanoma must always be considered in patients with LM (**Figures 161-5** to **161-7**). Separating benign from malignant lesions is often difficult. Both arise most often in the thumb or index fingers, and both are more common in dark-skinned persons.[5] A biopsy should be performed if the cause of LM is suspicious for melanoma. **Table 161-1** lists diagnostic clues for subungual melanomas. Many subungual melanomas have a history of trauma preceding the diagnosis so it is important to not be fooled by this history (**Figure 161-7**).

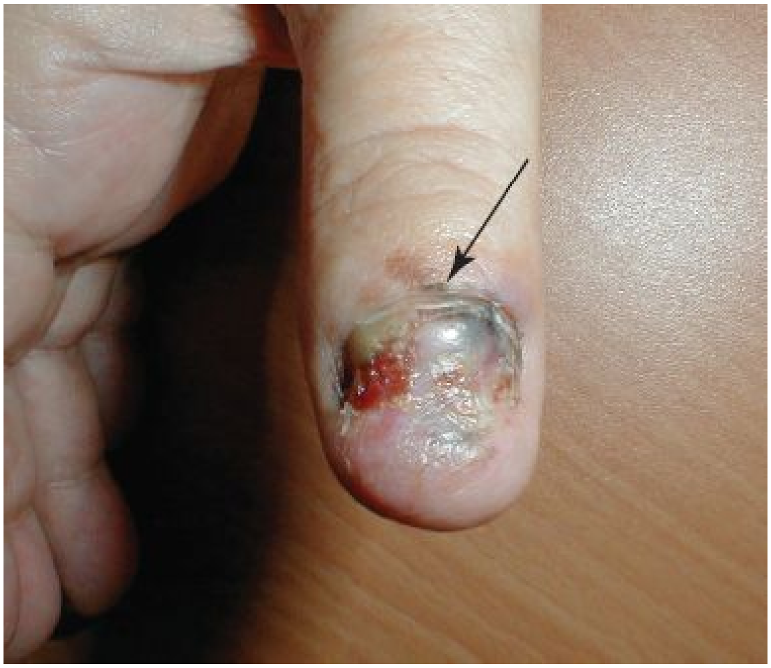

FIGURE 161-5 Advanced acral lentiginous melanoma of the thumb with destruction of the nail plate and ulceration. Note the hyperpigmentation of the proximal nail fold (Hutchinson sign), which is strongly indicative of melanoma. (*Used with permission from Dr. Dubin at http://www.skinatlas.com.*)

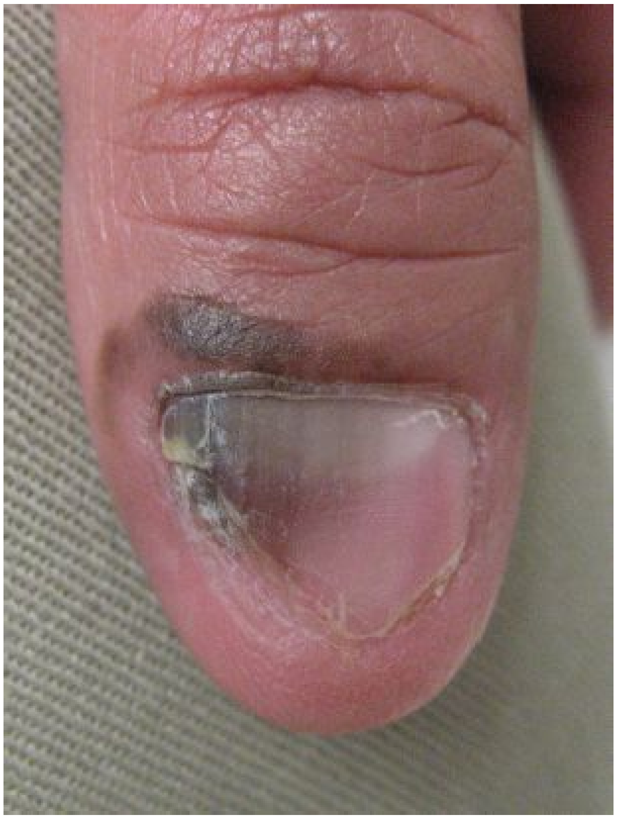

FIGURE 161-6 Acral lentiginous melanoma of the thumb with a very positive Hutchinson sign. Note how the pigmented band on the nail is greater than 3 mm in width. (*Used with permission from Robert T. Gilson, MD*.)

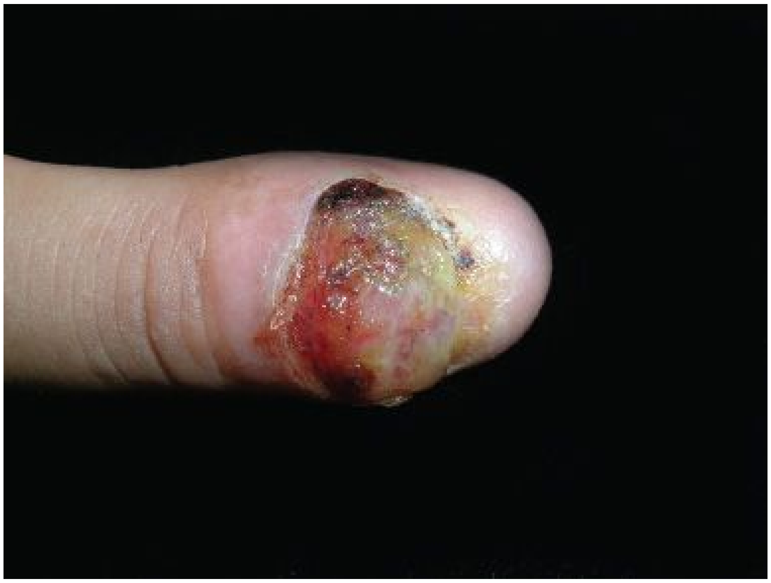

FIGURE 161-7 Nodular melanoma growing within the pinkie nail (not the thumb) of a young woman. The patient claims that it started with a dark spot under the nail of this fifth digit after she caught it in a dresser drawer. When it did not heal she pursued medical care and was treated for a presumed nail fungus and then a paronychia until she was finally seen by a physician who recognized the gravity of this situation. A biopsy was performed immediately and it showed a thick nodular melanoma greater than 3 mm in depth with a high mitotic index and ulceration. The patient will undergo an amputation of the finger at the PIP joint along with a sentinel node biopsy. (*Used with permission from Richard P. Usatine, MD*.)

- Hutchinson sign is the extension of pigmentation to the skin adjacent to the nail plate involving the nail folds or the fingertip. It is an important indicator for nail melanoma (**Figures 161-5** to **161-6**).[6]
- Pseudo-Hutchinson sign is the presence of dark pigment around the proximal nail fold secondary to benign conditions such as racial melanosis and not melanoma (**Figure 161-8**). Another cause of pseudo-Hutchinson sign is a translucent cuticle below which the pigment of LM is visible. Trauma and drug-induced pigmentation can also produce a pseudo-Hutchinson sign.

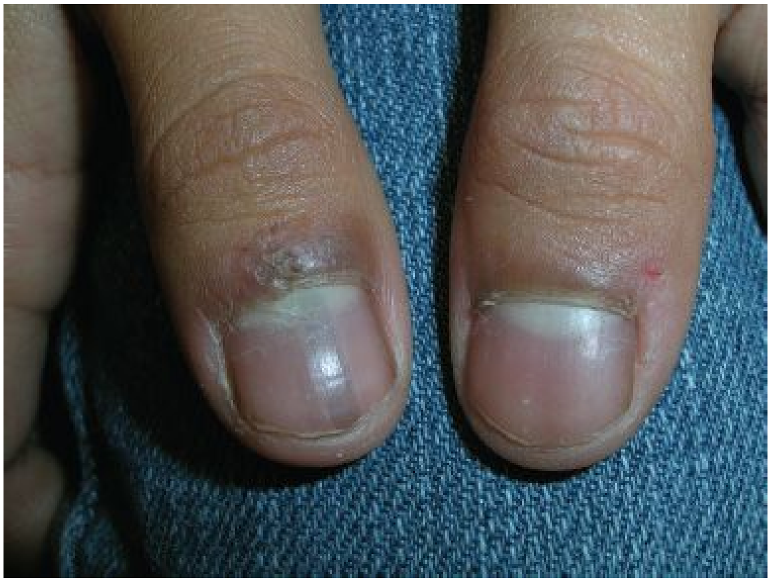

FIGURE 161-8 The fingers of this child demonstrate longitudinal melanonychia with pseudo-Hutchinson sign that was found to be due to racial melanosis. The small bruise on the proximal nail fold of the right

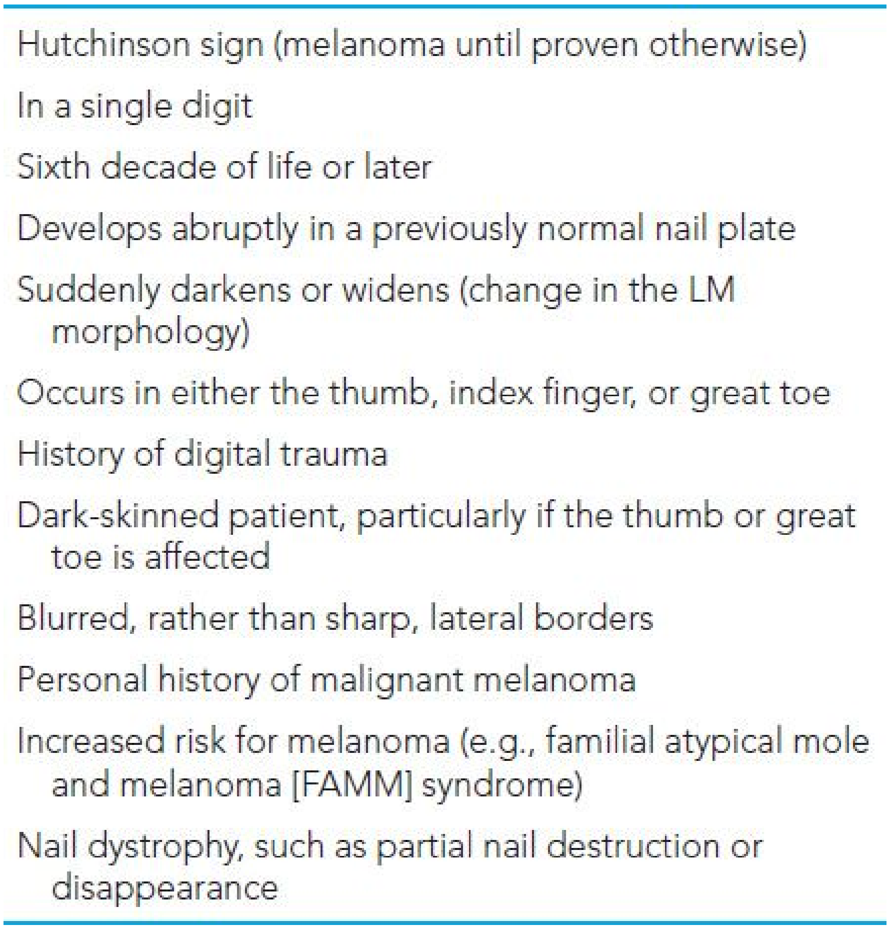
thumb was due to recent trauma and not melanoma. (*Used with permission from Richard P. Usatine, MD*.)A

- Subungual melanoma arises on the hand in 45 to 60 percent of cases, and most of those occur in the thumb (**Figures 161-5** to **161-6**).[4] On the foot, subungual melanoma usually occurs in the great toe.[5] The median age at which subungual melanoma is usually diagnosed is in the sixth and seventh decades. It appears with equal frequency in males and females.[5]

RISK FACTORS

Table 161-1 lists diagnostic clues that indicate an increased risk for the presence of subungual melanoma.



Hutchinson sign (melanoma until proven otherwise)
In a single digit
Sixth decade of life or later
Develops abruptly in a previously normal nail plate
Suddenly darkens or widens (change in the LM morphology)
Occurs in either the thumb, index finger, or great toe
History of digital trauma
Dark-skinned patient, particularly if the thumb or great toe is affected
Blurred, rather than sharp, lateral borders
Personal history of malignant melanoma
Increased risk for melanoma (e.g., familial atypical mole and melanoma [FAMM] syndrome)
Nail dystrophy, such as partial nail destruction or disappearance

DIAGNOSIS

CLINICAL FEATURES

There is an ABCDEF mnemonic system that applies to subungual melanoma:

- In this system “A” stands for age (peak incidence being between the fifth to seventh decades) and African Americans, Asians, and Native Americans in whom subungual melanoma accounts for 1/3 of melanoma cases.
- “B” stands for “brown to black” and with “breadth” of 3 mm or more.
- “C” stands for change in the nail band coloration or lack of change after adequate treatment.
- “D” stands for the digit most commonly involved.
- “E” stands for extension of the pigment onto the proximal and/or lateral nailfold (Hutchinson sign).
- “F” stands for family or personal history of dysplastic nevus or melanoma.

TYPICAL DISTRIBUTION

The digits used for grasping (thumb, index finger, and middle finger) are the most commonly involved in LM and melanoma, but either may be found in any finger or toe.

BIOPSY

Definitive diagnosis of a nail discoloration may be made with a biopsy of the nail matrix. Patients with darker skin color and multiple digits with translucent LM often need only be observed. Single dark lines in whites should always be biopsied. A 3-mm punch biopsy can be performed at the origin of the darkest part of a dark band within the nail matrix (**Figure 161-**

9). Histologic diagnosis of atypical melanocytic hyperplasia necessitates the complete removal of the lesion.

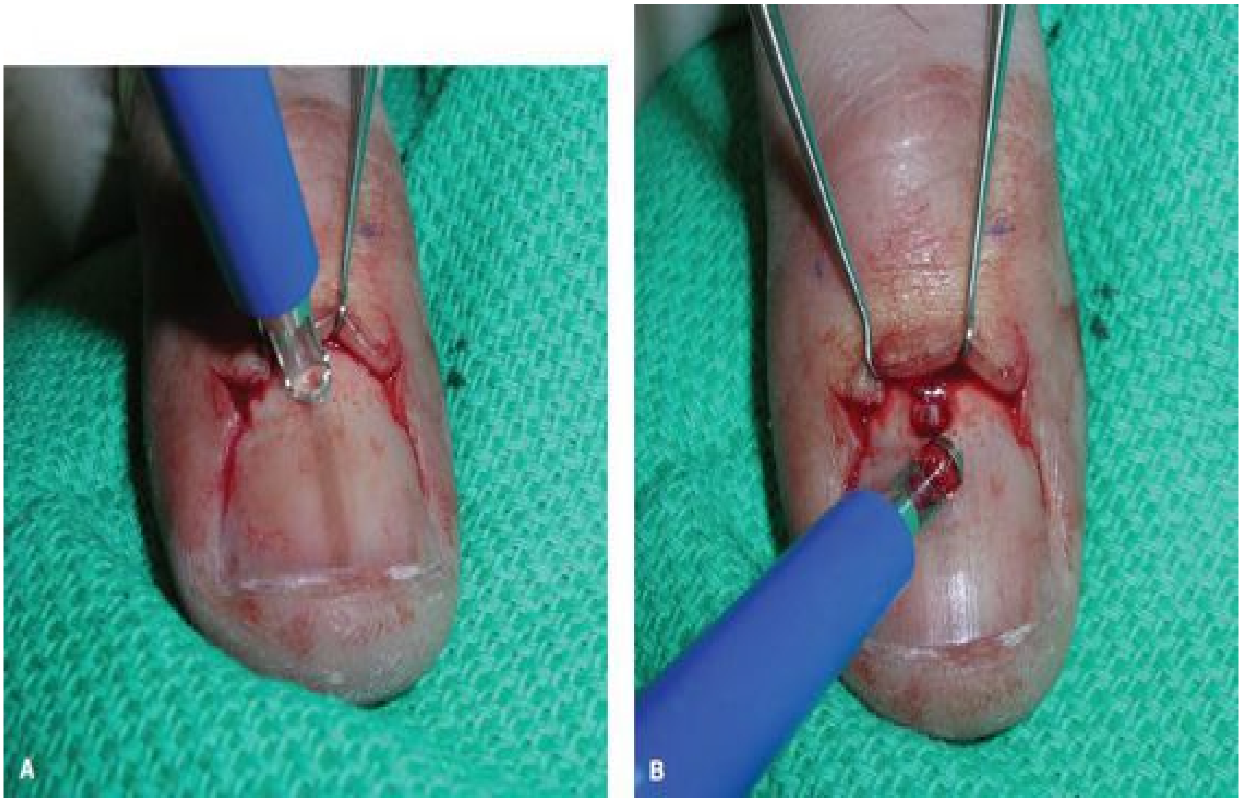


FIGURE 161-9 **A.** The proximal nail fold is reflected back to perform a nail matrix biopsy in a young man with new onset of longitudinal melanonychia. The 3-mm punch is placed over the origin of the dark band at the distal matrix. **B.** The 3-mm punch now contains the specimen for pathology. The longitudinal melanonychia was caused by melanocytic hyperplasia. (*Used with permission from Richard P. Usatine, MD.*)

DIFFERENTIAL DIAGNOSIS

- Pigmented lesions in the nail bed usually do not cause LM and are viewed through the nail as a grayish to brown or black spot.[7]
- Subungual hematoma may be confused with LM, but the color grows out with the nail plate, exhibiting a proximal border that reproduces the shape

of the lunula. A hole punched in the nail plate allows for the visualization of the underlying nail bed and confirmation of the nature of the coloration (see Chapter 166, Subungual Hematoma).

MANAGEMENT

NONPHARMACOLOGIC

No treatment is required for benign LM.

REFERRAL OR HOSPITALIZATION

Treatment of primary subungual melanomas includes amputation at the level of the interphalangeal joint for thumb lesions, SOR B the distal or proximal interphalangeal joint for fingers, SOR C and the metatarsophalangeal joint for toes.[8] For melanoma in situ, it may be possible to remove the full nail apparatus and save the digit. Sentinel lymph node biopsy is often indicated to establish the disease stage. Chemotherapy is recommended for nodal or visceral metastases.

PROGNOSIS

The 5-year survival is approximately 74 percent for patients with stage I subungual melanoma and 40 percent for patients with stage II disease. Prognostic variables negatively affecting survival include stage at diagnosis, deeper Clark level of invasion, African American race, and ulceration.[9]

FOLLOW-UP

Because LM may indicate an undiagnosed melanoma of the nail unit, biopsy, or regular monitoring is extremely important. If there is any doubt about the diagnosis of melanoma, biopsy immediately or refer to someone who can. Have the patient report any changes in pigmentation of the nail plate or nail folds, and strongly consider biopsy in these individuals.

162 INGROWN TOENAIL

E.J. Mayeaux, Jr., MD
Heather M. Guillot, MD

PATIENT STORY

A 13-year-old boy presents with recurrent ingrown toenails. He presents to the clinic with another episode (**Figure 162-1**). He was treated with partial nail avulsion and a lateral matrixectomy was performed using topical phenol to ablate the matrix. This treatment produced long-term remission of his condition.

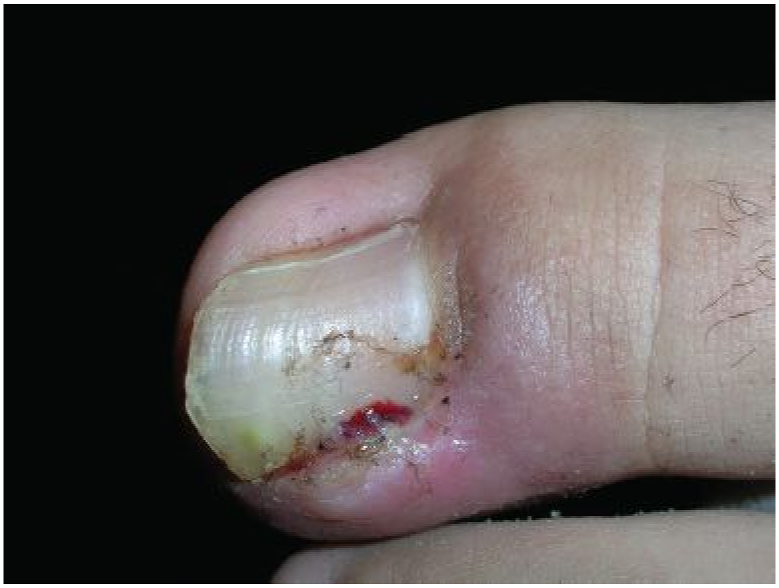

FIGURE 162-1 Recurrent ingrown toenail in a 13-year-old boy. Note the local redness and swelling. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Onychocryptosis (ingrown toenails) is a common childhood and adult problem. Patients often seek treatment because of the significant levels of discomfort and disability associated with the condition.

SYNONYMS

Onychocryptosis, unguis incarnatus.

EPIDEMIOLOGY

- The prevalence of onychocryptosis is unknown as many patients do not seek medical care and it is not a reportable disease. The toenails, especially the great toenail, are most commonly affected. Ingrown toenails at birth and in early childhood do occur, but are very rare.

ETIOLOGY AND PATHOPHYSIOLOGY

Onychocryptosis occurs when the lateral nail plate damages the lateral nail fold. The laterally edge of the nail plate penetrates and perforates the adjacent nail fold skin. Perforation of the lateral fold skin results in painful inflammation that manifests clinically as mild edema, erythema, and pain. In advanced stages, drainage, infection, and ulceration may be present. Hypertrophy of the lateral nail wall occurs, and granulation tissue forms over the nail plate and the nail fold during healing of the ulcerated skin.[1] It is a common affliction that can result from a variety of conditions that cause improper fit of the nail plate in the lateral nail grove (**Figure 162-1**).

RISK FACTORS[1]

- Genetic predisposition.
- Poor-fitting footwear.
- Excessive trimming of the lateral nail plate.
- Pincer nail deformity (**Figure 162-2**).

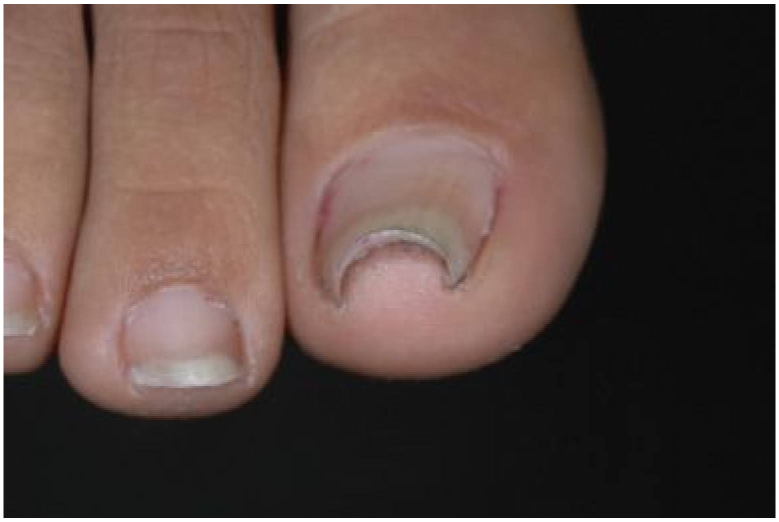

FIGURE 162-2 The curved infolding of the lateral edges of the nail plate indicates this patient has a pincer nail, which predisposes to onychocryptosis. (*Used with permission from Richard P. Usatine, MD.*)

- Trauma.
- Sports in which kicking or running is important.
- Hyperhidrosis.
- Anatomic features such as nail fold width.
- Congenital malalignment of the digit.
- Overcurvature of the nail plate.
- Onychomycosis and other diseases that result in abnormal changes in the nail plate.

- Obesity causing deepening of the nail groove.

DIAGNOSIS

CLINICAL FEATURES—HISTORY AND PHYSICAL

- The diagnosis is based upon clinical appearance and rarely is difficult. Characteristic signs and symptoms include pain, edema, exudate, and granulation tissue (**Figure 162-1**).

TYPICAL DISTRIBUTION

- The great toe is most commonly affected; fingers are rarely involved except when nail biting is present.

LABORATORY TESTING

- Since the diagnosis is made clinically, laboratory testing is usually not necessary.

DIFFERENTIAL DIAGNOSIS

- Cellulitis—Presents with redness, pain, and swelling beyond the nail fold (see Chapter 103, Cellulitis).
- Paronychia—Presents with redness and abscess formation (pus) in a nail fold (see Chapter 164, Paronychia).
- Pseudo-ingrown toenails—Presents in infants 0 to 12 months of age; common and transient deformity, which usually self-corrects.

- Osteomyelitis—Presents with redness, pain, and swelling of the toe and fever.

MANAGEMENT

- The treatment of ingrown toenails depends upon the age of the patient and the severity of the lesion.

NONPHARMACOLOGIC

- Lesions characterized by minimal to moderate pain and no discharge can be treated conservatively with soaking the affected foot in warm water for 20 minutes, 3 times per day, and pushing the lateral nailfold away from the nail plate.[2] SOR Ⓒ
- Other palliative measures include cotton wedging underneath the lateral nail plate and trimming the lateral part of the nail plate below the area of nail fold irritation.
- Numerous alternative methods of conservative treatment have been described, including splints and commercially available devices. Devices that have shown promise include shape memory alloys (SMAs), either of a Cu-Al-Mn base or a Ni-Ti base.[3–5]

MEDICATIONS

- Although many elect to treat apparent infections with oral antibiotics, studies show the use of antibiotics does not decrease healing time or postprocedure morbidity in otherwise normal patients.[6] SOR Ⓐ
- A medium- to high-potency topical corticosteroid can be applied after soaking to decrease inflammation, but is often unnecessary.
- If nail avulsion and/or matrix ablation is used, pain relievers for mild to moderate pain may be necessary.

- When placing digital blocks for surgical procedures, the best evidence indicates the use of lidocaine with epinephrine is equally safe and efficacious for anesthesia.[7]

SURGICAL

- Nonresponders to conservative therapy and patients with more severe lesions (substantial erythema, granulation tissue and pus) need surgical therapy.[8,9] SOR Ⓒ
- Surgical interventions are more effective at preventing the recurrence of an ingrowing toenail when compared to non-surgical interventions.[10]
- Surgical intervention involves partial or full nail plate avulsion. Usually it is only necessary to remove the part of the nail that is placing pressure on the lateral nail fold (**Figure 162-3**). SOR Ⓒ

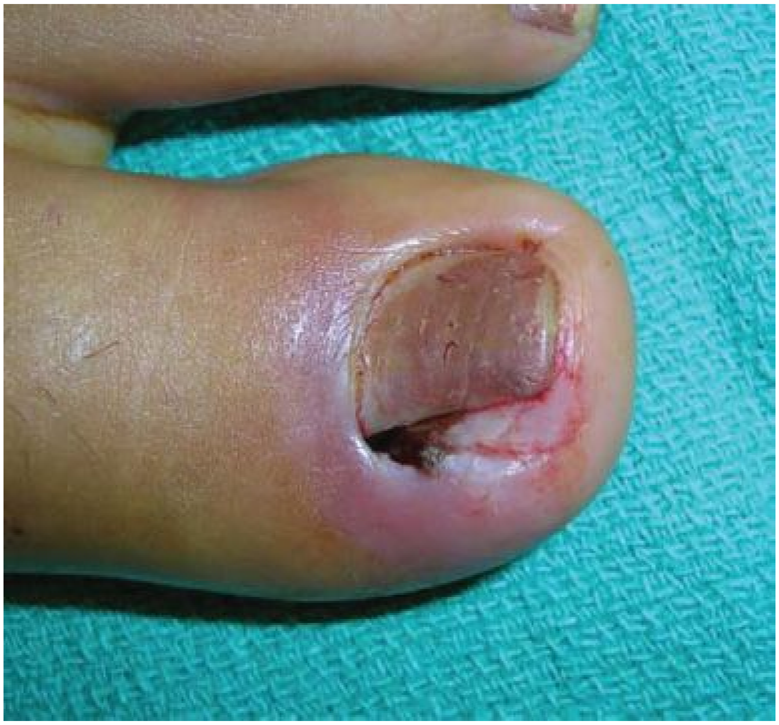

FIGURE 162-3 Status post partial nail avulsion procedure for an ingrown toenail. (*Used with permission from Richard P. Usatine, MD.*)

- Patients who develop recurrent ingrown toenails benefit from permanent nail ablation of the lateral nail matrix. This may be achieved with the combination of partial nail plate avulsion plus phenol matrixectomy, which can cut recurrence rates by 90 percent (**Figure 162-4**).[8,9,11,12] SOR A

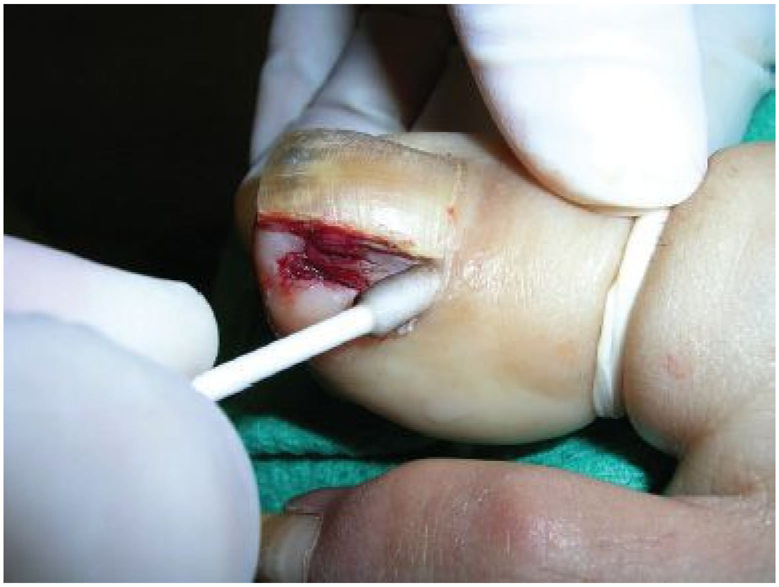

FIGURE 162-4 Phenol matrixectomy to destroy a portion of the nail matrix to prevent a recurrent ingrown toenail. Note the phenol is applied with a twisting motion. (*Used with permission from Richard P. Usatine, MD.*)

- In a Cochrane Systematic Review of surgical treatments for ingrowing toenails nail avulsion with the use of phenol is more effective at preventing symptomatic recurrence than nail avulsion without the use of phenol.[11] Unfortunately the use of phenol does increase the risk of postoperative infection (by 5 times) compared with simple nail avulsion.[11,13] SOR A
- Chemical matrixectomy is performed mainly by phenol (full-strength 88%), but 10 percent sodium hydroxide is another alternative. In a comparison study of the use of chemical matrixectomy for the treatment of ingrown toenails, the overall success rates were 95 percent for both phenol and sodium hydroxide.[14] SOR A

- One study found that partial nail avulsion with phenolization gave better results than partial avulsion with matrix excision. Local antibiotics applied to the surgical site did not reduce signs of infection or recurrence. The use of phenol did not produce more signs of infection than matrix excision.[15] SOR Ⓑ
- Electrosurgical ablation can be performed with electrosurgery units on the fulguration setting or using a special matrixectomy electrode with a high-frequency electrosurgical unit (**Figure 162-5**). SOR Ⓒ

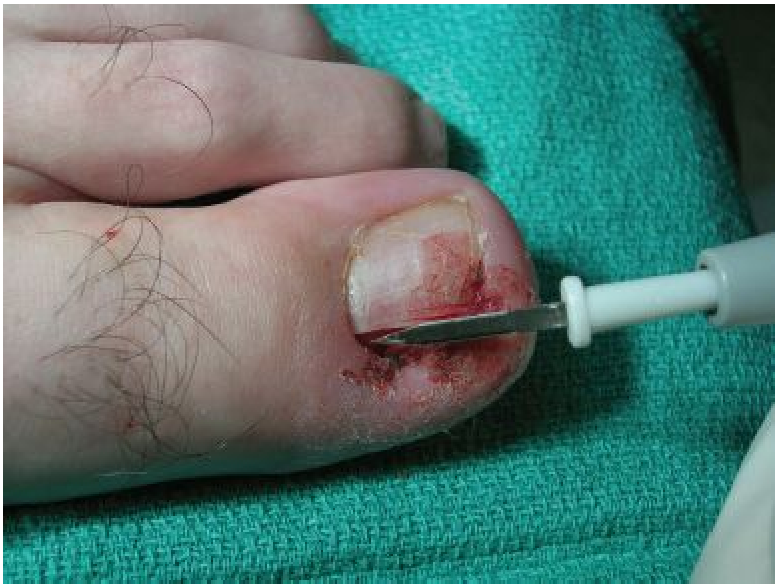

FIGURE 162-5 Use of electrosurgery to ablate the lateral nail matrix. This results in a narrower nail and a decreased likelihood of onychocryptosis recurrence. (*Used with permission from Richard P. Usatine, MD.*)

- A surgical alternative to nail plate avulsion with or without matrixectomy is soft tissue nail fold excision consisting of excision of the offending nail fold, leaving a soft tissue defect that heals by secondary intention (Vandenbos procedure). No portion of the nail or matrix is excised using this procedure. One case series report found no recurrence of ingrown toenail after a median 14-month follow-up.[16]
- A Cochrane Systematic Review of treatments for ingrowing toenails found that no postoperative intervention including postoperative antibiotics, manuka honey, povidone-iodine with paraffin, hydrogel with

paraffin, or paraffin gauze was effective in reducing the risk of postoperative infection or pain or reducing healing time.[10]

PREVENTION

There are several things that the patient may do to decrease the likelihood of getting an ingrown toenail.

- Trim nails straight across the top, not in a rounded shape.
- Wear shoes that fit properly. Shoes that place excessive pressure on the toes or pinch the toes.
- Switch to longer shoes with a bigger toe box.
- Wear protective footwear, especially if there is a risk of injuring the toes.

FOLLOW-UP

- After surgical intervention, consider follow-up in 3 to 4 days to assess treatment and exclude cellulitis.

PATIENT EDUCATION

- Patients should be educated about proper nail trimming so as to minimize trauma to the lateral nail fold. The lateral nail plate should be allowed to grow well beyond the lateral nail fold before trimming horizontally.
- Patients should also be educated about the importance of avoiding shoes that are too tight over the toes to help minimize recurrences.

163 ONYCHOMYCOSIS

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 12-year-old boy was brought in by his mother with discoloration and some pain in his toenails (**Figure 163-1**). The clinical diagnosis of onychomycosis was confirmed with microscopic examination of a potassium hydroxide preparation. The onychomycosis resolved after a 3 month course of oral terbinafine.

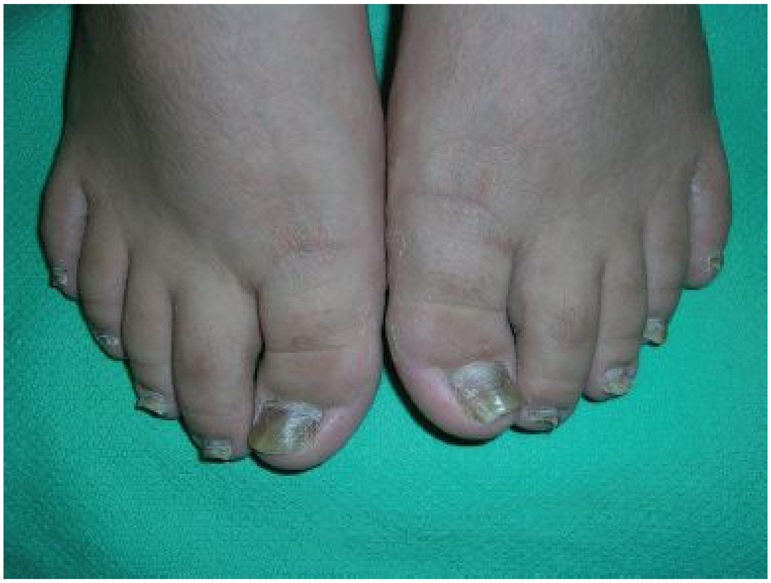

FIGURE 163-1 Onychomycosis in a child. Note the discoloration in the nail plate of the great toes, and the onycholysis and hyperkeratotic debris under the nail plate visible in the other toes. The diagnosis was confirmed with a positive nail culture. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Onychomycosis is a term used to denote nail infections caused by any fungus, including dermatophytes, yeasts, and nondermatophyte molds. One, some, and occasionally all of the toenails and/or fingernails may be involved. Although most toenail onychomycosis is caused by dermatophytes, many cases of fingernail onychomycosis are caused by yeast. Onychomycosis may involve the nail plate and other parts of the nail unit, including the nail matrix.

SYNONYMS

Toenail fungus, tinea unguium, dermatophytosis of nails.

EPIDEMIOLOGY

- The incidence of onychomycosis has been reported to be 2 to 13 percent in North America.[1]
- Most patients (7.6%) only have toenail involvement and only 0.15 percent have fingernail involvement alone.[2]
- The prevalence of onychomycosis varies from 4 to 18 percent.[3,4]
- The disease is very common in adults, but may also occur in children.

ETIOLOGY AND PATHOPHYSIOLOGY

- Dermatophytes are responsible for most toenail (**Figures 163-1** to **163-3**) and finger infections (**Figures 163-4** and **163-5**).

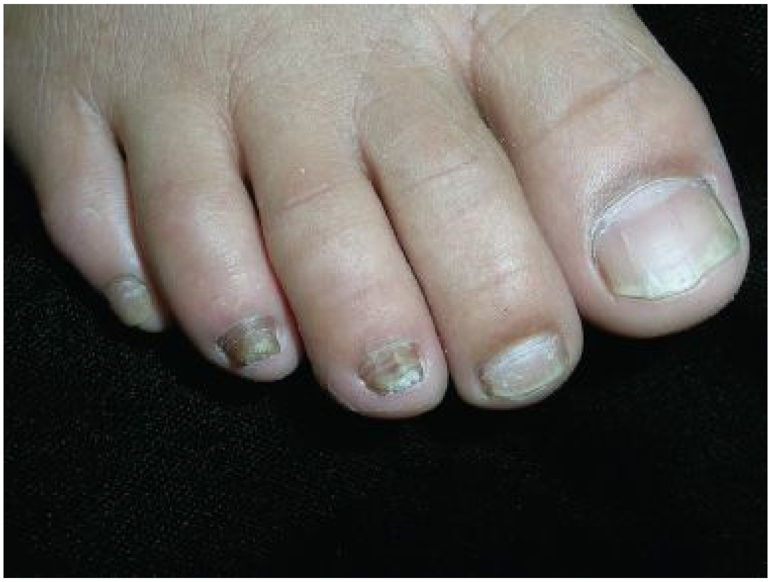

FIGURE 163-1 Onychomycosis in a child. Note the discoloration in the nail plate of the great toes, and the onycholysis and hyperkeratotic debris under the nail plate visible in the other toes. The diagnosis was confirmed with a positive nail culture. (*Used with permission from Richard P. Usatine, MD.*)

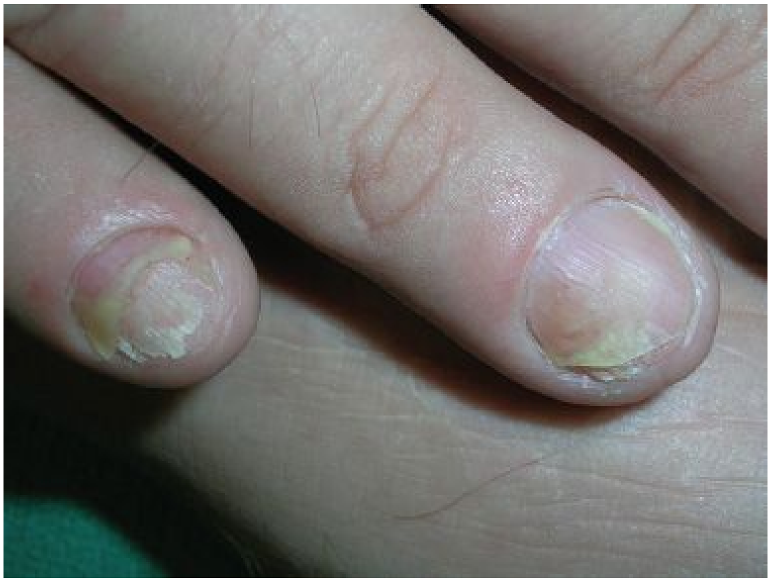

FIGURE 163-3 Onychomycosis in a 14-year-old Hispanic male. Note the coexisting tinea pedis between his toes. (*Used with permission from Richard P. Usatine, MD.*)

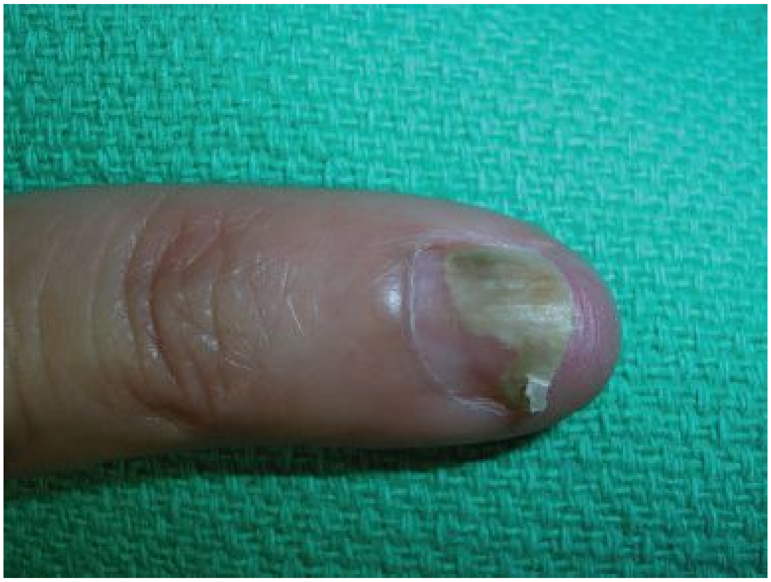

FIGURE 163-4 Fingernail onychomycosis demonstrating onycholysis and degeneration of the nail plane. (*Used with permission from Richard P. Usatine, MD.*)

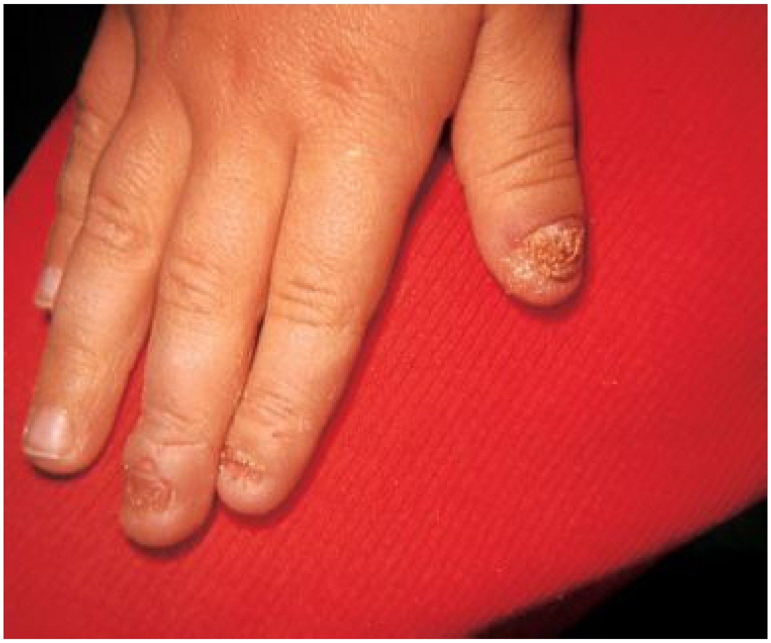

FIGURE 163-5 Onychomycosis in the finger nail proven by the visualization of hyphae under the microscope with a KOH preparation from a nail scraping. (*Used with permission from Richard P. Usatine, MD*.)

- Nonpathogenic fungi and *Candida* (including the rare syndrome of chronic mucocutaneous candidiasis) also can infect the nail plate (**Figure 163-6**).

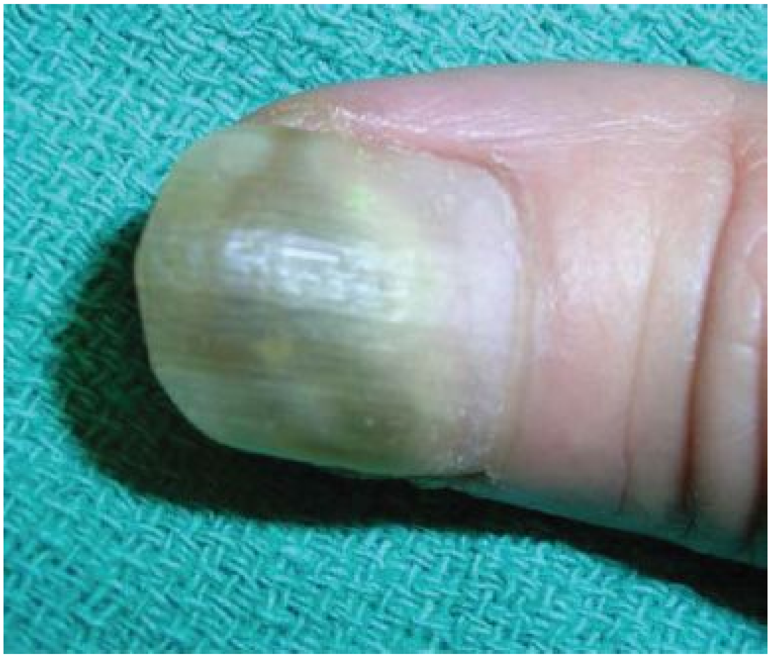

FIGURE 163-6 Mucocutaneous candidiasis in a child, which often associated with severe zinc or iron deficiency. (*Used with permission from Weinberg S, Prose NS, Kristal. Color Atlas of Pediatric Dermatology, 4th edition, New York: McGraw-Hill, 2008, Figure 6-47*.)

- Dermatophytic onychomycosis (tinea unguium) occurs in three distinct forms: distal subungual, proximal subungual, and white superficial.
- The vast majority of distal and proximal subungual onychomycosis results from *Trichophyton rubrum*.
- White superficial onychomycosis is usually caused by *Trichophyton mentagrophytes*, although cases caused by *T. rubrum* have also been reported.
- Yeast onychomycosis is most common in the fingers caused by *Candida albicans* (**Figure 163-6**).

RISK FACTORS

- Tinea pedis.[5]
- Trauma predisposes to infection but can also cause a dysmorphic nail that can be confused for onychomycosis.[5]
- Older age.[5]
- Swimming.[5]
- Diabetes.[5]
- Living with family members who have onychomycosis.[5]
- Immunosuppression.[6]

DIAGNOSIS

CLINICAL FEATURES

- Distal subungual onychomycosis is the most common presentation.
- Distal subungual onychomycosis begins with a whitish, yellowish, or brownish discoloration of a distal corner of the nail, which gradually spreads to involve the entire width of the nail plate and extends slowly toward the cuticle. Keratin debris collecting between the nail plate and its bed is the cause of the discoloration (**Figures 163-1** to **163-3**).
- Proximal subungual onychomycosis progresses in a manner similar to distal subungual onychomycosis but affects the nail in the vicinity of the cuticle first and extends distally. It usually occurs in individuals with a severely compromised immune system.
- White superficial onychomycosis appears as dull white spots on the surface of the nail plate. Eventually the whole nail plate may be involved. The white areas may be soft and can be lightly scraped to yield a chalky scale that may be examined or cultured.

TYPICAL DISTRIBUTION

- Nail infection may occur in a single digit but most often occurs simultaneously in multiple digits of the foot (**Figure 163-1** to **163-3**). Toenails and fingernails may be affected at the same time especially in patients that are immunocompromised.

LABORATORY TESTING

- KOH and culture—Clippings of nail plate and scrapings of subungual keratosis can be examined with KOH and microscopy and/or sent to the laboratory in a sterile container to be inoculated onto Sabouraud medium to culture.
- Dermatophyte test medium (DTM) culture is an alternative to Sabouraud medium culture. DTM is less expensive and can be performed in the physician's office, with results becoming available within 3 to 7 days. Dermatophyte growth is indicated by a change in the medium's color from

yellow to red. It is important that DTM cultures be read in a timely fashion, as saprophytic organisms may grow over several weeks and cause a false-positive result. DTM does not identify the specific causative organism, but such identification is unnecessary as all dermatophyte infections are treated the same way. DTM cultures had good positive and negative correlation with culture on Sabouraud medium.[7]

- Clippings—Nail clippings may be sent to pathology in formalin to be examined with periodic acid-Schiff (PAS) stain for fungal elements. This can be more sensitive than KOH and culture.[8]
- Comparison of diagnostic methods:
  - In a 2003 study by Weinberg et al, the sensitivities for onychomycosis detection were KOH 80 percent, Bx/PAS 92 percent, and culture 59 percent. The specificities were KOH 72 percent, Bx/PAS 72 percent, and culture 82 percent. The positive predictive values were KOH 88 percent, Bx/PAS 89.7 percent, and culture 90 percent. The negative predictive values were KOH 58 percent, Bx/PAS 77 percent, and culture 43 percent.[8]
  - In a 2007 study of the diagnosis of onychomycosis by Hsiao et al, the sensitivities of KOH, PAS, and culture were 87 percent, 81 percent, and 67 percent, respectively, and the negative predictive values of KOH, PAS, and culture were 50 percent, 40 percent, and 28 percent, respectively. One reason that the KOH may have done so well is that the nail specimen was immersed in 20 percent KOH in a test tube for 30 minutes or longer before looking under the microscope.[9]
  - KOH may be equivalent to PAS if done and read properly. It is less expensive and the results are available while the patient is in the office. PAS is a good second line if the KOH is negative and the suspicion for onychomycosis is still present.

DIFFERENTIAL DIAGNOSIS

- Nail trauma can cause a dysmorphic nail that is discolored and thickened. It is especially seen in the big toenail in runners. Ask about nail trauma before diagnosing onychomycosis. Although onychomycosis often starts in the big toenail, it usually spreads to other nails. Traumatic changes often present with only one nail involved.

- Psoriatic and lichen planus nail changes may easily be confused with onychomycosis, especially when the nail becomes thickened and discolored. Pitting of the nail plate surface, which is common in psoriasis, is not a feature of fungal infection. It is possible for a patient with psoriasis to get onychomycosis. Fungal studies can help determine if the changes are truly secondary to onychomycosis (see Chapter 165, Psoriatic Nails).
- Pseudomonal nail infection—Produces a blue-green tint to the nail plate (**Figure 163-7**).

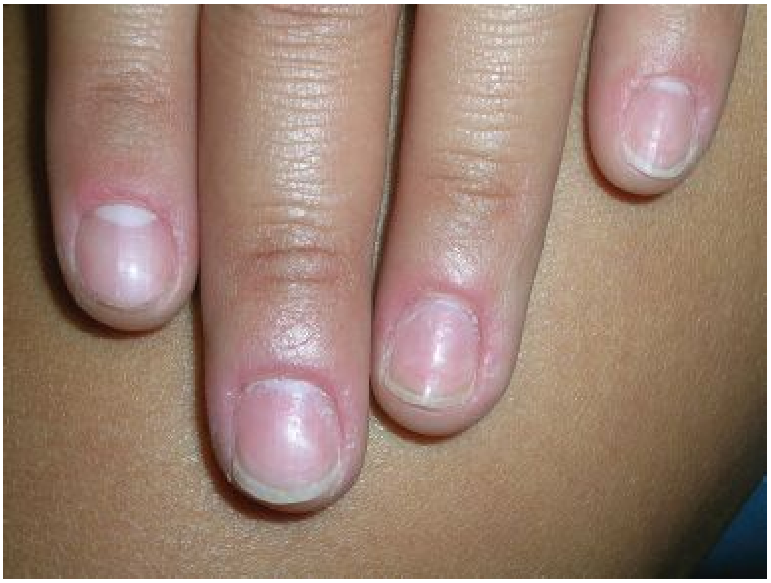

FIGURE 163-7 *Pseudomonas* of the nail showing a blue-green discoloration. (*Used with permission from Richard P. Usatine, MD*.)

- Leukonychia—White spots or bands that appear proximally and proceed out with the nail may be confused with white superficial onychomycosis (see Chapter 160, Normal Nail Variants).
- Habitual picking of the proximal nail fold—induces the nail plate to be wavy and ridged, although its substance remains intact and hard (see Chapter 160, Normal Nail Variants).

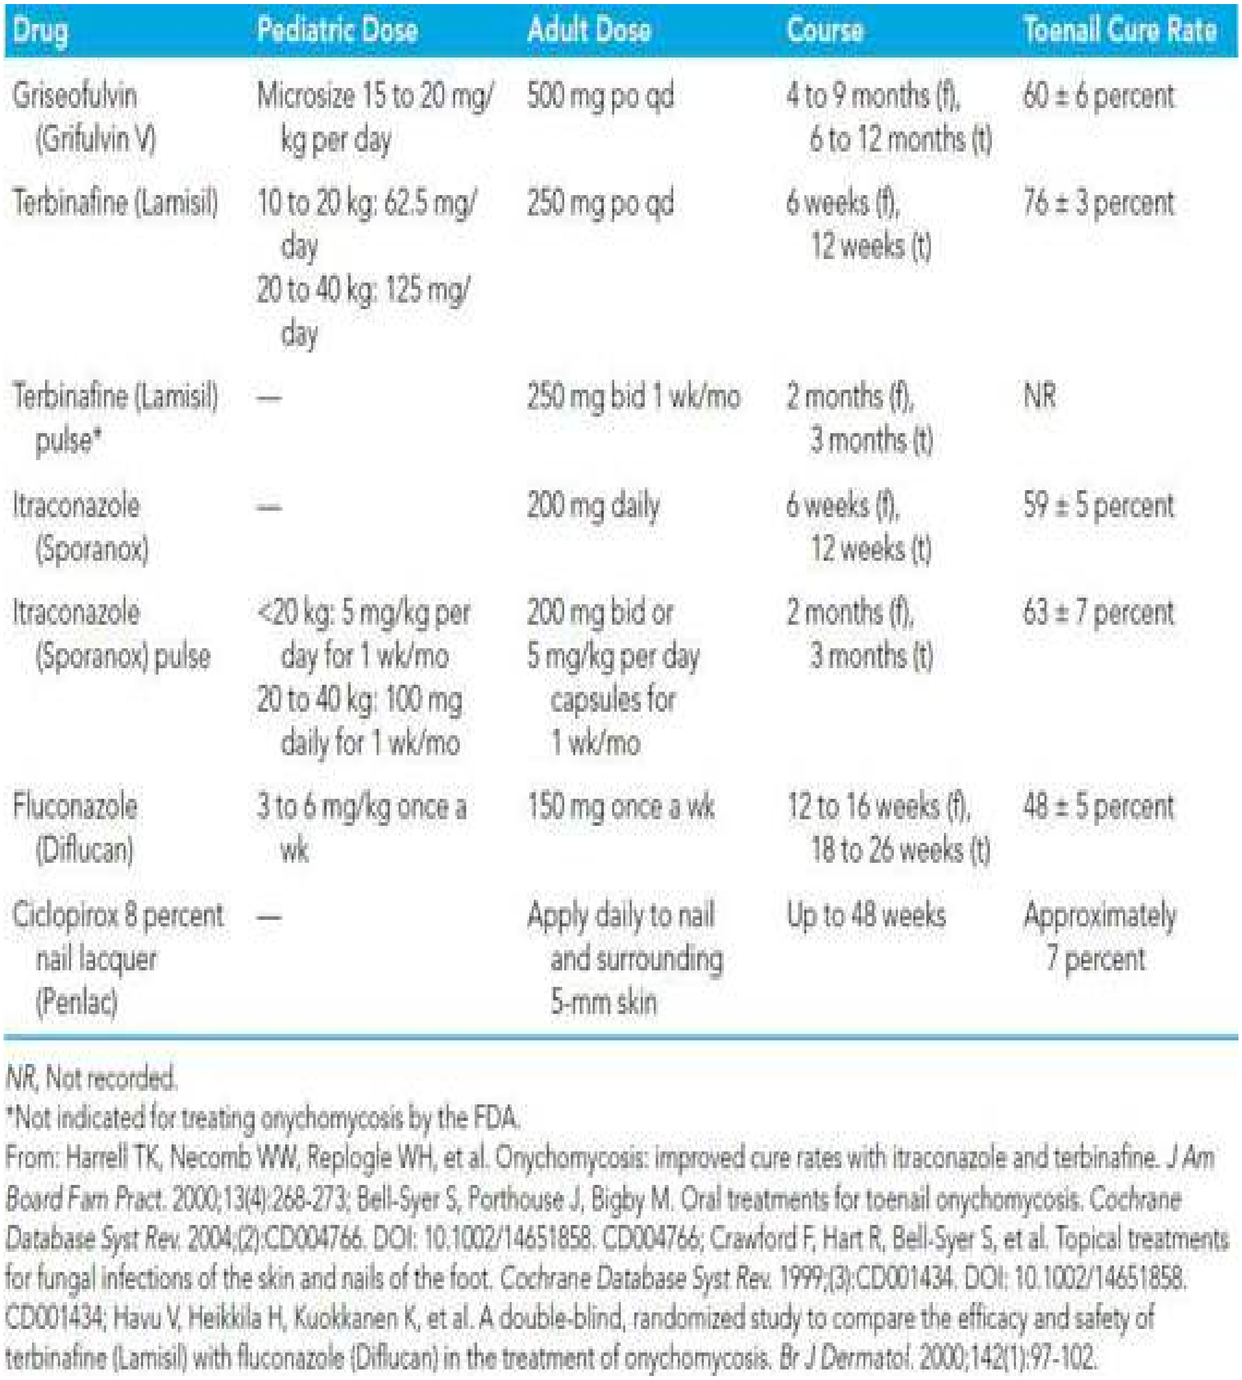
MANAGEMENT

- Treating onychomycosis can be discouraging. Most topical creams and lotions do not penetrate the nail plate well and are of little value except in controlling inflammation at the nail folds.
- Surgical avulsion may be used to decrease pain caused by pressure on an elevated nail plate because of a dermatophytoma (a collection of dermatophytes and cellular debris under the nail plate). Recurrences are common in the absence of additional systemic or topical therapy with ciclopirox, as the infection typically involves the nail matrix and bed. SOR C
- There has been a resurgence of interest in phototherapy modalities for the treatment of onychomycosis. UV light therapy, near-infrared photoinactivation therapy, photodynamic therapy, and photothermal ablative therapy are being studied for treatment of onychomycosis.[10] Further studies are required to determine the clinical role of laser and light therapy in the treatment of onychomycosis. The Pinpointe FootLaser was approved for use to treat onychomycosis in February 2011. SOR C

MEDICATIONS

- Oral therapy (**Table 163-1**) is no longer expensive now that terbinafine is generic and on many discounted drug lists.

TABLE 163-1 Common Treatments for Onychomycosis



Drug	Pediatric Dose	Adult Dose	Course	Toenail Cure Rate
Griseofulvin (Grifulvin V)	Microsize 15 to 20 mg/kg per day	500 mg po qd	4 to 9 months (f), 6 to 12 months (t)	60 ± 6 percent
Terbinafine (Lamisil)	10 to 20 kg: 62.5 mg/day 20 to 40 kg: 125 mg/day	250 mg po qd	6 weeks (f), 12 weeks (t)	76 ± 3 percent
Terbinafine (Lamisil) pulse*	—	250 mg bid 1 wk/mo	2 months (f), 3 months (t)	NR
Itraconazole (Sporanox)	—	200 mg daily	6 weeks (f), 12 weeks (t)	59 ± 5 percent
Itraconazole (Sporanox) pulse	<20 kg: 5 mg/kg per day for 1 wk/mo 20 to 40 kg: 100 mg daily for 1 wk/mo	200 mg bid or 5 mg/kg per day capsules for 1 wk/mo	2 months (f), 3 months (t)	63 ± 7 percent
Fluconazole (Diflucan)	3 to 6 mg/kg once a wk	150 mg once a wk	12 to 16 weeks (f), 18 to 26 weeks (t)	48 ± 5 percent
Ciclopirox 8 percent nail lacquer (Penlac)	—	Apply daily to nail and surrounding 5-mm skin	Up to 48 weeks	Approximately 7 percent

NR, Not recorded.

*Not indicated for treating onychomycosis by the FDA.

From: Harrell TK, Necomb WW, Replogle WH, et al. Onychomycosis: improved cure rates with itraconazole and terbinafine. *J Am Board Fam Pract*. 2000;13(4):268-273; Bell-Syer S, Porthouse J, Bigby M. Oral treatments for toenail onychomycosis. *Cochrane Database Syst Rev*. 2004;(2):CD004766. DOI: 10.1002/14651858. CD004766; Crawford F, Hart R, Bell-Syer S, et al. Topical treatments for fungal infections of the skin and nails of the foot. *Cochrane Database Syst Rev*. 1999;(3):CD001434. DOI: 10.1002/14651858. CD001434; Havu V, Heikkila H, Kuokkanen K, et al. A double-blind, randomized study to compare the efficacy and safety of terbinafine (Lamisil) with fluconazole (Diflucan) in the treatment of onychomycosis. *Br J Dermatol*. 2000;142(1):97-102.

- A Cochrane review found that the evidence suggests that terbinafine is more effective than griseofulvin and that terbinafine and itraconazole are more effective than no treatment.[11] SOR A
- Terbinafine is used daily for 3 months for toenail onychomycosis and daily for 2 months to treat fingernail involvement.[11] SOR A

- Another Cochrane review found two trials of nail infections that did not provide any evidence of benefit for topical treatments (ciclopirox not included) compared with placebo.[12] SOR A
- Terbinafine has a preferable drug interaction profile, may have better long-term cure rates, and daily dosing may be the most effective treatment.[6,11] SOR A
- Itraconazole (Sporanox) has more drug interactions. Pulse dosing is as effective as daily dosing, but even with pulse dosing, therapy is more costly than terbinafine. Consider itraconazole if terbinafine does not effectively treat onychomycosis caused by fungus other than dermatophytes. SOR C
- Fluconazole (Diflucan) is not currently FDA approved for nail therapy and is not as effective as other oral therapies.[6,13] SOR B
- Ciclopirox 8 percent nail lacquer (Penlac) used daily (with weekly nail cleaning and filing) is an FDA-approved topical treatment for ages 12 years and above for mild to moderate onychomycosis. A metaanalysis of 2 randomized controlled trials showed a clinical cure rate of 8 percent versus 1 percent for vehicle alone.[14] Such a low cure rate is disappointing, but a larger group of patients had some improvement without cure. This is one option for persons able to afford this topical treatment but who are not able to take oral antifungals.
- Amorolfine is a topical antifungal agent with activity against dermatophytes, yeasts, and fungi that is available over the counter in Australia and the United Kingdom, but is not approved for use in the US. Amorolfine 5 percent nail lacquer has been used as monotherapy for the treatment of onychomycosis. It is applied once weekly after the surface of the nail is filed with a disposable file and wiped with alcohol. Once weekly application of amorolfine 5 percent nail lacquer for 6 months led to both clinical and mycologic cure in 38 percent and 46 percent of patients. It may also be used to increase cure rates when used in combination with oral antifungals.[15]

COMPLEMENTARY/ALTERNATIVE THERAPY

- There are numerous complementary and alternative medicine (CAM) therapies described on the Internet, most of which have minimal or no evidence of clinical efficacy.
- Mentholated chest rub—There is minimal data on the efficacy of a mentholated chest rub (Vicks VapoRub) in the treatment of onychomycosis. In a series of 18 patients who applied the medication to affected nails daily for 48 weeks, 4 patients (22%) achieved both clinical and mycologic cure.[16] Although these products are unlikely to be harmful, additional studies that support their efficacy in onychomycosis are necessary before widespread use can be recommended.

PREVENTION

Patients should be educated about the use of appropriate footwear, especially in high-exposure areas such as communal bathing facilities and health clubs.

PROGNOSIS

The condition may persist indefinitely if left untreated.

In patients with diabetes or other immunocompromised states, onychomycosis may increase the risk of secondary bacterial infections.[17]

FOLLOW-UP

Routine monitoring of liver function tests during therapy is probably not necessary in patients without underlying liver disease. However, because the manufacturer of terbinafine recommends checking pretreatment serum aminotransferases and monitoring for potential symptoms of hepatotoxicity during treatment, many clinicians routinely obtain pretreatment and mid-therapy values.

PATIENT EDUCATION

Patients should be advised that with treatment, nails may not appear normal for up to 1 year. The normal nail must grow out as treatment progresses. The appearance of normal appearing nails at the proximal edge of the nail is an encouraging sign at the completion of therapy.

164 PARONYCHIA

Brian Elkins, MD
E.J. Mayeaux, Jr., MD

PATIENT STORY

A teenage girl presents with mild itching and redness in her finger nail folds (**Figure 164-1**). The pediatrician diagnosed her with chronic paronychia, probably due to chronically pushing back her cuticles for cosmetic reasons. Behavior modification resulted in resolution of symptoms.

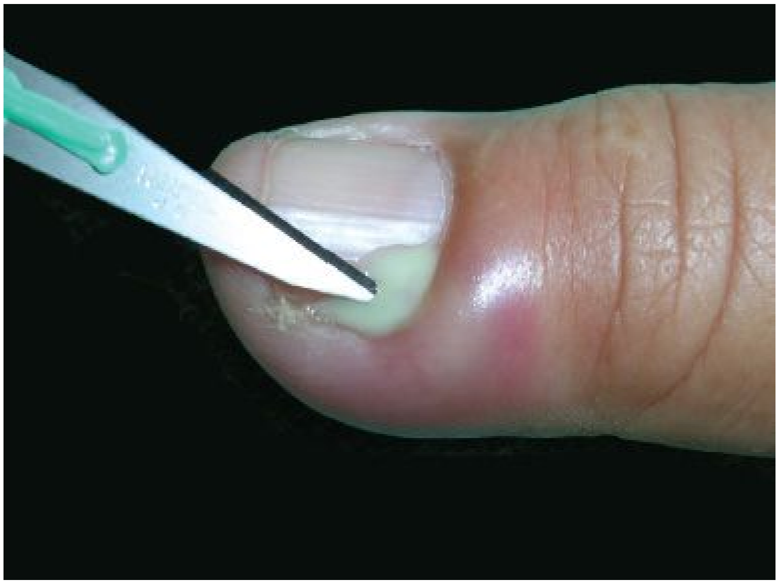

FIGURE 164-1 Chronic paronychia in a teenage girl probably due to chronically pushing back her cuticles for cosmetic reasons. Note the redness in the finger nail folds. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Paronychia is a localized, superficial infection or abscess of the nail folds. Paronychia can be acute or chronic. Acute paronychia usually presents as an acutely painful abscess in the nail fold. It is most commonly treated with incision and drainage (**Figure 164-2**). Chronic paronychia is defined as bring present for longer then 6 weeks duration. It is a generalized red, tender, swelling of the proximal or lateral nail folds. It is usually nonsuppurative and is more difficult to treat.

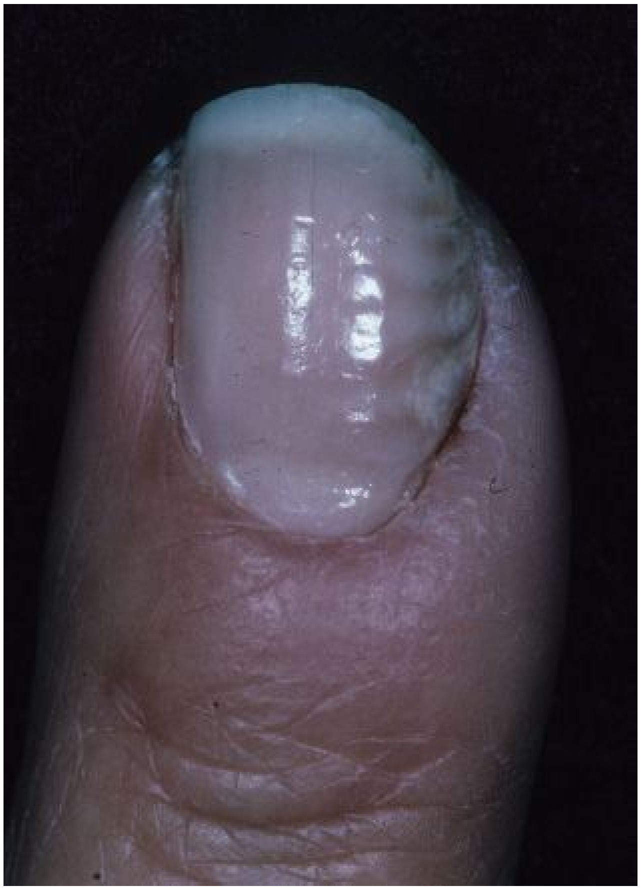

FIGURE 164-2 Incision and drainage of the acute paronychia with a #11 scalpel. Note the exuberant pus draining from the incision. (*Used with permission from Richard P. Usatine, MD*.)

EPIDEMIOLOGY

Paronychia is the most common infection of the hand representing 35 percent of all hand infections in the US.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Paronychial infections develop when a disruption occurs between the seal of the nail fold and the nail plate or the skin of a nail fold is disrupted and allows a portal of entry for invading organisms.[2]
- Acute paronychia is most commonly caused by *S. aureus*, followed by *Streptococcus pyogenes*, *Pseudomonas pyocyanea*, and *Proteus vulgaris*.[3]
- Chronic paronychia is thought to be a multifactorial inflammatory and/or allergic phenomenon in which a variety of microorganisms, including bacteria and fungi, may be secondarily present.[4]
- Untreated persistent chronic paronychia may cause horizontal ridging, undulations and other changes to the nail plate (**Figures 164-3** and **164-4**).

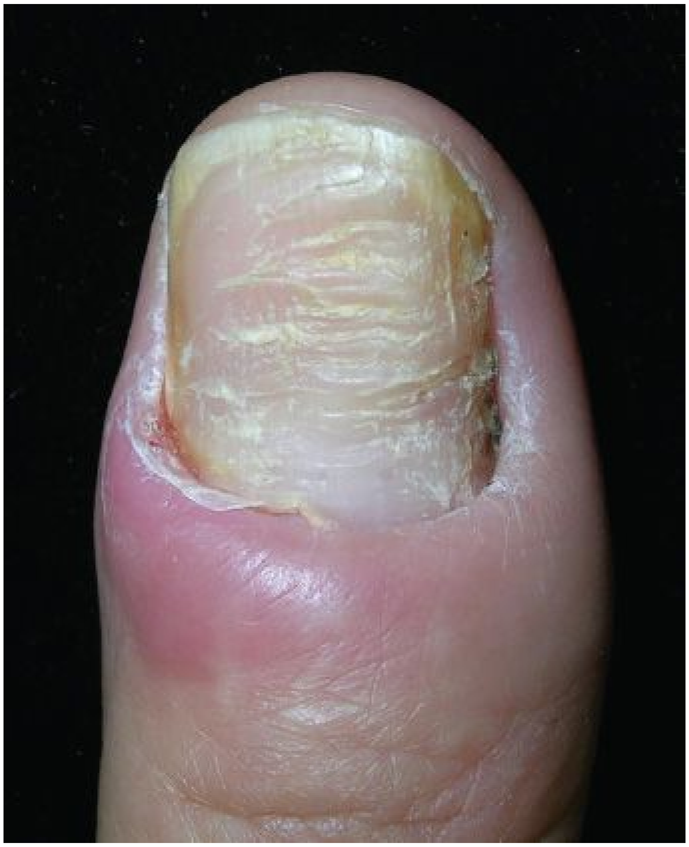

FIGURE 164-3 Chronic paronychia. Note horizontal ridges on one side of the nail plate as a result of chronic inflammation. (*Used with permission from Richard P. Usatine, MD*.)

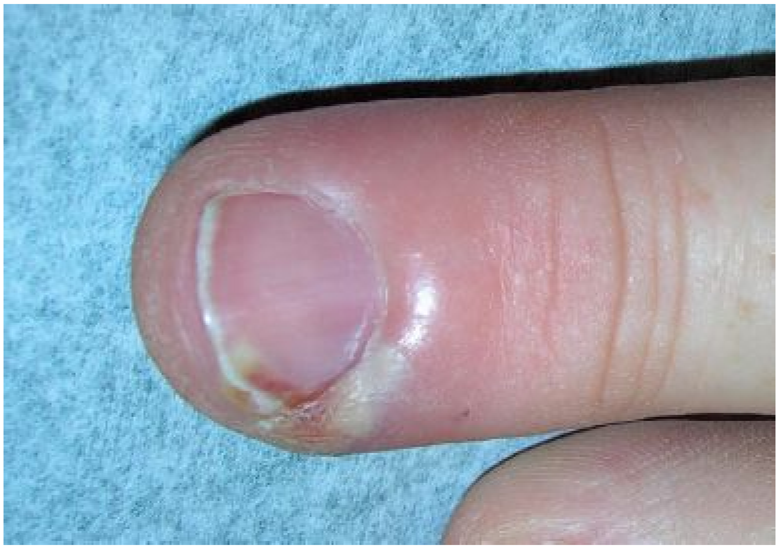

FIGURE 164-4 Chronic Candida paronychia causing a dysmorphic fingernail with horizontal ridging. (*Used with permission from Richard P.*

Usatine, MD.)

RISK FACTORS

- Acute paronychia commonly results from nail biting (**Figure 164-5**), finger sucking, aggressive manicuring (**Figure 164-6**), hang nails (**Figure 164-7**), trauma, and artificial nails.[2]

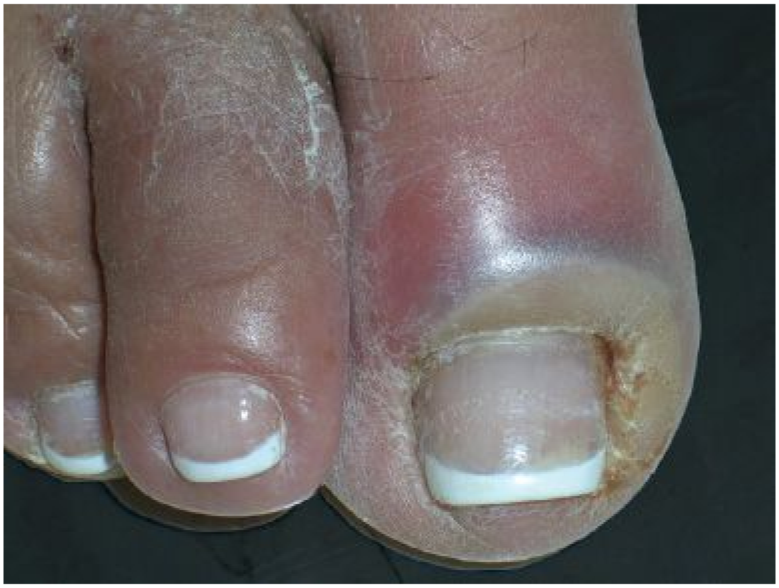

FIGURE 164-5 Acute paronychia from nail biting. Note abscess formation in the lateral nail fold that is extending into the proximal fold. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

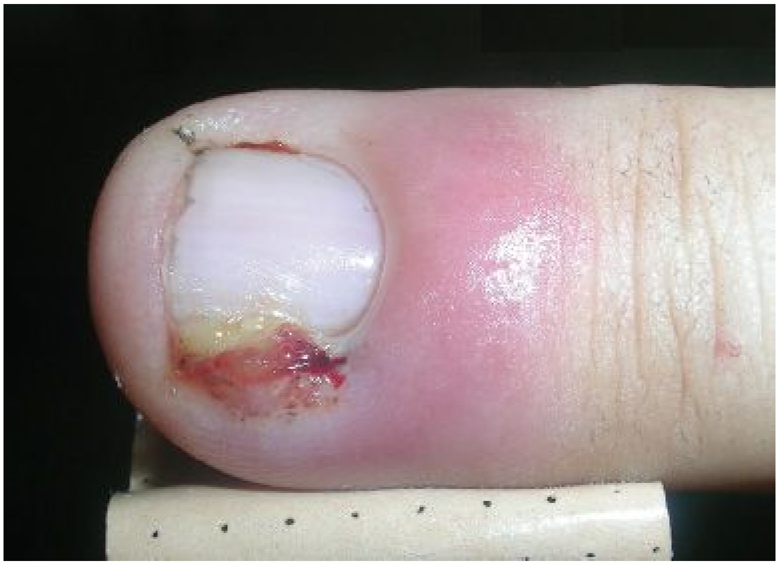

FIGURE 164-6 Acute paronychia of the great toe. Note extensive manicure of the nails, which may predispose to paronychia if the cuticle or nail folds are disrupted. (*Used with permission from Jennifer P. Pierce, MD*.)

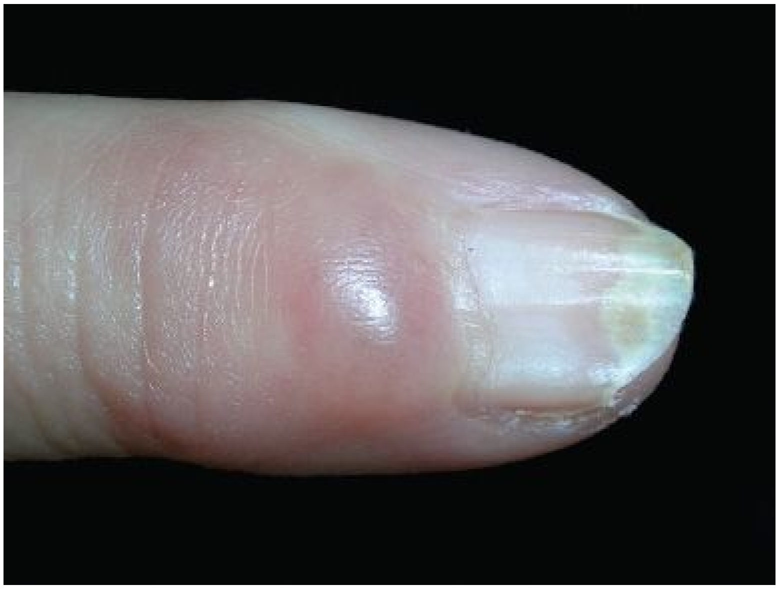

FIGURE 164-7 Paronychia with cellulitis of the skin of the fingertip and granulation tissue formation. This all started when the patient began manipulating a hang nail. (*Used with permission from Richard P. Usatine, MD*.)

- Children are prone to acute paronychia through direct infection of fingers with mouth flora from finger sucking and nail biting.

- Patients with diabetes mellitus, compromised immune systems, or a history of oral steroid use are at increased risk for paronychia, as well as children with chronic pulmonary disease.[5]
- Paronychia may in some cases be a manifestation of zinc deficiency.[6]
- Retroviral therapy use, especially indinavir and lamivudine, may be associated with an increased incidence of paronychia.[7] Several cancer chemotherapeutic drugs, especially taxanes/anthracyclines and epidermal growth factor receptor (EGFR) inhibitors, have also been implicated.[8,9]

DIAGNOSIS

CLINICAL FEATURES

- Acute paronychia presents with localized pain and tenderness. The nail fold appears erythematous and inflamed, and a collection of pus usually develops (**Figures 164-1**, **164-2**, **164-5**, and **164-6**). Granulation tissue may develop along the nail fold and cellulitis may develop (**Figure 164-7**).
- Chronic paronychia is a red, tender, painful swelling of the proximal or lateral nail folds. A small collection of pus or abscess may form but typically only redness and swelling are present. Eventually, the nail plates may become thickened and discolored, with pronounced horizontal ridges (see **Figures 164-3** and **164-4**).[10]

DIFFERENTIAL DIAGNOSIS

- Mucus cyst, which presents as a painless swelling lateral and proximal to the nail plate (**Figure 164-8**). This can also cause changes in the nail morphology.

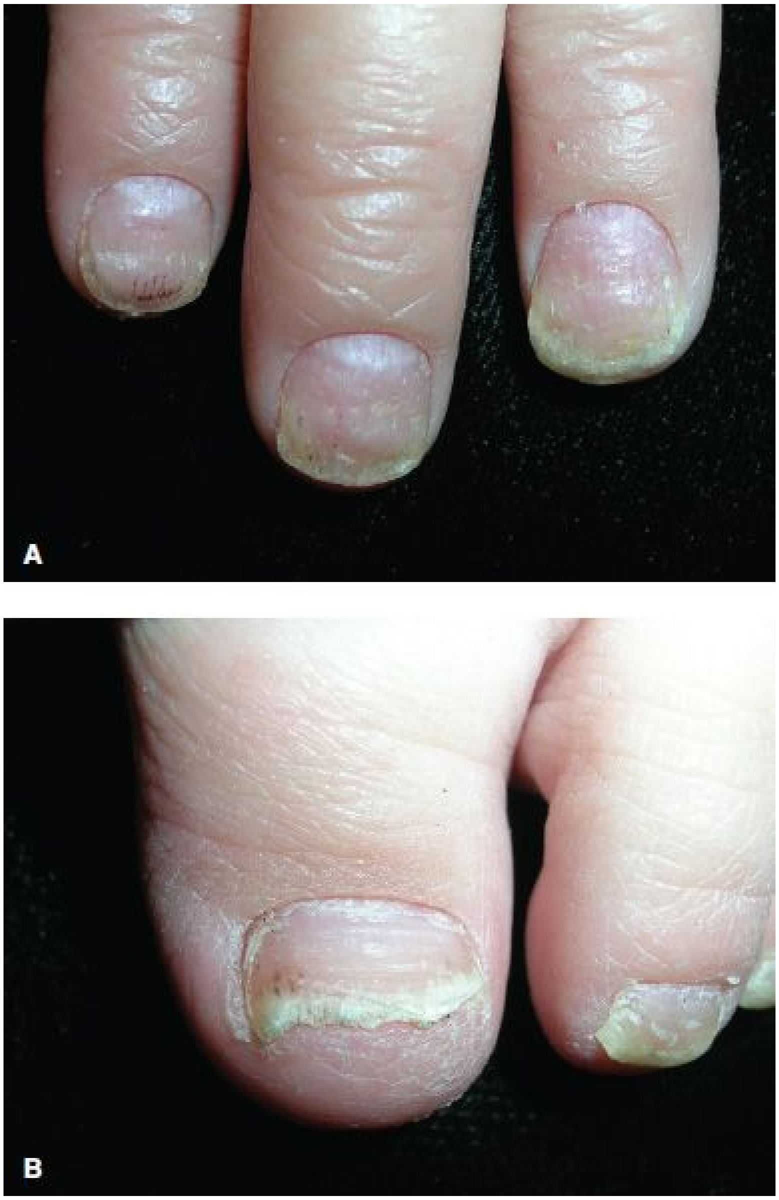

FIGURE 164-8 Digital mucus cyst presenting as a painless swelling of the nail fold in a young woman. Note the indented area of the nail caused by the pressure of the mucus cyst on the nail matrix. (*Used with permission from Richard P. Usatine, MD*.)

- Ingrown nail (onychocryptosis) is a condition in which the nail plate is too large for the nail bed. The pressure applied to the lateral nail fold causes a painful inflammation. Although this is sometimes called paronychia, it is different from the type of paronychia caused by an infection of the nail fold (see Chapter 162, Ingrown Toenail).

- Glomus tumor, which presents with constant severe pain, nail plate elevation, bluish-discoloration of the nail plate, and blurring of the lunula.
- Herpetic whitlow, which results from herpes simplex virus (HSV) infection presents with acute onset of vesicles or pustules, severe edema, erythema, and pain. Tzanck staining of vesicles will demonstrate multinucleated giant cells and viral culture will grow HSV (see Chapter 114, Herpes Simplex).
- Felon—Paronychia must be distinguished from a felon, which is an infection of the digital pulp. It is characterized by severe pain, swelling, and erythema in the pad of the fingertip.
- Benign and malignant neoplasms, which may present early with redness and swelling should always be ruled out when chronic paronychia does not respond to conventional treatment.

MANAGEMENT

NONPHARMACOLOGIC

- Milder cases of acute paronychia without abscess formation may be treated with warm soaks for 20 minutes 3 to 4 times a day.[2] SOR Ⓒ
- When an abscess or fluctuance is present, drainage is necessary.[11] SOR Ⓒ It is performed with digital block anesthesia. The affected nail fold is incised with a scalpel with the blade parallel to the edge of the nail plate and the pus expressed (see **Figure 164-2**). Warm soaks 4 times a day are initiated to keep the incision from sealing until all of the pus is gone.[12] Between soakings, an adhesive bandage can protect the nail fold. Antibiotic therapy is usually not necessary unless there is accompanying cellulitis. SOR Ⓒ

MEDICATIONS

- Acute cases with more inflammation but no abscess formation may be treated with a topical antibiotic cream (e.g., mupirocin [Bactroban], bacitracin) combined with a topical corticosteroid such as betamethasone.[13]
- Lesions that persist after drainage, or which are associated with surrounding cellulitis, should be treated with antistaphylococcal antibiotics (e.g., cephalexin 25 to 50 mg/kg/day divided q6-8hr or dicloxacillin 12.5to 25 mg/kg/day divided q6hr), and cultures should be obtained in severe cases to guide antimicrobial therapy.[13] Clindamycin (20 to 40 mg/kg/day divided q6-8hr) or trimethoprim/sulfamethoxazole (8 to 12 mg TMP/kg/day divided q12hr) may be preferred in communities with a high incidence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA).
- Both children who suck their fingers and patients who bite their nails and who require antibiotics should be covered against anaerobes. Clindamycin and amoxicillin-clavulanate potassium are effective against most pathogens isolated from infections originating in the mouth.[14]
- Long-term treatment of chronic paronychia primarily involves avoiding predisposing factors such as prolonged exposure to water, nail trauma, and finger sucking. Treatment with topical antifungals (topical miconazole or ketoconazole) or a combination of topical steroids and an antifungal agent has been shown to be successful.[2,7] SOR Ⓑ Oral antifungal therapy is usually not necessary.[2]

SURGICAL

- The most common treatment for acute paronychia is incision and drainage. The basic procedures involves obtaining informed consent then performing a digital block on the affected digit. A #11 scalpel blade is places against the nail plate and the abscess is incised where the nail fold meets the nail plate (see **Figure 164-2**). Express the pus and lightly bandage. Have the patient soak the digit several times daily. Antibiotics are usually not necessary unless there is coexisting cellulitis.[15]

PREVENTION

- Trim hangnails to a semilunar smooth edge with a clean sharp nail plate trimmer. Trim toenails flush with the toe tip.
- Avoid nail biting, picking, manipulation, and finger sucking.
- Avoid prolonged hand exposure to moisture. If hand washing must be frequent, use antibacterial soap, thoroughly dry hands with a clean towel, and apply an antibacterial moisturizer. Use cotton glove liners under waterproof gloves to keep hands dry from sweat and condensation.
- Wear rubber or latex-free gloves when there is potential exposure to pathogens.
- Control diabetes mellitus.
- Keep fingernails clean.
- Moisturize the skin, don't let it become chafed and cracked.

PROGNOSIS

Although the nail fold should improve with treatment, some chronic nail plate changes may not resolve. Paronychia has rarely been associated with distant, necrotizing soft-tissue infections,[15] so it may be prudent to advise caregivers to observe for signs of remote infection.

FOLLOW-UP

Patients can perform warm soaks 3 to 4 times per day and should have a follow-up examination several days after incision and drainage to assure the infection is resolving appropriately.

PATIENT EDUCATION

Educate patients on measures that may prevent or improve paronychia.

165 PSORIATIC NAILS

E.J. Mayeaux, Jr., MD
Joshua Rai Clark, MD

PATIENT STORY

A 3-year-old girl presents with one year of rashes from head to toe that are not responding to topical steroids. The girl's mother and her chart reflect a diagnosis of severe atopic dermatitis. The physician meticulously examines the girl's skin and nails and finds splinter hemorrhages, pitting, longitudinal ridging and onycholysis in the fingernails with splinter hemorrhages and nail thickening of the toenails (**Figure 165-1**). With this new information in mind, the physician notes other skin findings that are more suggestive of psoriasis than atopic dermatitis. This careful examination of the nails leads the clinician to the correct diagnosis and more effective treatment of the psoriasis.

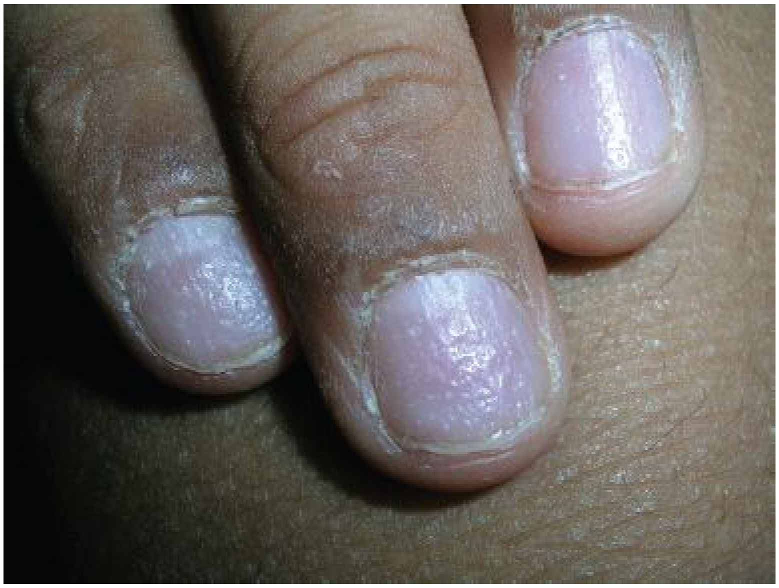

FIGURE 165-1 Nail psoriasis in a 3-year-old girl that helped to correctly diagnose her skin rash as psoriasis and not atopic dermatitis. A. Note the nail pitting, onycholysis, oil drop sign, longitudinal ridging and splinter hemorrhages in the fingernails. B. Note the splinter hemorrhages and nail thickening in the toenails. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Psoriasis is a hereditary disorder of skin with numerous clinical expressions. It affects millions of people throughout the world.[1] Nail involvement is common and can have a significant cosmetic impact.

EPIDEMIOLOGY

- Nails are involved in 30 to 50 percent of psoriasis patients at any given time, and up to 90 percent develop nail changes over their lifetime.[1] In most cases, nail involvement coexists with cutaneous psoriasis, although the skin surrounding the affected nails need not be involved. Psoriatic nail disease without overt cutaneous disease occurs in 1 to 5 percent of psoriasis. Patients with nail involvement are thought to have a higher incidence of associated arthritis.[2]
- The most common nail change seen with psoriasis is nail plate pitting (**Figures 165-1** and **165-2**).

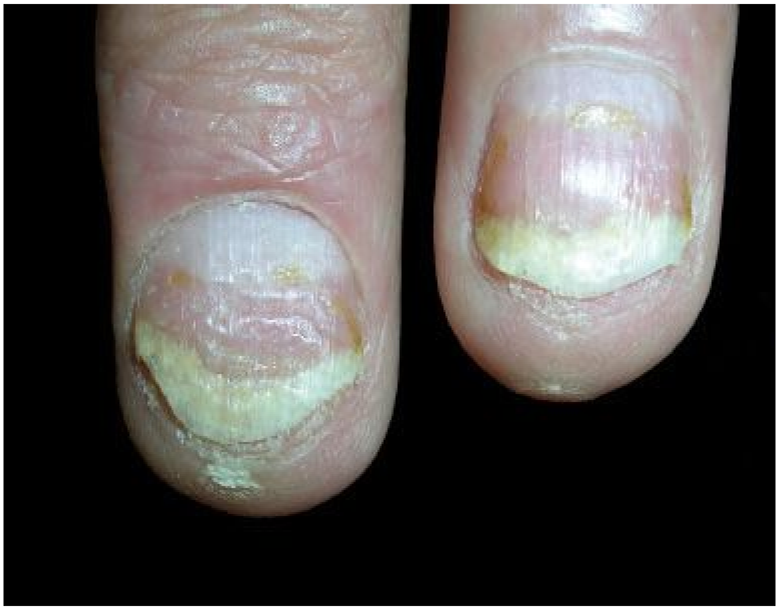

FIGURE 165-2 Nail pitting in a young boy with psoriasis. (*Used with permission from Richard P. Usatine, MD.*)

ETIOLOGY AND PATHOPHYSIOLOGY

- In psoriasis, parakeratotic cells within the stratum corneum of the nail matrix alters normal keratinization.[3] The proximal nail matrix forms the superficial portion of the nail plate, so that involvement in this part of the matrix results in pitting of the nail plate (**Figures 165-1** and **165-2**.) The pits may range in size from pinpoint depressions to large punched-out lesions. People without psoriasis can have nail pitting.
- Longitudinal matrix involvement produces longitudinal nail ridging or splitting (**Figure 165-3**). When transverse matrix involvement occurs, solitary or multiple “growth arrest” lines (Beau lines) may occur (see Chapter 160, Normal Nail Variants). Psoriatic involvement of the intermediate portion of the nail matrix leads to leukonychia and diminished nail plate integrity.

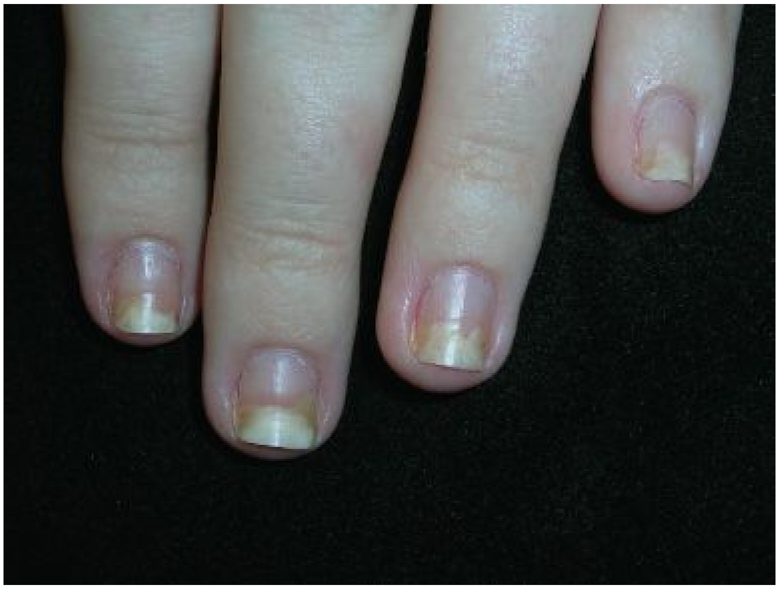

FIGURE 165-3 Nail psoriasis demonstrating onycholysis, pits, and transverse and longitudinal ridging. (*Used with permission from Richard P. Usatine, MD.*)

- Parakeratosis of the nail bed with thickening of the stratum corneum causes discoloration of the nail bed, producing the “salmon spot” or “oil drop” signs (**Figure 165-4**).[3]

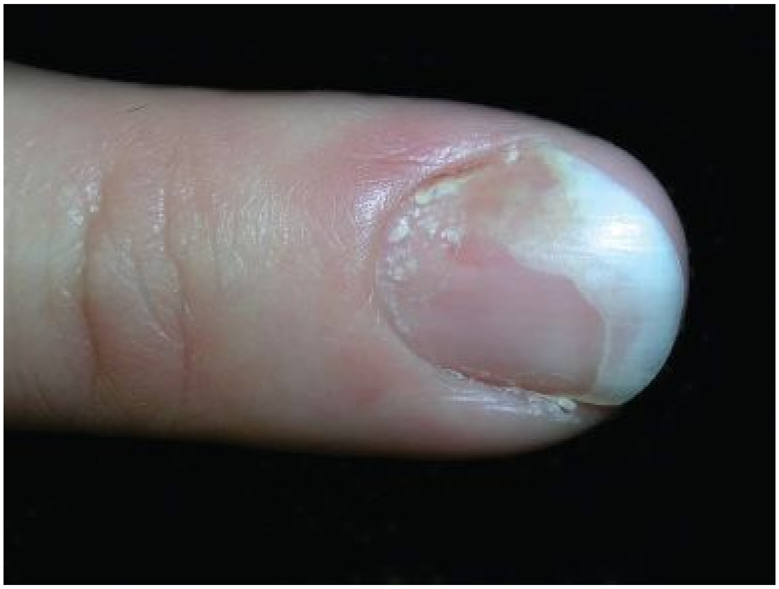

FIGURE 165-4 Nail psoriasis with onycholysis and oil drop sign in a teenage female. Note that end of the nail plates are no longer attached to the

nail bed and there is a light brown discoloration where the nail loses its attachment. (*Used with permission from Richard P. Usatine, MD*.)

- Desquamation of parakeratotic cells at the hyponychium leads to onycholysis, which may allow for bacteria and fungi infection (**Figure 165-5**).[4]

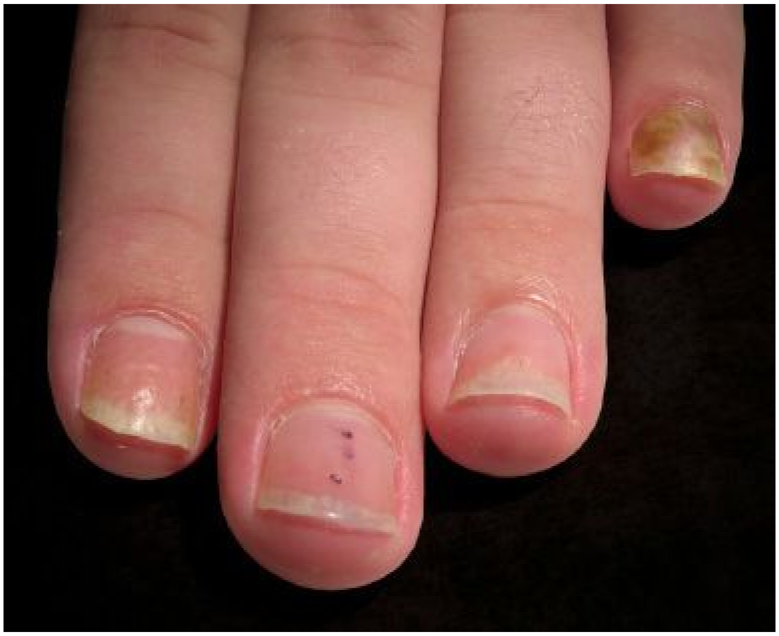

FIGURE 165-5 Nail psoriasis with the oil drop sign proximal to the lighter onycholysis at the distal nail. (*Used with permission from Richard P. Usatine, MD*.)

RISK FACTORS

- Psoriasis of the skin.
- Psoriatic arthritis.
- Nail unit trauma.
- Generalized psoriasis flair.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis of nail psoriasis is usually straightforward when characteristic nail findings coexist with cutaneous psoriasis. Nail pitting and onycholysis are the most common findings (**Figures 165-1** to **165-5**).
- Nail psoriasis and onychomycosis are often indistinguishable by clinical examination alone. Psoriasis at the hyponychium produces subungual hyperkeratosis and distal onycholysis (**Figures 165-4** and **165-5**). Trauma may accentuate this process. Secondary microbial colonization by *Candida* or *Pseudomonas* organisms may occur (**Figure 165-6**).

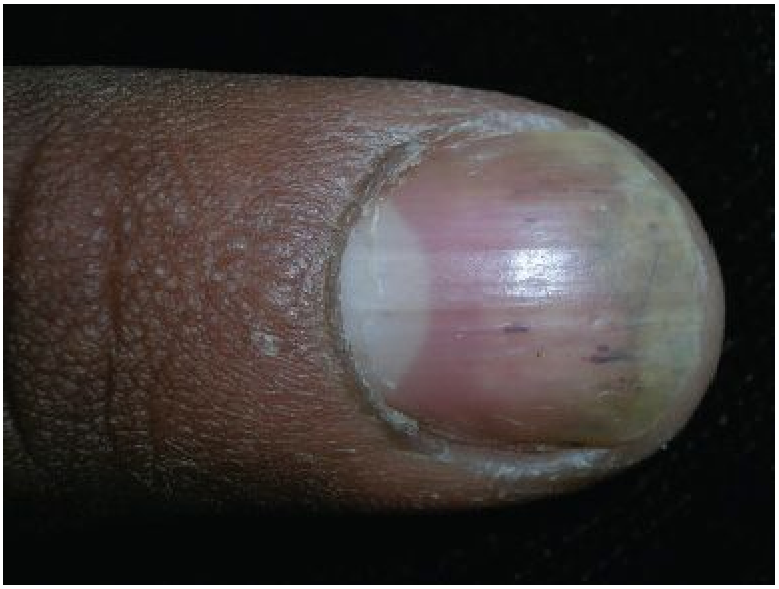

FIGURE 165-6 Patient with nail psoriasis demonstrating the oil drop sign (second digit), nail pitting (second and third digit), onycholysis (second, fourth and fifth digit), and secondary pseudomonas infection (fifth digit). (*Used with permission from E.J. Mayeaux, Jr., MD.*)

- Nail bed psoriasis produces localized onycholysis which often appears like a drop of oil on a piece of paper (oil drop sign; see **Figures 165-4**, and **165-5**). This same condition is also called the salmon patch sign.

- Extensive germinal matrix involvement may result in loss of nail integrity and transverse (horizontal) ridging (**Figure 165-3**).
- Psoriasis causes dermal vascular dilation and tortuosity, and in the nails is associated with splinter hemorrhages of the nail bed caused by foci of capillary bleeding. Extravasated blood becomes trapped between the longitudinal troughs of the nail bed and the overlying nail plate grows out distally along with the plate (**Figures 165-1** and **165-7**). The splinter hemorrhages of the psoriatic nail are analogous to the cutaneous Auspitz sign.

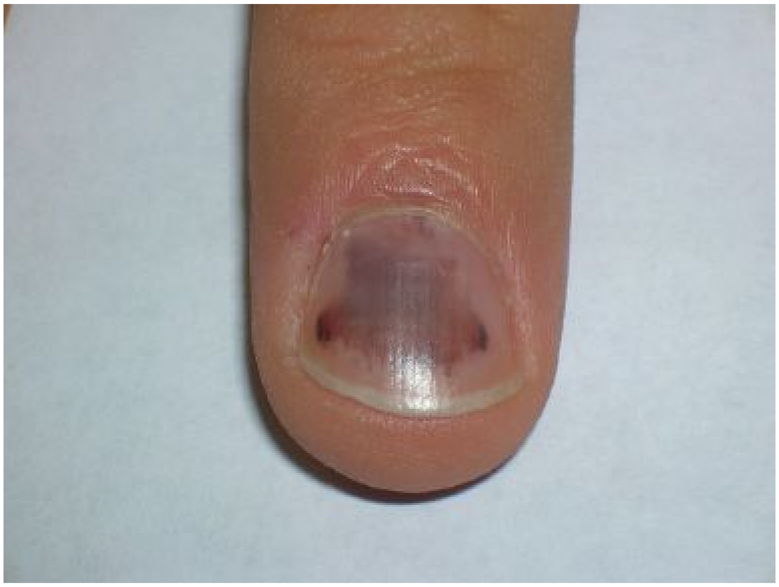

FIGURE 165-7 Prominent splinter hemorrhages and onycholysis in the nail of a person with psoriasis. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY TESTING

- KOH preparation and fungal culture will usually provide an answer. However, it may be necessary to clip a portion of the nail plate and send it for fungal staining (periodic acid-Schiff [PAS] stain) if the first test results are not consistent with the clinical picture.[5] Psoriasis and onychomycosis can occur concomitantly.

BIOPSY

- Biopsy of the nail unit is rarely necessary unless a malignancy is suspected.

DIFFERENTIAL DIAGNOSIS

- Onychomycosis produces distal onycholysis and hyperkeratosis that appear identical to psoriasis and may coexist with it (see Chapter 163, Onychomycosis).
- Alopecia areata also can produce pitting of the nails. As a general rule, pitting in psoriasis is more irregular and broader based; pitting in alopecia areata is more regular, shallow, and geometric and produces fine pits (see Chapter 158, Alopecia Areata).
- Neoplastic and dysplastic diseases may produce psoriasiform nail changes in a single nail. Bowen disease, squamous cell carcinoma, and verruca vulgaris may appear as an isolated subungual or periungual plaque, possibly with accompanying nail plate destruction. A biopsy can establish a definitive diagnosis.

MANAGEMENT

NONPHARMACOLOGIC

- Psoriatic nail disease is often persistent and refractory to treatment. There is insufficient evidence to recommend a standard treatment.
- The nails should be kept short, to avoid traumatic exacerbation of onycholysis and to avoid the accumulation of exogenous material under the nail.[3] SOR Ⓒ

- Nail polish may be very helpful in concealing a range of nail unit changes.[6] SOR Ⓒ
- Nail plate buffing may diminish surface imperfections.[6] SOR Ⓒ

MEDICATIONS

- Unfortunately, specific evidence for systemic therapy in nail psoriasis is generally lacking. It should be considered in those with significant cutaneous involvement in addition to nail disease.
- One treatment option for nail psoriasis, especially with matrix involvement, is intralesional corticosteroid injection. Triamcinolone acetonide (0.4 mL, 10 mg/mL) is injected into the nail bed, matrix, or proximal fold following digital block, and then at 3-month intervals.[3,7] SOR Ⓐ Subungual hyperkeratosis, ridging, and thickening respond better than pitting and onycholysis, with benefit sustained for at least 9 months.[7] Pain, periungual hypopigmentation, subungual hemorrhage and atrophy have been reported.[3]
- Nail bed disease, including subungual hyperkeratosis, distal onycholysis, and “oil drop” changes may also need the lateral nail folds injected close to the nail bed. Direct injection into the nail bed is prevented by the nail plate and extreme pain sensitivity of the hyponychial region. Atrophy and subungual hematoma formation are potential complications.
- Topical tazarotene improves onycholysis and nail pitting (if applied under occlusion) in those treated for 24 weeks.[3] SOR Ⓐ
- Narrow-band UVB and psoralen UVA (PUVA) phototherapy for 3 to 6 months is effective for cutaneous psoriasis but it’s efficacy for nail psoriasis is poorly defined.[3]
- Systemic retinoid therapy is often effective for pustular psoriasis, and early intervention is most likely to prevent chronic nail-associated scarring.
- However, in a single uncontrolled retrospective study in patients ranging in ages from 15 to 81 years old found that Infliximab (5mg/kg) given at 0,

2, 6 and every 8 weeks up to 38 weeks showed a decrease in psoriatic nail lesions. This study suggests that the psoriatic nail should be treated early as its presence may correlate with an increased chance of developing psoriatic arthritis. This study is limited by sample size and lack of long term follow up.[8] SOR B

PREVENTION[9]

- Wearing gloves during wet work and during exposure to harsh materials may minimize trauma to the skin and nail unit.
- Trimming the nail short to minimize leverage at the free edge and resulting trauma.
- If dry skin or scaling develop, application of emollients may be helpful.
- Cosmetic manipulations of the nail risk exacerbating the disease due to minor trauma. Discretion and care should be exercised when trimming the cuticle and clearing subungual debris.

PROGNOSIS

- Psoriatic nail changes may be reversible because scarring typically does not occur. An exception to this may develop in severe cases of generalized pustular psoriasis.

FOLLOW-UP

- Follow-up can be combined with regular follow-ups for cutaneous psoriasis.

PATIENT EDUCATION

- Nail psoriasis is mainly a cosmetic problem. Nail polish or artificial nails can be used in some patients to conceal psoriatic pitting and onycholysis. When subungual hyperkeratosis becomes uncomfortable because of pressure exerted by footwear, the nail can be pared down to relieve the pressure.
- Patients should be instructed to trim nails back to the point of firm attachment with the nail bed to minimize further nail-bed and nail-plate disassociation. Wearing gloves while working may minimize trauma to the nails. Tell patients to avoid vigorous cleaning and scraping under the nails as this may break the skin where the nail is attached and lead to an infection.

166 SUBUNGUAL HEMATOMA

E.J. Mayeaux, Jr., MD

PATIENT STORY

A 14-year-old boy presented to the office 1 week after slamming his finger in a car door. He was seen at an urgent care clinic after the acute event and told to follow-up in 1 week. A healing subungual hematoma was evident (**Figure 166-1**). He has full range-of-motion and no pain. Since there is no pain, there is no indication for nail perforation and drainage.

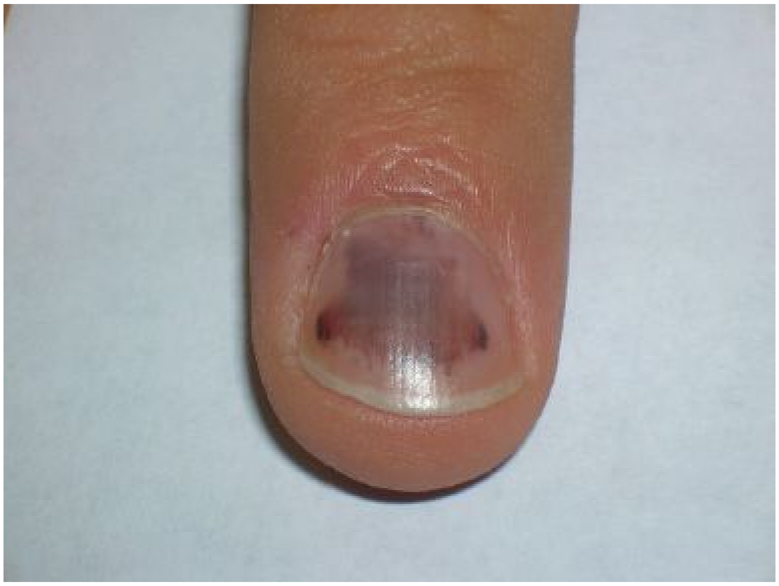

FIGURE 166-1 Subungual hematoma healing in a 14-year-old boy one week after slamming his finger in a car door. (*Used with permission from E.J. Mayeaux, Jr., MD*.)

INTRODUCTION

Subungual hematoma (blood under the fingernail or toenail) is a common injury. It is typically caused by a blow to the distal phalanx (e.g., smashing with a tool, crush in a door jamb, stubbing one’s toe). The blow causes bleeding of the nail matrix or bed with resultant subungual hematoma formation. Patients usually present because of throbbing pain associated with blue-black discoloration under the nail plate. Subungual hematomas may be simple (i.e., the nail and nail fold are intact) or accompanied by significant injuries to the nail fold and digit.[1] The patient may not be aware of the precipitating trauma, because it may have been minor and/or chronic (e.g., rubbing in a tight shoe).

EPIDEMIOLOGY

Subungual hematoma is a common childhood injury.

ETIOLOGY AND PATHOPHYSIOLOGY

- The injury causes bleeding of the nail matrix and nail bed, which results in subungual hematoma formation. Pain is produced by the pressure in the contained space under the nail plate pressing against nerve receptors, although soft tissue or bony injury may also contribute to the pain when present (**Figures 166-1** to **166-5**).

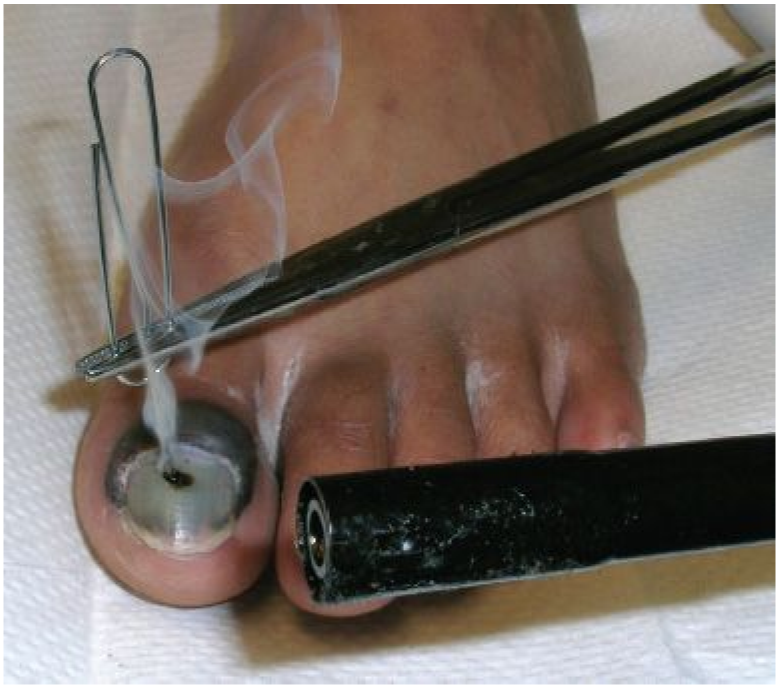

FIGURE 166-2 A subungual hematoma occurred when an iron fell on the toe of this young woman. A paperclip was held in a hemostat and heated with a torch to pierce the patient’s nail plate in order to relieve the subungual hematoma. (*Used with permission from Richard P. Usatine, MD*.)

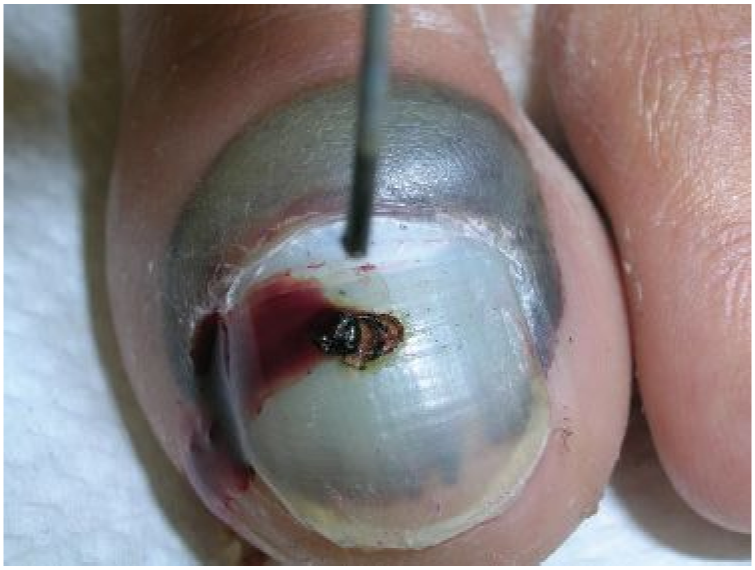

FIGURE 166-3 The hot paper clip formed a nice hole in the nail plate and the blood drained out spontaneously. This relieved the pressure and gave

the patient immediate pain relief. (*Used with permission from Richard P. Usatine, MD.*)

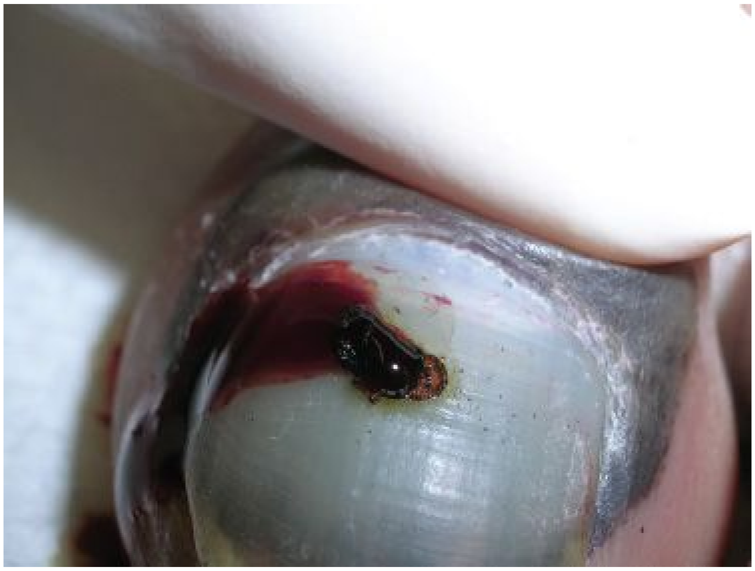

FIGURE 166-4 After the nail plate is pierced, the blood drains easily with a little pressure on the proximal nail fold. (*Used with permission from Richard P. Usatine, MD.*)

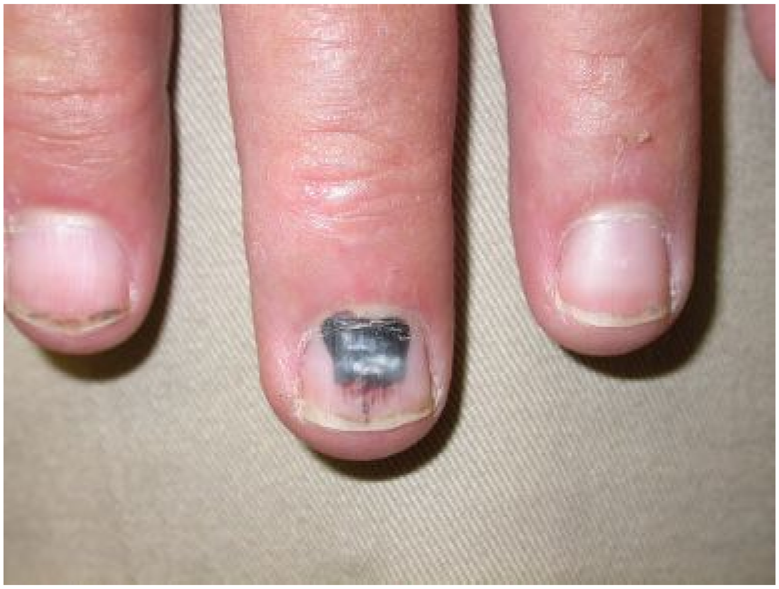

FIGURE 166-5 This persistent discoloration of the nail in this adolescent was correctly diagnosed as a subungual hematoma by history and physical exam so a nail plate biopsy was not needed. (*Used with permission from Richard P. Usatine, MD.*)

- In most cases the discoloration grows out with the nail plate, exhibiting a proximal border that reproduces the shape of the lunula. Occasionally, a hematoma does not migrate because of repeated daily trauma. An extended, nonmigrating "hematoma" should be considered suspicious. Nail plate punch biopsy can be performed if melanoma is a worry. If the dark area was only a hematoma the dark color lifts off with nail plate.
- Potential complications of subungual hematoma include onycholysis, nail deformity (usually splitting as in **Figure 166-6**), and infection. Complications are more likely to occur when presentation is delayed or there is an underlying fracture.[2]

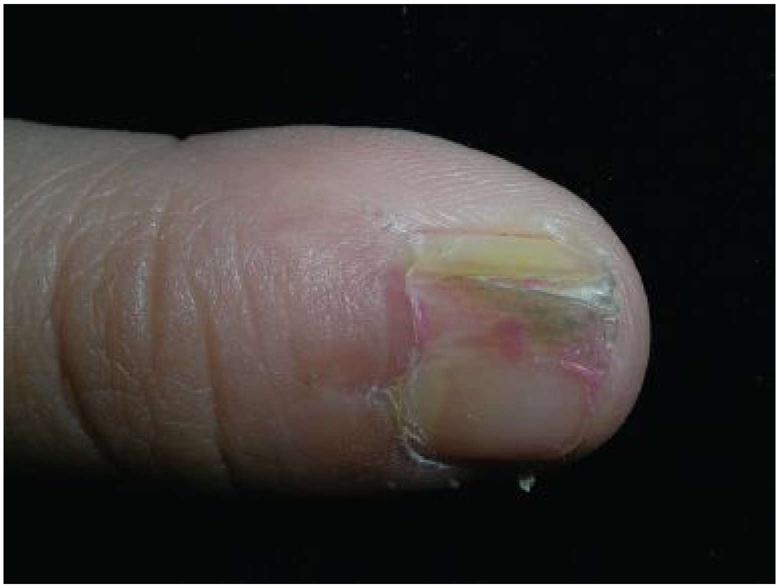

FIGURE 166-6 Split-nail deformity in a 6-year-old girl 1 year after her finger was closed in a car door and sutured in the emergency department. The matrix did not come together well and the nail will remain split (onychoschizia). (*Used with permission from Richard P. Usatine, MD.*)

DIAGNOSIS

CLINICAL FEATURES

- Patients experience throbbing pain and blue-black discoloration under the nail as the hematoma progresses. Pain is relieved immediately in most patients with simple nail trephination (**Figure 166-3**).

IMAGING

- If the mechanism of injury and clinical picture suggest a possible distal phalanx or distal interphalangeal (DIP) fracture, obtain a radiograph. SOR Ⓒ

DIFFERENTIAL DIAGNOSIS

- Nail bed nevus—Appears as a stable or slowly growing painless dark spot in the nail bed or matrix.
- Longitudinal melanonychia—Appears as painless pigmented bands that start in the matrix and extend the length of the nail (see Chapter 161, Pigmented Nail Disorders).
- Subungual melanoma—May start as a painless darkly pigmented band in the matrix and extend the length of the nail. It may be associated with pigment deposition in the proximal nail fold (Hutchinson sign; see Chapter 161, Pigmented Nail Disorders).
- Splinter hemorrhages—Appears as reddish streaks in the nail bed and are seen in psoriasis more commonly than endocarditis (see Chapter 165, Psoriatic Nails).
- The diagnosis of child abuse must be considered in cases of chronic or frequently recurrent subungual hematomas in children.[3]

MANAGEMENT

NONPHARMACOLOGIC

- Subungual hematomas are treated with nail trephination, which removes the extravasated blood and relieves the pressure and resulting pain. Beyond 48 hours, most subungual hematomas have clotted and pain has decreased, so trephination is ineffective. SOR Ⓒ

SURGERY

- Nail perforation is a painless procedure because there are no nerve endings in the nail plate that is perforated. The nail is perforated with a steel paper clip (**Figures 166-2** to **166-4**) or an electrocautery device. This allows the collected blood to drain out (**Figures 166-3** and **166-4**). The hole must be large enough for continued drainage, which can continue for 24 to 36 hours. The puncture site should be kept covered with sterile gauze dressing while the wound drains, and the gauze should be changed daily. Extreme caution should be used with open flame in a medical (and especially pediatric) setting.
- The bevel of a large-bore needle may be twisted against the nail plate like a mechanical spade bit to produce a hole to drain the hematoma.[4] This method causes compression of the nail against the hematoma and nail bed during the procedure and may temporarily increase pain.
- Insulin syringe needle (29 gauge) may also be used for aspiration of distal nail subungual hematomas.[5]
- Mesoscission device (e.g., PathFormer) may be used to bore multiple holes in the nail over the hematoma. It monitors electrical resistance to determine depth of mechanical boring, thus avoiding inadvertent puncture of the nail bed.[6]

MEDICATIONS

- The use of prophylactic antibiotics does not appear to improve outcomes in patients with subungual hematomas and intact nail folds.[7] SOR Ⓑ If a prophylactic antibiotic is used, a first generation cephalosporin (e.g., cephalexin 25–50 mg/kg/day divided every 6 to 8 hours for 10 days) would be the drug of choice.[8,9]

- Oral analgesia such as ibuprofen 10 mg/kg (maximum dose: 800 mg) every 6 to 8 hours may be used with more painful digits. SOR C

REFERRAL

- Some authors recommend removal of the nail with inspection instead of nail trephination when the hematoma involves more than 25 to 50 percent of the nail because of the increased likelihood of significant nail bed injury and fracture of the distal phalanx.[10,11] SOR C
- When deeper injuries are involved, nail plate removal after a digital block allows for nail bed repair.[12] SOR C

PROGNOSIS

The potential complications of a subungual hematoma include onycholysis (separation of the nail plate from the nail bed), nail deformity, nail loss, and infection. Complications are more likely to occur when care is delayed.

A retrospective analysis of 123 patients treated with simple trephination found that 85 percent of patients reported an excellent or very good outcome, 2 percent reported a poor outcome (nail splitting), and no correlation was found between outcome and size of the hematoma or the presence of fracture or infection.[2]

FOLLOW-UP

After drainage, instruct the patient to soak the affected digit in warm water several times per day for 2 days, and to keep the area dressed between soaks. Have the patient return if there are any signs of reaccumulation of blood or infection.

PATIENT EDUCATION

- Potential complications of subungual hematoma and nail trephination should be discussed with the patient and/or the patient's parents or guardian.
- Inform the patient that residual discoloration usually slowly grows out with the nail.

SECTION 15 PIGMENTARY CONDITIONS

167 VITILIGO AND HYPOPIGMENTATION

Richard P. Usatine, MD
Karen A. Hughes, MD
Mindy A. Smith, MD, MS

PATIENT STORY

An 8-year-old Hispanic boy is brought in to the clinic by his mother, who is concerned about his pigment loss (**Figure 167-1**). He is starting to develop this vitiligo around the mouth and his mother wants him to be treated. The child was started on a topical steroid and the use of narrow band UVB was discussed if the steroid does not prove helpful. Realistic expectations of the treatments were provided to the mother and her son.

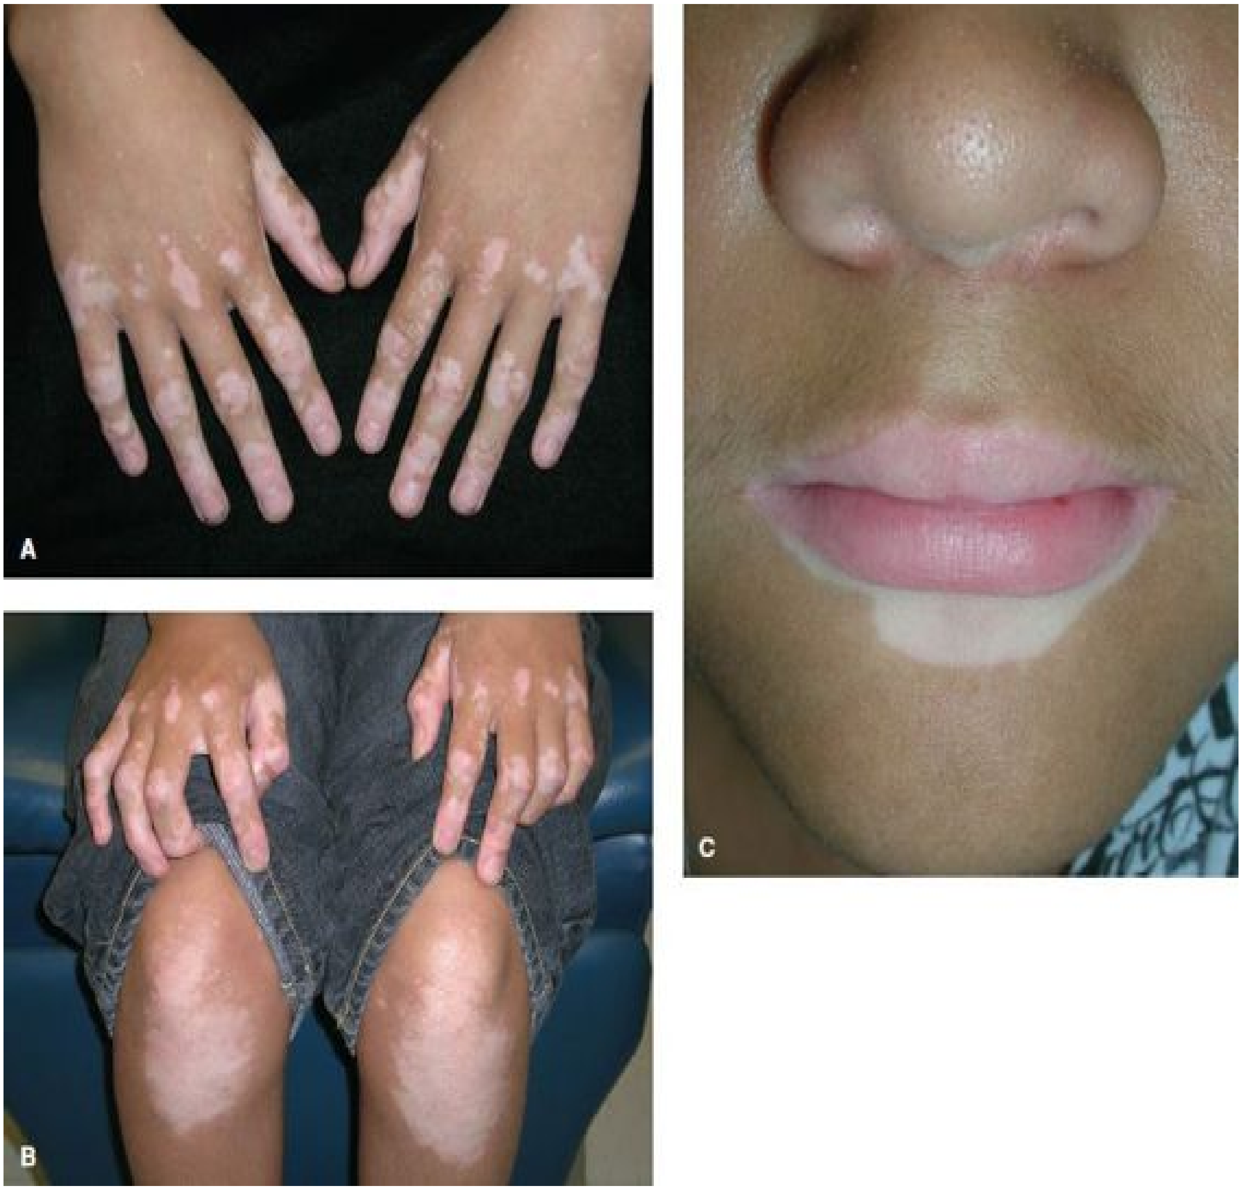

FIGURE 167-1 Vitiligo in an 8-year-old Hispanic boy. A. Hands. B. Knees and hands. C. Perioral. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Vitiligo is an acquired, progressive loss of pigmentation of the epidermis. The Vitiligo European Task Force defines nonsegmental vitiligo as “an acquired chronic pigmentation disorder characterized by white patches, often symmetrical, which usually increase in size with time, corresponding to a substantial loss of functioning epidermal and sometimes hair follicle melanocytes."[1] Segmental vitiligo is defined similarly except for a unilateral distribution that may totally or partially match a dermatome; occasionally more than one segment is involved.[1]

SYNONYMS

Vitiligo vulgaris.

EPIDEMIOLOGY

- Vitiligo occurs in approximately 0.5 to 2 percent of the worldwide population.[2,3]
- It can occur at any age but typically develops between the ages of 10 and 30 years.[2]
- Vitiligo has equal rates in males and females.[2]
- It occurs in all races but is more prominent in those with darker skin.

ETIOLOGY AND PATHOPHYSIOLOGY

- Autoimmune disease with destruction of melanocytes.
- Genetic component in approximately 30 percent of cases. Toll-like receptor genes were found to be associated with vitiligo in a population of Turkish patients.[4]
- Can trigger or worsen with illness, emotional stress, and/or skin trauma (Koebner phenomenon).

DIAGNOSIS

CLINICAL FEATURES

- Macular regions of depigmentation with scalloped, well-defined borders (**Figures 167-1** to **167-3**).

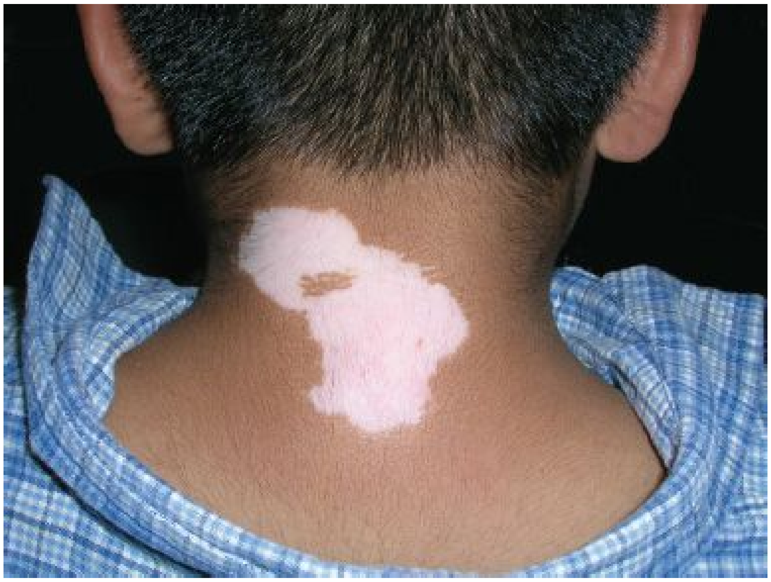

FIGURE 167-2 Vitiligo on the neck of a Hispanic boy. (*Used with permission from Richard P. Usatine, MD*.)

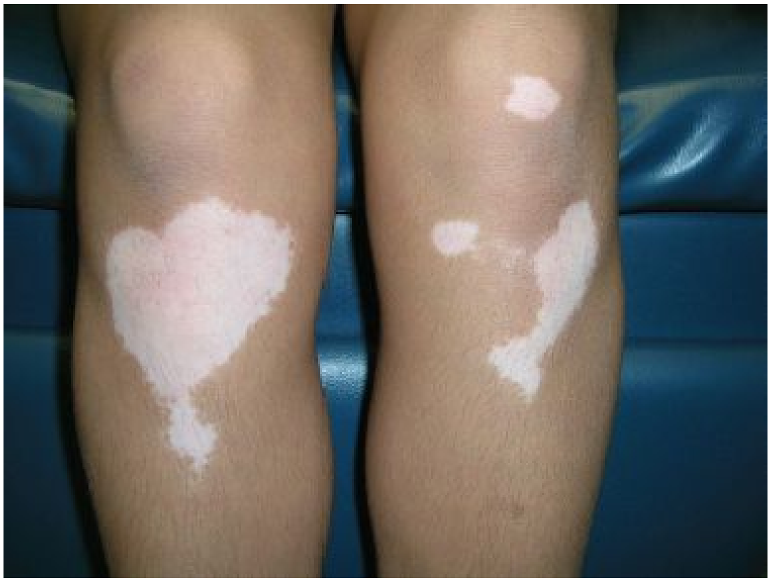

FIGURE 167-3 Vitiligo on the knees with the typical jagged edges. (*Used with permission from Richard P. Usatine, MD*.)

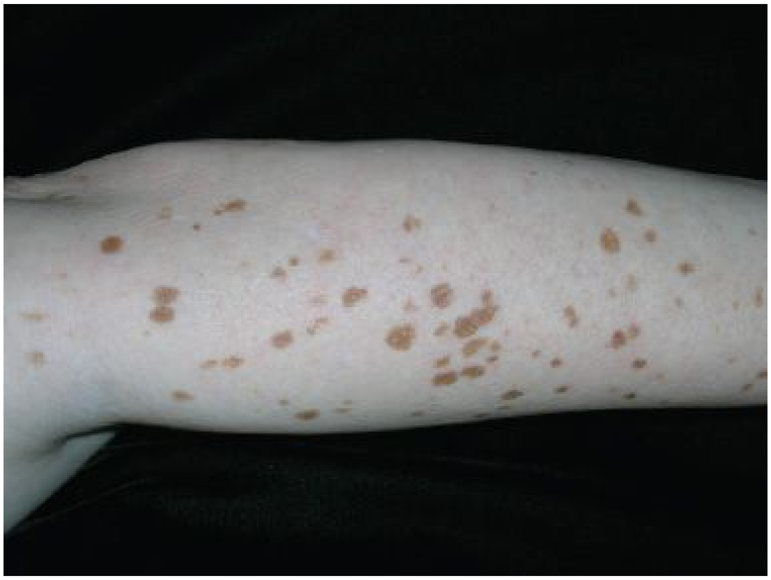

FIGURE 167-4 This previously dark-skinned patient has only a few spots of pigment remaining on her arm because of the extensive vitiligo. Her father has the same condition. (*Used with permission from Richard P. Usatine, MD*.)

- Depigmented areas often coalesce over time to form larger areas (**Figure 167-4**).

- Depigmented areas are more susceptible to sunburn. Tanning of the normal surrounding skin makes the depigmented areas more obvious.
- There is no standardized method for assessing vitiligo; strategies include subjective clinical assessment, semiobjective assessment (e.g., Vitiligo Area Scoring Index [VASI] and point-counting methods), macroscopic morphologic assessment (e.g., visual, photographic in natural or UV light, or computerized image analysis), micromorphologic assessment (e.g., confocal laser microscopy), and objective assessment (e.g., software-based image analysis or spectrophotometry).[5] Authors of a literature review concluded that the VASI, the rule of 9, and Wood's lamp were the best techniques for assessing the degree of pigmentary lesions and measuring the extent and progression of vitiligo.[5]
- Conditions associated with vitiligo include thyroid disease and the presence of thyroid antibodies,[6,7] congenital nevi (in one study, 6.2 percent versus 2.8 percent in those without vitiligo),[4] and halo nevi,[1] and possibly primary open-angle glaucoma (57% of patients in one case series).[8]

TYPICAL DISTRIBUTION

- Widespread, but generally seen first on the face, hands, arms, and genitalia.
- Depigmentation around body openings such as eyes, mouth, umbilicus, and anus is common (**Figure 167-5**). When the eyelashes are involved it is called *leukotrichia*. When other hair is involved it is called *poliosis*.

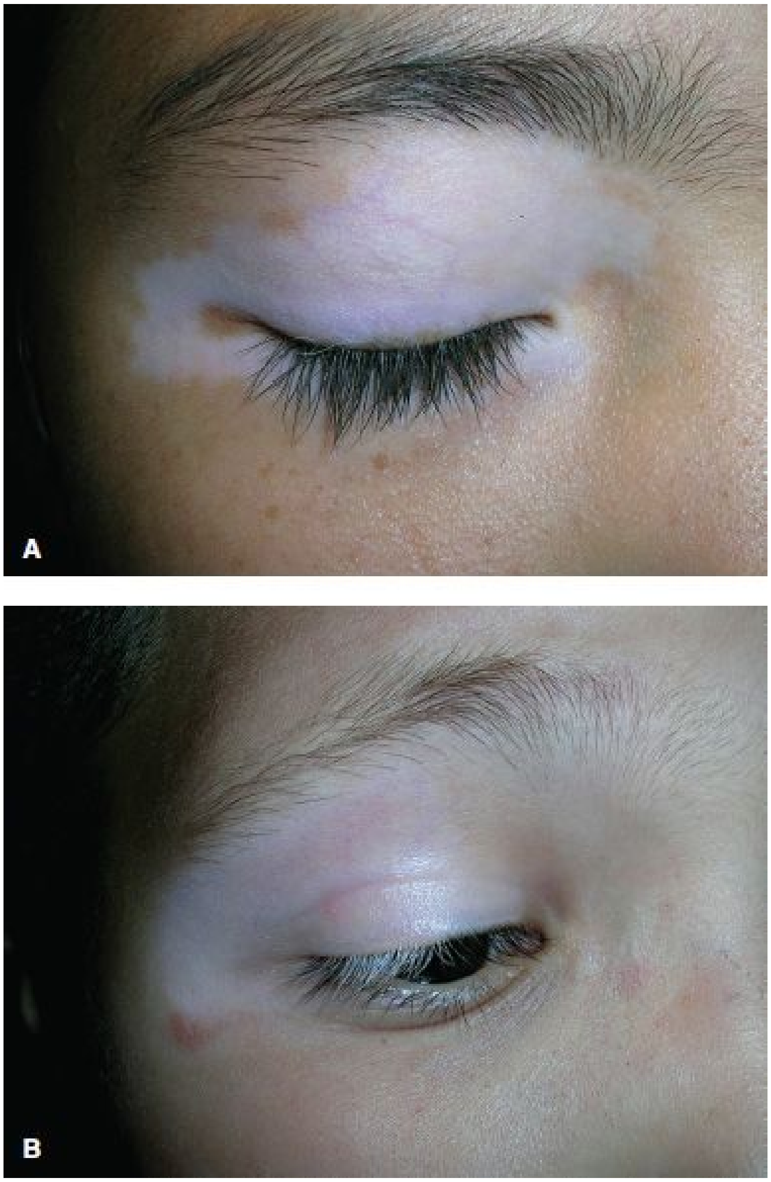

FIGURE 167-5 Vitiligo occurs commonly around the eye. A. Vitiligo with normal eyelashes. B. Vitiligo with leukotrichia. The loss of melanocytes has turned some of the eyelashes white. (*Used with permission from Richard P. Usatine, MD.*)

- Vitiligo can be unilateral or bilateral; in one study, patients with unilateral vitiligo were younger, and had an earlier age at onset while those with bilateral vitiligo were more likely to have light skin types and more commonly had associated autoimmune disease.[9]

LABORATORY AND IMAGING

- Evaluation for endocrine disorders such as hyper- or hypothyroidism (e.g., thyroid-stimulating hormone [TSH]) and diabetes mellitus (e.g., fasting blood sugar) should be considered, as vitiligo can be associated with these disorders.[10]

BIOPSY

Not indicated unless the diagnosis is not clear and then a 4-mm punch biopsy will suffice.

DIFFERENTIAL DIAGNOSIS

- Pityriasis alba—Areas of decreased pigmentation with scaling and mild itching. Seen in young children and usually associated with eczema and improves with age (see Chapter 130, Atopic Dermatitis).
- Ash leaf spots—Lance-shaped macules of hypopigmentation, which remain stable in size and shape over time (**Figure 167-6**). Often the earliest sign of tuberous sclerosis. More concerning if there are 3 or more present in one child (see Chapter 205, Tuberous Sclerosis).

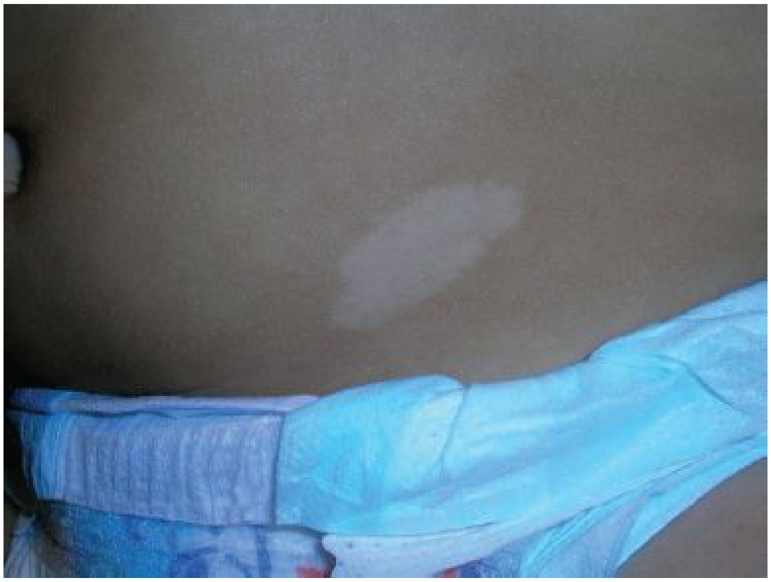

FIGURE 167-6 A hypopigmented patch on the abdomen of an infant in a shape that suggests an ash leaf. The child is otherwise healthy with no seizures or developmental delay but should be monitored for signs of tuberous sclerosis. This may be nothing more than nevus depigmentosus. (*Used with permission from Richard P. Usatine, MD*.)

- Halo nevus—Hypopigmentation confined to areas surrounding pigmented nevi that typically appear in adolescents and young adults (see Chapter 143, Benign Nevi).
- Hypomelanosis of Ito is a rare syndrome with hypopigmented whorls of skin present at birth along the Blaschko lines of development. This pattern may be accompanied by congenital abnormalities involving the eyes, or neurologic or renal systems. Its presence at birth helps distinguish it from vitiligo (**Figures 167-7** and **167-8**).

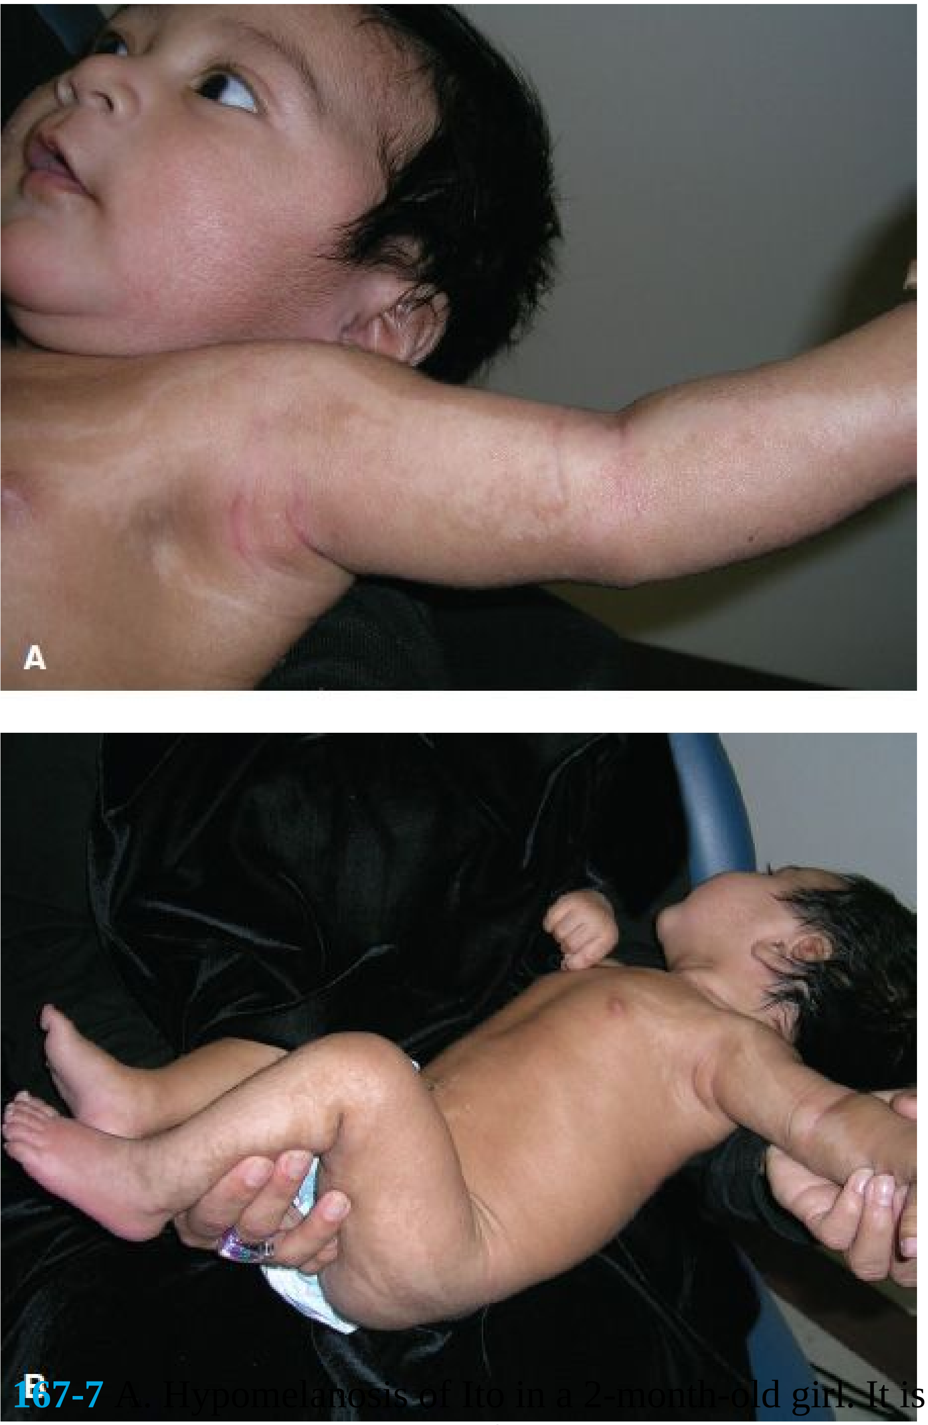

FIGURE 167-7 A. Hypomelanosis of Ito in a 2-month-old girl. It is a rare syndrome with hypopigmented whorls of skin present at birth along the Blaschko lines of development. It is typically unilateral and extends down an extremity. B. Note the whorls on the chest and upper arm. (*Used with permission from Richard P. Usatine, MD.*)

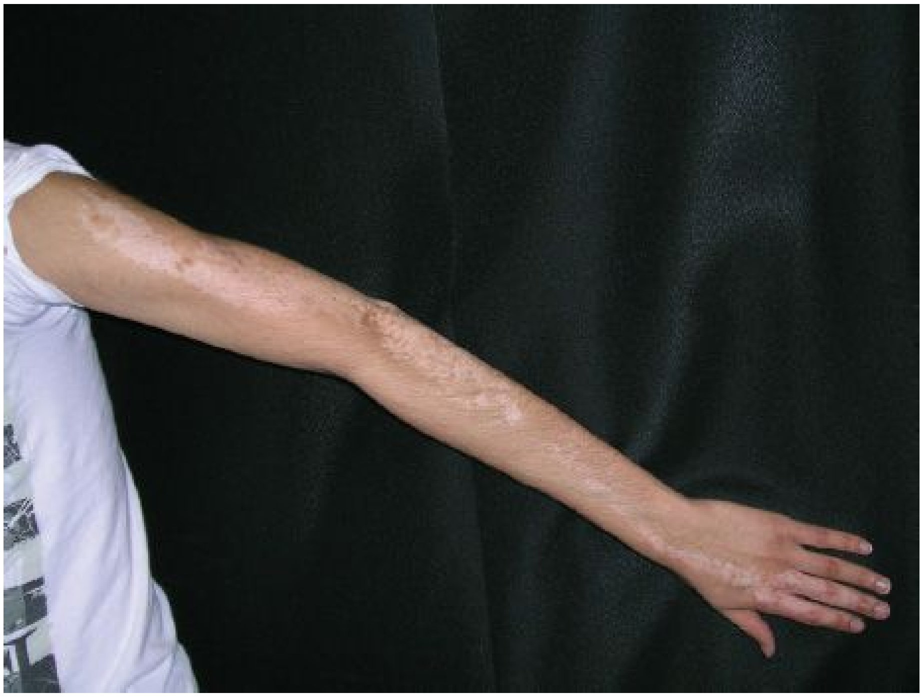

FIGURE 167-8 Hypomelanosis of Ito extending down the arm of this 17-year-old boy since birth. This was unilateral and could be mistaken for segmental vitiligo if it had not been present since birth. (*Used with permission from Richard P. Usatine, MD.*)

- Nevus anemicus—A congenital hypopigmented macule or patch that is stable in relative size and distribution. It occurs as a result of localized hypersensitivity to catecholamines and not a decrease in melanocytes. On diascopy (pressure with a glass slide) the skin is indistinguishable from the surrounding skin. Its presence from birth helps distinguish it from vitiligo (**Figure 167-9**).

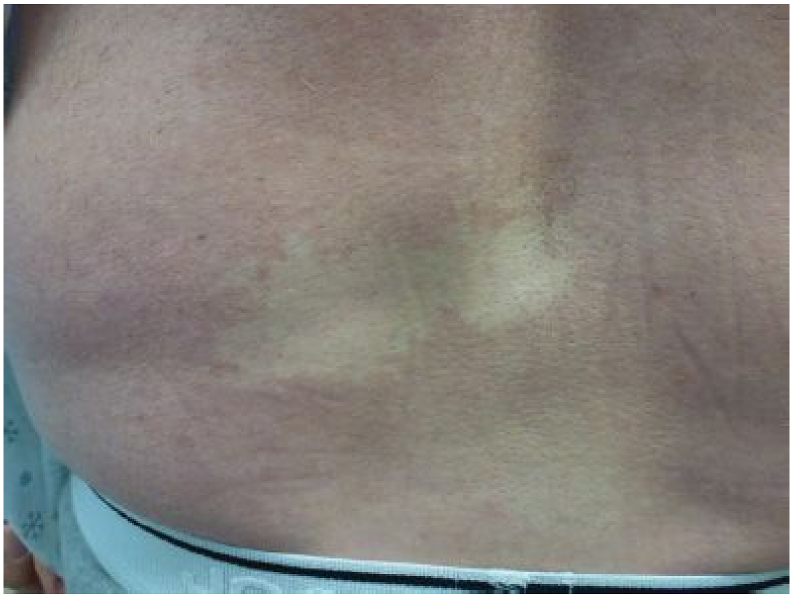

FIGURE 167-9 Nevus anemicus on the back of this patient since birth. This is a congenital hypersensitivity to localized catecholamines. On diascopy the skin was indistinguishable from the surrounding skin. The irregular broken-up outline is seen in nevus anemicus and nevus depigmentosus. (*Used with permission from Ryan O'Quinn, MD.*)

- Nevus depigmentosus is usually present at birth or starts in early childhood. There is a decreased number of melanosomes within a normal number of melanocytes. It typically has a serrated or jagged edge. Its presence at birth or early in childhood helps to differentiate it from vitiligo (**Figure 167-10**).

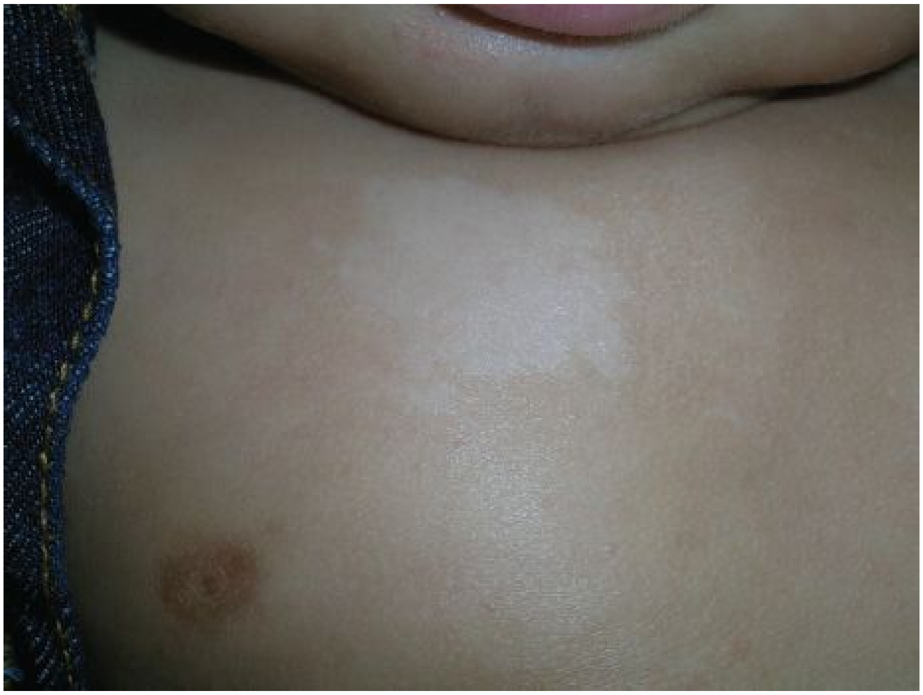

FIGURE 167-10 Nevus depigmentosus, present since birth, on the chest of this 4-month-old infant. Note the serrated or jagged edge. Vitiligo is not present at birth. (*Used with permission from Richard P. Usatine, MD*.)

MANAGEMENT

For assessing outcomes to treatment, the Vitiligo European Task Force suggests a system combining analysis of extent using percentage of body area involved (rule of 9), stage of disease based on cutaneous and hair pigmentation in vitiligo patches and staged 0 to 4 (with 0 representing normal pigment and 4 complete hair whitening) on the largest macule in each body region except hands and feet, and disease progression (spreading) assessed with Wood's lamp examination of the same largest macule in each body area.[1] An evaluation sheet can be found in the citation.[1]

NONPHARMACOLOGIC

- Addressing the psychological distress that this disfiguring skin disorder causes should be a primary focus as the clinical course is unpredictable and, in some cases, little can be done to modify the condition itself.
- Management of inciting factors such as illness, stress, and skin trauma may be useful. SOR Ⓒ

MEDICATIONS

Topical treatments used for vitiligo include corticosteroids, immunomodulators, vitamin D analogs, and psoralens; these treatments had mixed outcomes based on a systematic review, with topical steroids having the highest rate of adverse events.[11] SOR Ⓑ Ineffective topical agents include melagenina, topical phenylalanine, topical L-DOPA (levodopa), coal tar, anacarcin forte oil, and minoxidil.[12]

- In a retrospective study of 101 children with vitiligo treated with moderate- to high-potency topical corticosteroids 64 percent (45/70) had repigmentation of the lesions, 24 percent (17/70) showed no change, and 11 percent (8/70) were worse than at the initial presentation.[13] SOR Ⓑ (**Figure 167-11**). Local steroid side effects were noted in 26 percent of patients at 81.7 ± 44 days of follow-up. Two children were given the diagnosis of steroid-induced adrenal suppression. Children with head and/or neck affected areas were eight times more likely to have an abnormal cortisol level compared with children who were affected in other body areas.[13] Therefore, a trial of topical steroids may be useful for patients with localized vitiligo that does not predominantly involve the head and neck. SOR Ⓒ

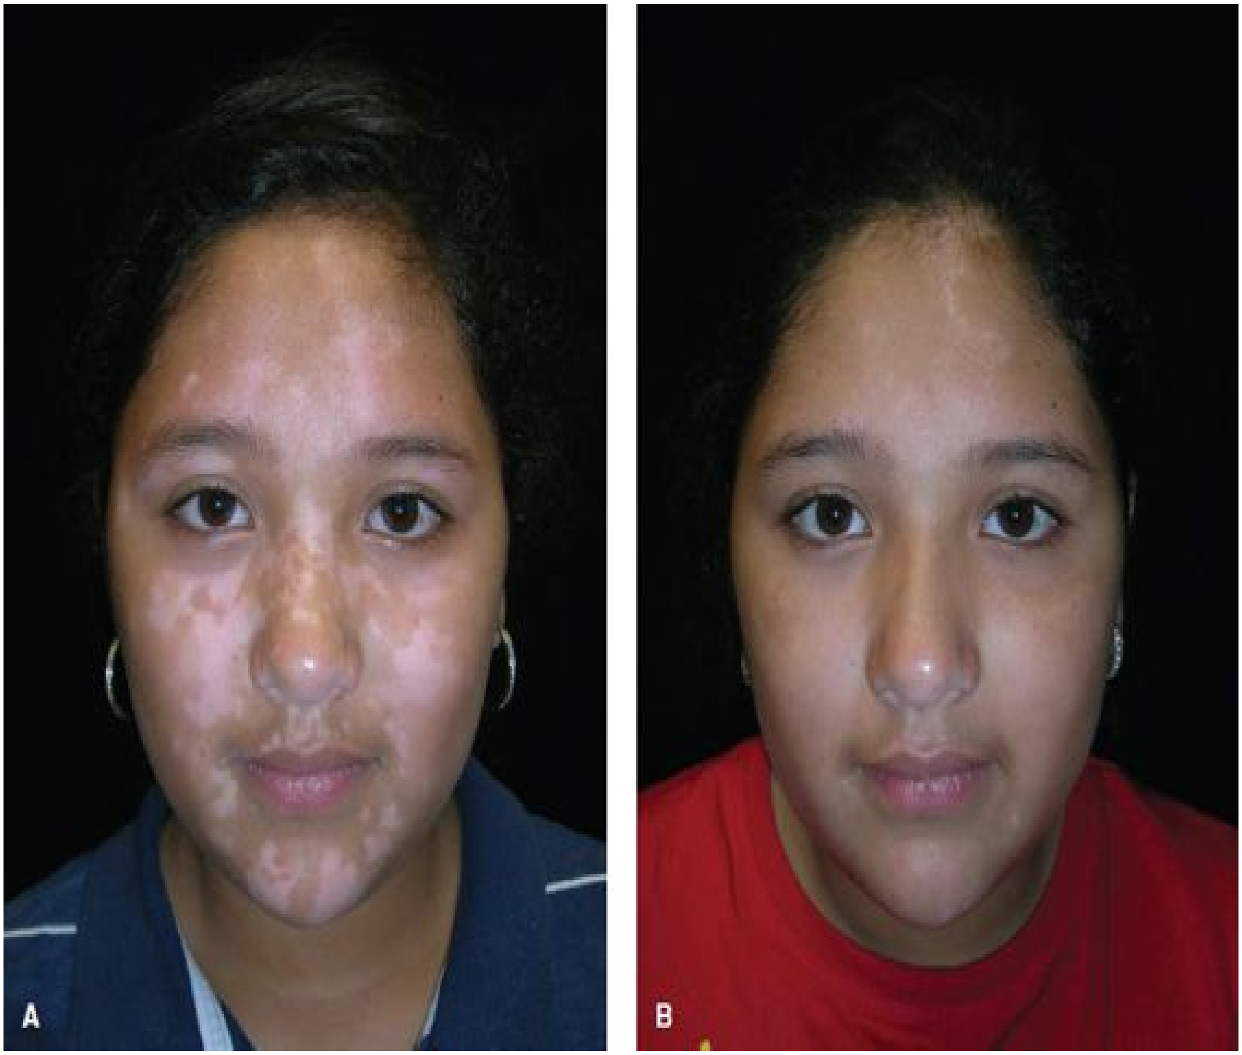

FIGURE 167-11 A. Vitiligo on the face of an 11-year-old girl. B. Significant resolution of the vitiligo 2 months later after using 0.1 percent triamcinolone cream once to twice daily. The patient and the mother were so happy with the results. There were no signs of skin atrophy or steroid side effects. (*Used with permission from Richard P. Usatine, MD.*)

- Based on several reviews, topical corticosteroids (potent or very potent) are the preferred drugs for localized vitiligo (<20% of skin area);[11,12] a less-than-2-month trial is recommended.[12] SOR B
- Topical immunomodulators (tacrolimus, pimecrolimus) are an alternative for localized vitiligo and display comparable effectiveness with fewer side effects.[14] SOR B

- In a small case series (N = 6), various antitumor necrosis factor a agents (infliximab, etanercept, and adalimumab given according to treatment regimens used for psoriasis) were not effective for widespread nonsegmental vitiligo.[15]

COMPLEMENTARY/ALTERNATIVE THERAPY

- Antioxidants may be useful adjunctive therapy.[11]

OTHER TREATMENT

- Use sunscreen to prevent burns to the depigmented areas and further trauma to unaffected skin, and to minimize contrast between these areas.[14] SOR A
- Bleaching the unaffected skin in patients with widespread depigmentation to reduce contrast with depigmented areas can improve cosmetic appearance.[14] SOR B A monobenzylether of hydroquinone 20 percent cream (Benoquin) is available by prescription to produce a permanent bleaching of the skin around the vitiligo. It is irreversible and makes the skin at higher risk for sunburn.

PROCEDURES

- Combination therapies are likely to be more effective than monotherapy, and most combinations include a form of phototherapy; narrow-band UVB appears to be the most effective with the fewest adverse effects (**Figure 167-12**).[11,14] SOR B Psoralen UVA (PUVA) is the second-best choice. Authors of a Cochrane review concurred that majority of analyses showing statistically significant differences in treatment outcomes were from studies that assessed combination interventions including some form of light treatment.[16]

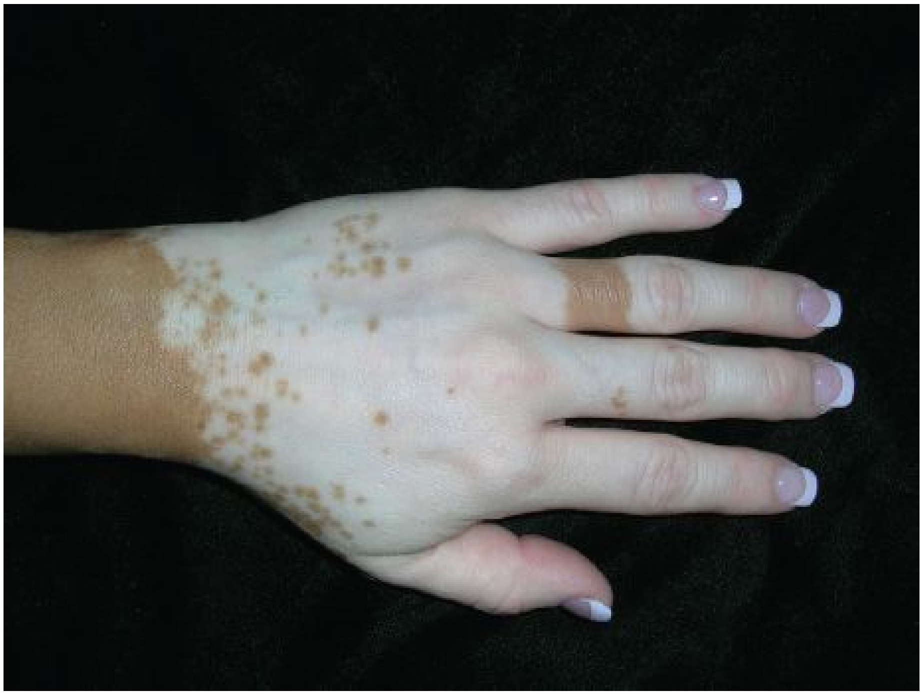

FIGURE 167-12 Vitiligo, which spared the area under a ring; the patient has spotty return of pigment on hand with narrowband UVB treatment. (*Used with permission from Richard P. Usatine, MD*.)

- Excimer laser is an alternative to UVB therapy, achieving good responses especially in localized vitiligo of the face, where the excimer laser may be superior to UVB therapy. By combining with topical immunomodulators, treatment response can be accelerated.[14] SOR B In one prospective study of 14 patients, repigmentation rates for once, twice, and thrice weekly treatment approached each other (60%, 79%, and 82%, respectively) at 12 weeks.[17] Although repigmentation occurred fastest with thrice weekly treatment, the final repigmentation depends on the total number of treatments, not their frequency. SOR B
- No single therapy for vitiligo can be regarded as the most effective as the success of each treatment modality depends on the type and location of vitiligo. SOR B

PROGNOSIS

The course of vitiligo varies, but is usually progressive with periods of activity interspersed with times of inactivity.[18] Spontaneous repigmentation can occur but is rare.

- The face and neck respond best to all therapeutic approaches, while the acral areas are least responsive.[14] SOR B
- Vitiligo does not appear to be associated with adverse outcomes in pregnancy.[19]

FOLLOW-UP

- Counseling and emotional support are a mainstay of follow-up treatment.
- Trials of various combination therapies may be needed.

PATIENT EDUCATION

- Reassurance that this is a benign condition while acknowledging any psychological distress.
- Advise patients about the highly variable course of vitiligo with usually progressive periods of activity interspersed with times of inactivity.
- Inform patients about the multiple treatment options and possible need for prolonged or repeat treatment.

168 DISORDERS OF HYPERPIGMENTATION

Sigrid M Collier, MD
Jennifer Krejci-Mannwaring, MD
Richard P. Usatine, MD

PATIENT STORY

A 7-year-old African American girl was brought to her pediatrician by her mom who was worried that she was itching and that her skin was getting darker. The pediatrician knew the girl well as a patient with asthma and allergic rhinitis. In fact, the girl performed the allergic salute more than once in the office as she rubbed her itchy nose. Morgan-Dennie lines were seen under her eyes (**Figure 168-1A**). The mom undressed the girl to show the dark patches of skin around her knees (**Figure 168-1B**). Atopic dermatitis is common in the popliteal fossae and this girl clearly demonstrated the atopic triad: atopic dermatitis, asthma, and allergic rhinitis. The darkening of the skin around the knees and also seen on the neck is related to the scratching and rubbing of the skin secondary to the pruritus of atopic dermatitis. The pediatrician explained to the mom and child about the need to more aggressively treat the atopic dermatitis with emollients and topical steroids. No promises were made about the reversibility of the hyperpigmentation as each patient will respond differently to treatment.

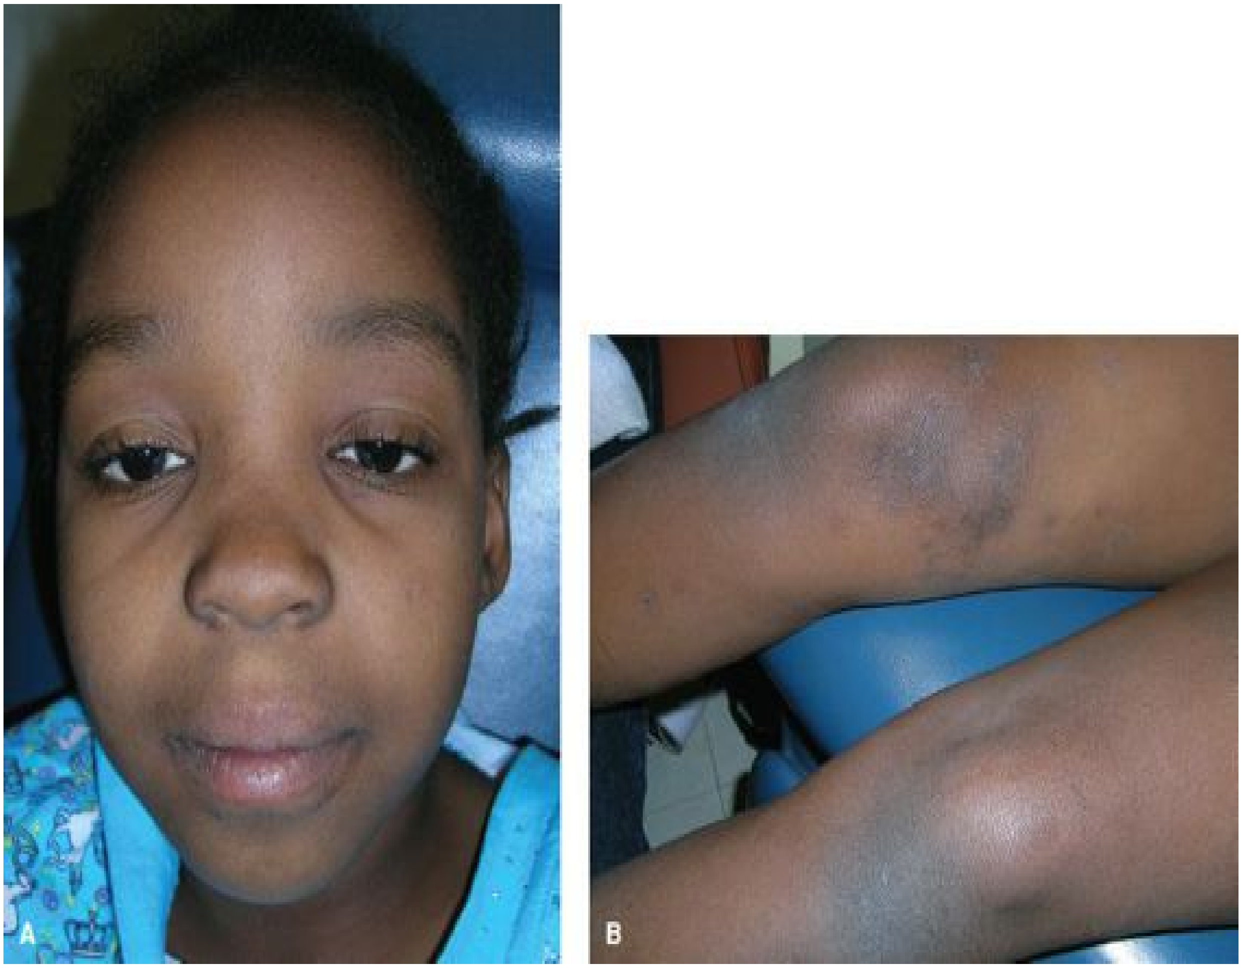

FIGURE 168-1 **A.** Atopic triad in a 7-year-old girl with Dennie-Morgan lines and a nasal crease. **B.** Postinflammatory hyperpigmentation around the knees in the same girl. (Used with permission from Richard P. Usatine, MD.)

INTRODUCTION

Postinflammatory hyperpigmentation (PIH) is an accumulation of melanin in response to chronic inflammation that usually appears as brown, black, or grey macules or patches in the pattern of an underlying inflammatory condition. Postinflammatory hyperpigmentation can result from any kind of irritant to the skin, but is more common in conditions resulting in chronic irritation and inflammation, and is more common in individuals with darker Fitzpatrick Skin Types IV, V, and VI. It is more severe and longer lasting if the underlying inflammatory condition goes untreated though most PIH will fade within 6 to 12 months of treating the underlying inflammatory condition. For the girl in the preceding case, the PIH may resolve without treatment after her atopic dermatitis clears up, but if the atopic dermatitis persists then the PIH will continue until the resolution of the underlying condition.

EPIDEMIOLOGY

- The prevalence of disorders of hyperpigmentation including post-inflammatory hyperpigmentation in the general population ranges from 0.42 percent in Kuwait to 55.9 percent in a sample population from Michigan.[1]
- The prevalence in children in the US is around 22 percent based on a sample of hospitalized children in Kentucky.[2]
- Postinflammatory hyperpigmentation (PIH) is one of the most common types of cutaneous hyperpigmentation, and although there are no good estimates of its prevalence in the children of the US, studies in Nigeria estimate PIH to represent 49.5 percent of skin lesions present in hospitalized children.[3] In studies of adults, “dyschromia” is often used to combine disorders of hyperpigmentation, which would include melasma, lentigines, and PIH so true prevalence is difficult to obtain. In one study dyschromia was the second most common diagnosis among African American patients, but failed to make it into the top 10 for Caucasian patients.[4]
- The distribution of PIH is equal among males and females of all ages.[5]
- PIH is more common in dark-skinned individuals (Fitzpatrick skin types IV, V, and VI), and therefore is frequently found in individuals from Asia, Africa (**Figure 168-2**), South America, and Native Americans.[6]

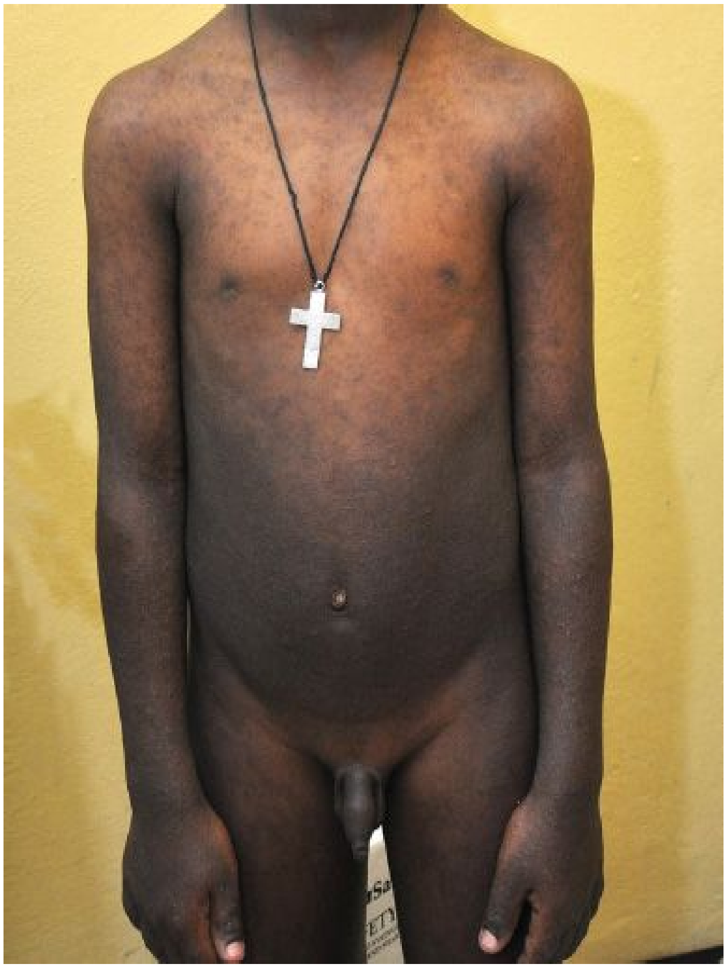

FIGURE 168-2 An African boy with a long history of atopic dermatitis and newly diagnosed scabies. Note how the postinflammatory hyperpigmentation is concentrated around the waist and forearms. (Used with permission from Richard P. Usatine, MD.)

- The age at which a child could present with a hyperpigmented lesion varies, and PIH, erythema ab igne, and confluent and reticulated papillomatosis (CARP) are more common in older children and young adults versus young children (**Figure 168-3**).[7]

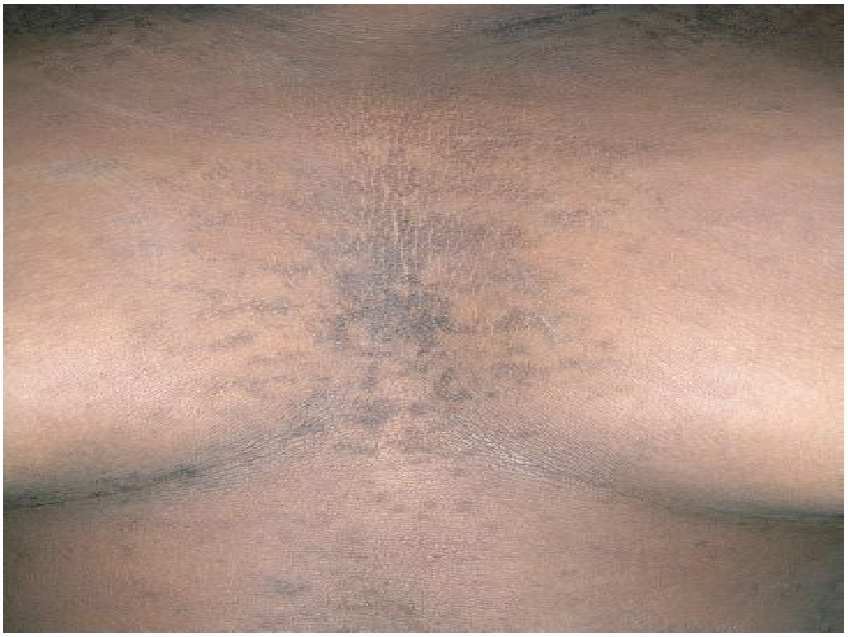

FIGURE 168-3 Confluent and reticulated papillomatosis (CARP) in an obese 15-year-old boy with gynecomastia. (Used with permission from Richard P. Usatine, MD.)

- Other hyperpigmented lesions such as “linear and whorled hypermelanosis,” nevus of Ota, and Café au Lait spots are linked to embryologic mosaicism or genetic abnormalities, and may be seen at birth or within a few weeks after birth (**Figures 168-4** and **168-5**). Mongolian spots are nearly always present at birth (**Figure 168-6**).[7]

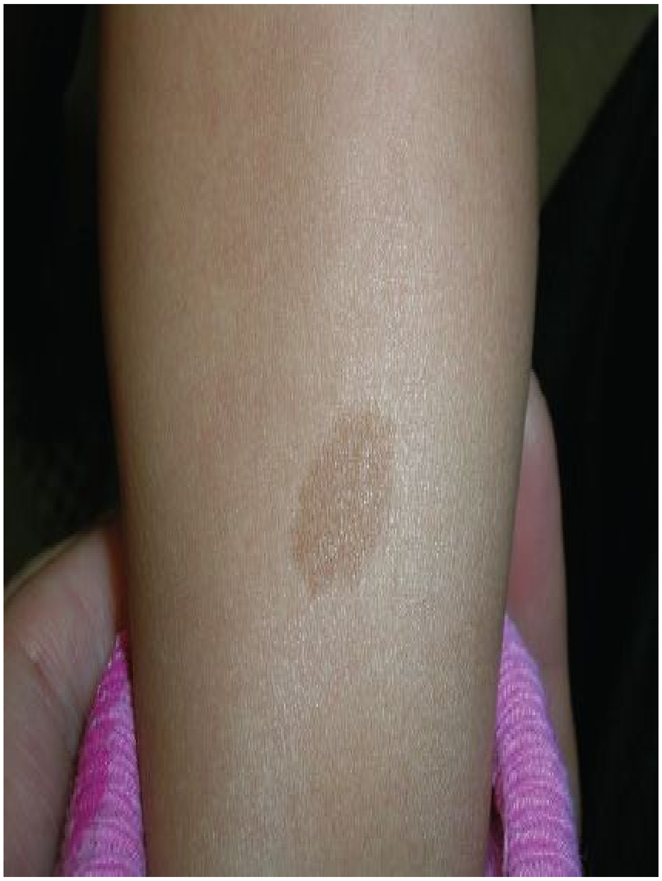

FIGURE 168-4 Cafe au lait macule in a girl found to have tuberous sclerosis. (Used with permission from Richard P. Usatine, MD.)

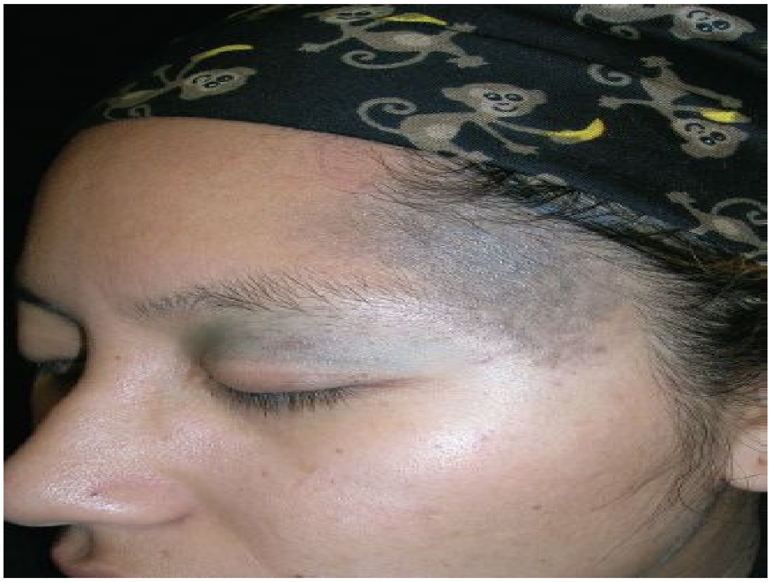

FIGURE 168-5 Nevus of the Ota with a blue-gray coloration around the eye. (Used with permission from Richard P. Usatine, MD.)

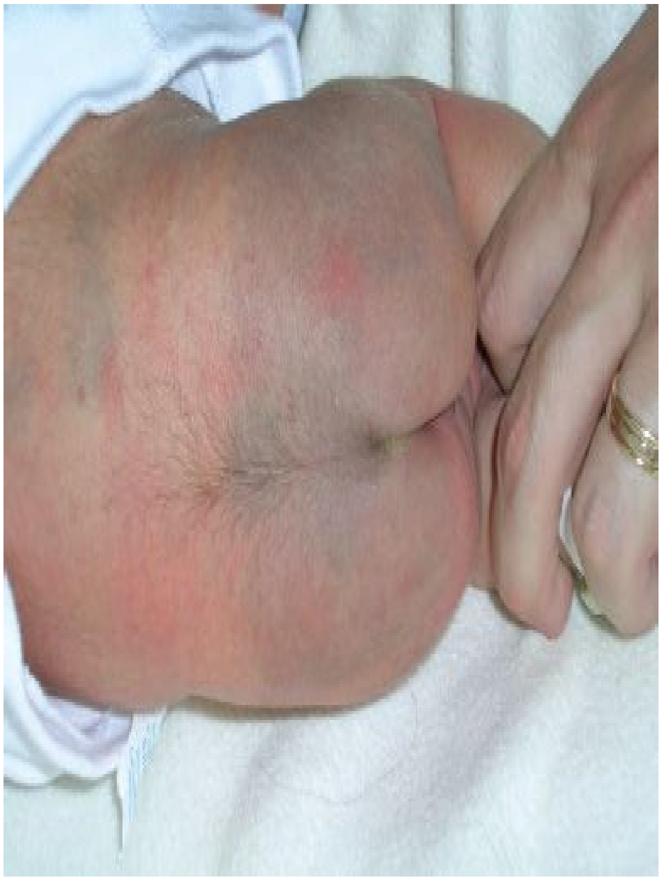

FIGURE 168-6 Dermal melanocytosis (Mongolian spot) over the buttocks of a newborn. (Used with permission from Richard P. Usatine, MD.)

- Just as PIH is most common in darker-skinned individuals, Nevus of Ota, Mongolian spot, Café au Lait macules, and CARP are more common in Asians and Blacks.[7] Conversely, linear and whorled hypermelanosis shows no racial predilection.[8]

ETIOLOGY AND PATHOPHYSIOLOGY

- The most common causes of postinflammatory hyperpigmentation are acne vulgaris, atopic dermatitis (**Figure 168-7**), and impetigo, but any insult to the skin from bug bites and minor burns to drug reactions and other rashes can result in postinflammatory hyperpigmentation.[1,5]

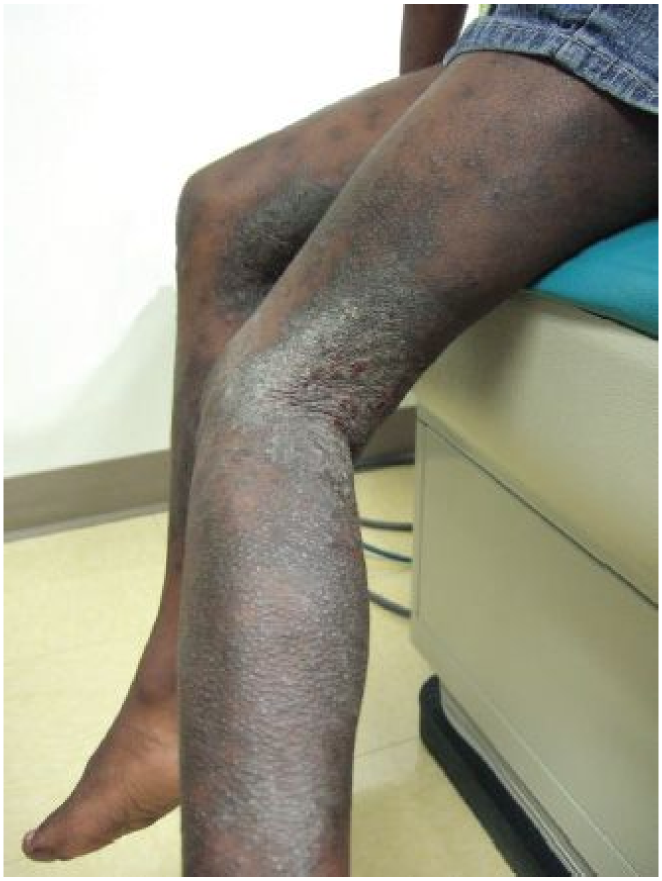

FIGURE 168-7 Postinflammatory hyperpigmentation over the legs in a black child with severe atopic dermatitis. (Used with permission from John Browning, MD.)

- Postinflammatory hyperpigmentation may be divided based on whether the pigment accumulates in the epidermis or in the dermis. This can be helpful in terms of understanding the pathophysiology, characteristic appearances, and treatment modalities associated with the two categories.
- Epidermal hyperpigmentation is thought to be in part caused by the release of inflammatory molecules such as prostanoids, cytokines, chemokines, and other products of arachidonic acid which leads to increased melanocyte activity, increased melanin production and release, and accumulation of melanin in adjacent keratinocytes.[1,5,9,10]

- Dermal hyperpigmentation is thought to result from inflammatory mediated destruction of keratinocytes, which results in melanin release and its accumulation within macrophages in the upper dermis.[1] Histologically this is described as “pigment incontinence.”
- The distinction between accumulation of pigment in the epidermis and accumulation of pigment in the dermis is reflected in the appearance of the lesion on the skin. Dermal lesions tend to be a blue-gray color with indistinct boundaries and epidermal lesions tend to be tan, brown, or dark brown and with more sharply demarcated borders.[1,11]
- In other disorders of hyperpigmentation the connection between the pathophysiology and the cutaneous appearance also exists; the color and shape of the pigment generally reflects both the location of melanin and the degree of melanocytic hyperplasia or release of melanin.[7]

DIAGNOSIS

CLINICAL FEATURES

- The degree of pigmentation is strongly correlated with the total duration of the inflammatory process, where chronic or relapsing inflammatory processes cause darker and longer lasting hyperpigmentation.[1]
- Darker-skinned individuals have larger and more densely distributed melanin pigment in their skin. In turn, they tend to react to inflammation with more accumulation of pigment, and therefore PIH tends to present with darker lesions that last longer.[1,12]
- UV exposure is also associated with darkening and persistence of hyperpigmented lesions.[13]
- The location of the pigmentation in the skin also effects the persistence of PIH, and dermal hyperpigmentation tends to last longer since the dermis does not continuously turnover like the epidermis.[13]

TYPICAL DISTRIBUTION

- Postinflammatory hyperpigmentation typically follows the pattern of the initial inflammatory process and consists of macules or patches.[12]

LABORATORY AND IMAGING

- A Wood’s lamp examination can be used to distinguish between epidermal and dermal hyperpigmentation, where epidermal lesions will have distinct margins and a prominent border whereas dermal lesions will have fluffy, indistinct margins.[5]

BIOPSY

In general, skin biopsies are unnecessary, but if the etiology is uncertain a 4-mm punch biopsy can help determine the underlying cause of PIH. The Fontana-Masson stain is used to identify melanin in the skin and is useful in distinguishing between epidermal and dermal hyperpigmentation.[5]

DIFFERENTIAL DIAGNOSIS

- CARP is characterized by hyperkeratotic or verrucous scaly brown papules that coalesce into plaques, with peripheral reticular pattern with or without pruritus (**Figure 168-8**). It is generally first seen in inframammary region or interscapular region, and often spreads to the chest or abdomen (**Figure 168-3**). It can be found on the face, neck, extremities, flanks, or gluteal cleft. The etiology is unknown, but potential causes include a keratinization disorder, a reaction to a fungal or bacterial infection, photosensitivity, amyloidosis, and genetic factors.[14,15]

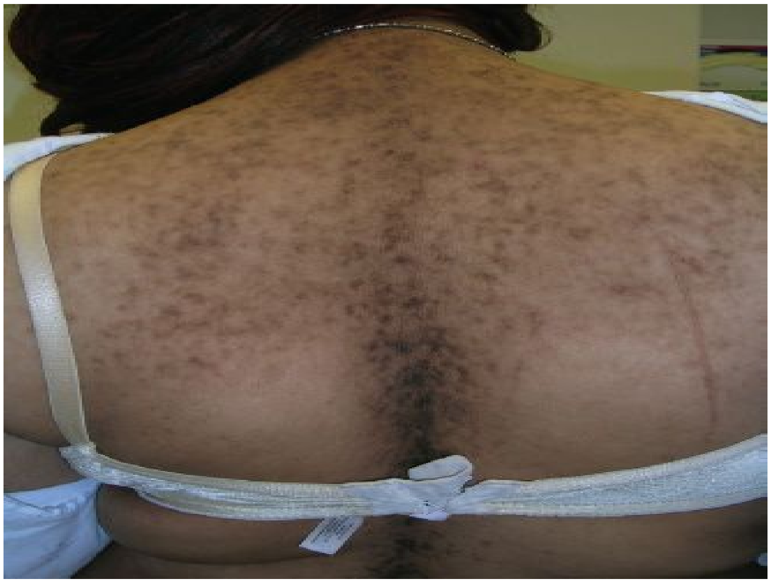

FIGURE 168-8 Confluent and reticulated papillomatosis (CARP) on the back of an African American girl. (Used with permission from Richard P. Usatine, MD.)

CARP can be distinguished from PIH both clinically and by its unique histology. CARP is raised and keratotic papules and plaques on the torso while PIH is typically flat macules or patches where there were previous lesions. Tinea versicolor occurs in a similar distribution to CARP (on the torso) but tinea versicolor is scaly patches and responds to oral or topical antifungal therapy (**Figures 168-9** and **168-10**).

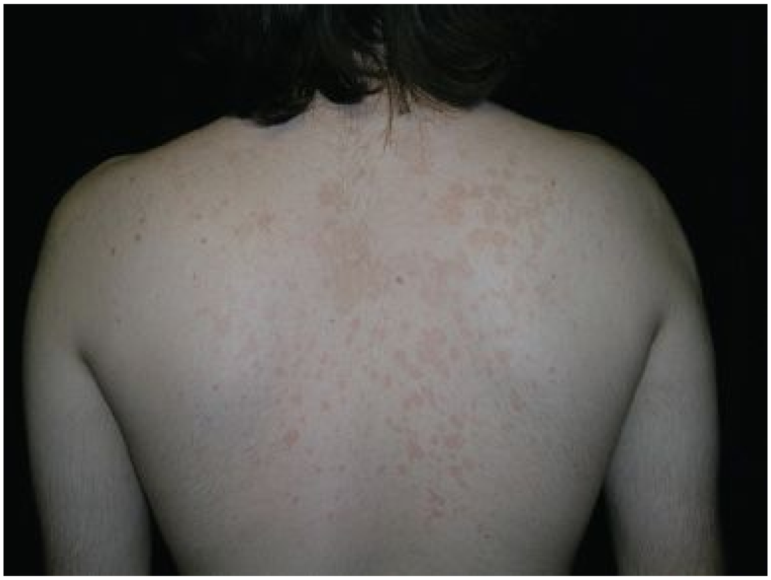

FIGURE 168-9 Tinea versicolor on the back of a 16-year-old boy. Note the pinkish brown coloration. (Used with permission from Richard P. Usatine, MD.)

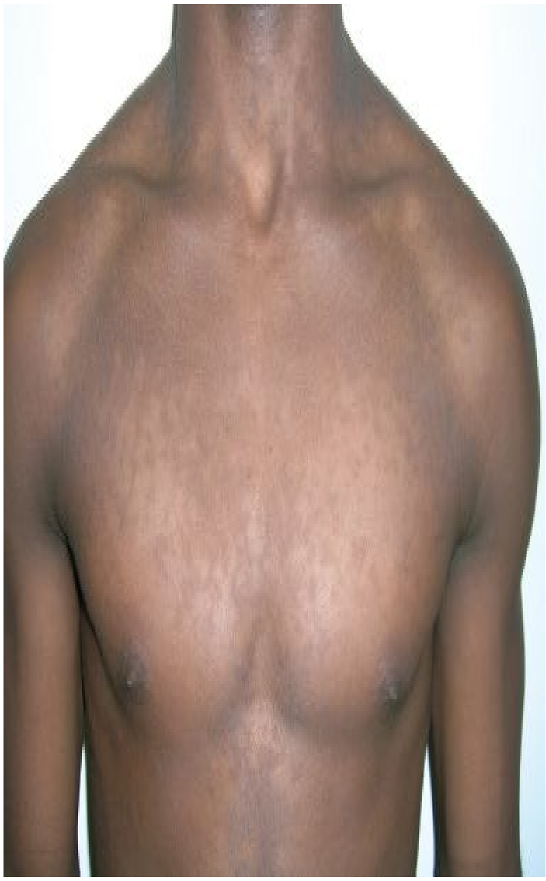

FIGURE 168-10 Tinea versicolor with a cape-like distribution over the chest in a black teenage boy. Note how the Malassezia furfur has caused a brown hyperpigmentation. (Used with permission from Richard P. Usatine, MD.)

CARP is a rare disorder, but it is most commonly seen in young adults (ages 18 to 21), and people with skin of color. In the US, it is more common in females than in males, but the gender distribution varies in different parts of the world. Minocycline is considered the first line treatment, but azithromycin, clarithromycin, fusidic acid, and retinoic acid have also been effective in case reports and case studies.[14]

- Linear and Whorled Hypermelanosis (LAWH; **Figure 168-11**) is characterized by linear and whorled patches that occur along the lines of

Blaschko (lines of embryological development).[16] The lesions can occur anywhere on the body, but typically spare the mucous membranes, palms, soles, and eyes.[16] LAWH appears within a few weeks of birth and will progressively expand and darken until the child is 1 to 2 years of age. The exact cause of LAWH is unknown, but it may be associated with underlying genetic mosaicism.[8] There have been a few cases where LAWH was associated with neurologic abnormalities, but the association is very rare.[16,17] In general, there is no need to do neurologic testing or brain imaging if the child seems normal and healthy.[8]

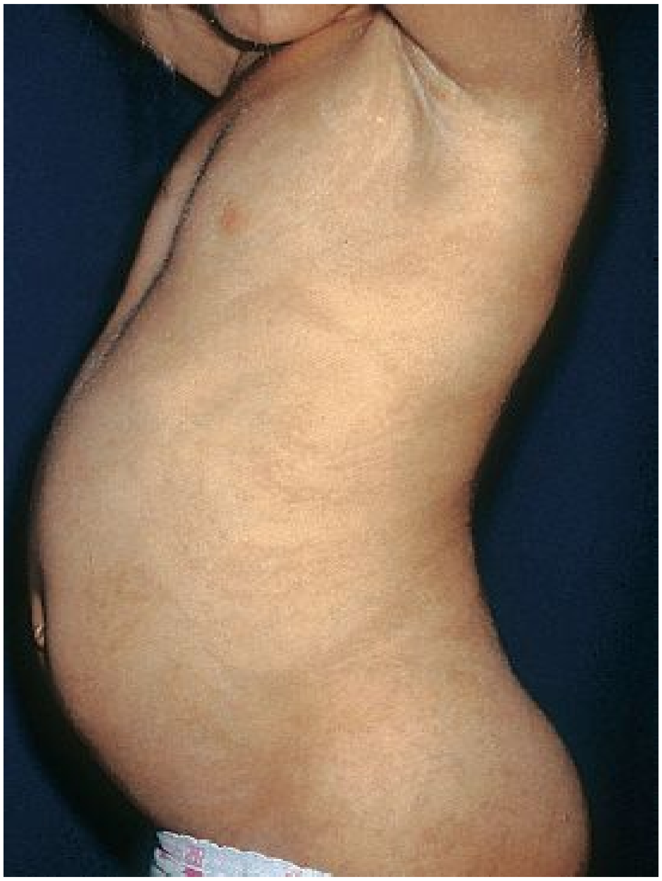

FIGURE 168-11 Linear and whorled hypermelanosis has been present since birth in this otherwise healthy child. (Used with permission from Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 12-8, New York, NY:McGraw-Hill, 2009.)

- Segmental Hyperpigmentation presents at birth or in early childhood as a hyperpigmented patch on the truck with a characteristic delineation at midline, usually ventral giving them a dermatomal appearance (**Figure 168-12**). They are typically not Blaschkoid like LAWH and are more geometric than CALMs. There are no known associated abnormalities and is thought to be due to a somatic mosaicism.[18]

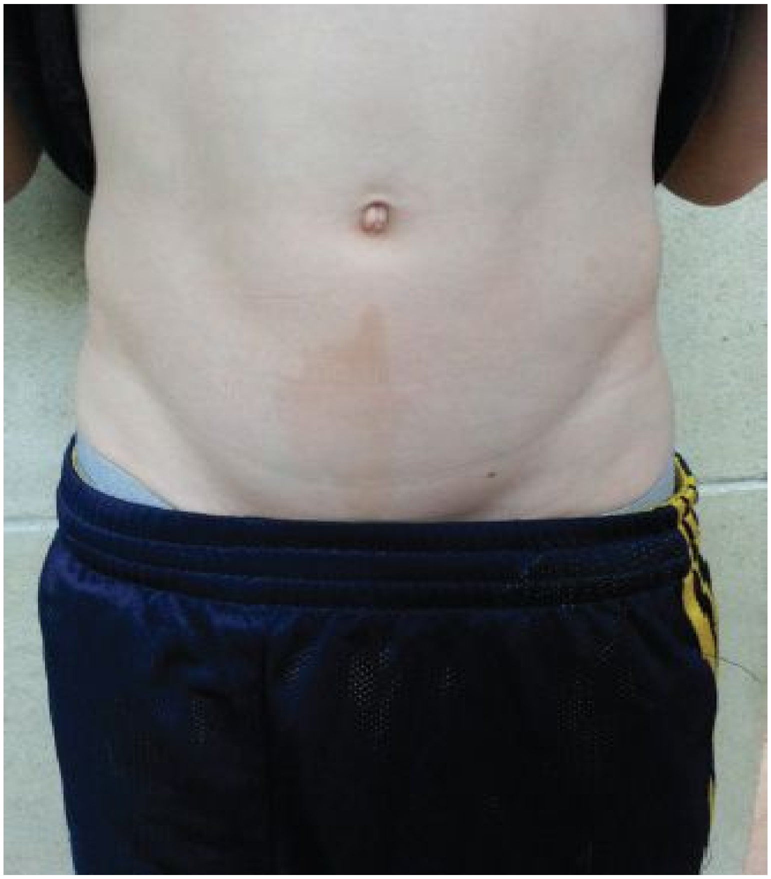

FIGURE 168-12 Segmental hyperpigmentation in a healthy 8-year-old boy. Lesion appeared shortly after birth as a faint patch and became more apparent in early childhood. (Used with permission from Jennifer Krejci-Mannwaring, MD.)

- Erythema ab igne is reticular tan-brown pigmented patch (**Figure 168-13**). It is most commonly caused by prolonged exposure to heat or infrared.[19] Although it is rare in children, it has been reported in children who use laptop computers directly on their laps.[19] Other common causes include hot-water bottles, heating pads, and heated blankets. It is generally a self-limited condition, but prolonged exposure and recurrence of the lesions may predispose to squamous cell carcinoma or Merkel cell carcinoma.[19]

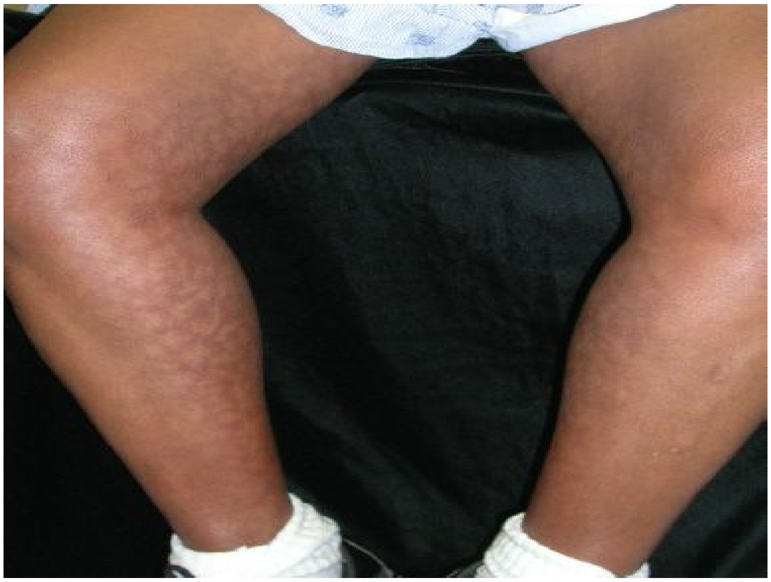

FIGURE 168-13 Erythema ab igne caused by repeated straddling of a place heater in an attempt to keep warm in a home without central heating. (Used with permission from Richard P. Usatine, MD.)

- Café au Lait Macules (CALMs) are evenly pigmented light brown macules or patches (**Figure 168-14**). They are commonly solitary and present at birth though they can appear any time in the first few years of life.[20] CALMs are also more common in blacks than whites. If CALMs continue to appear into adulthood or are multiple this warrants further investigation as these characteristics increase the likelihood of a coexisting condition like neurofibromatosis, tuberous sclerosis, McCune-Albright, or Noonan syndrome (**Figures 168-4** and **168-14**).[20] There is no medical reason to treat CALMs. These lesions are caused by epidermal melanin, giant melanosomes, and increased melanocyte density. Skin lightening creams are not effective, but several lasers have been used with variable responses including Pulsed Dye, Erbium:YAG, Q-Switched Nd:YAG, QS Ruby, and QS Alexandrite. The risks of laser surgery include hypo/hyperpigmentation, scarring, incomplete removal, and recurrence.[21]

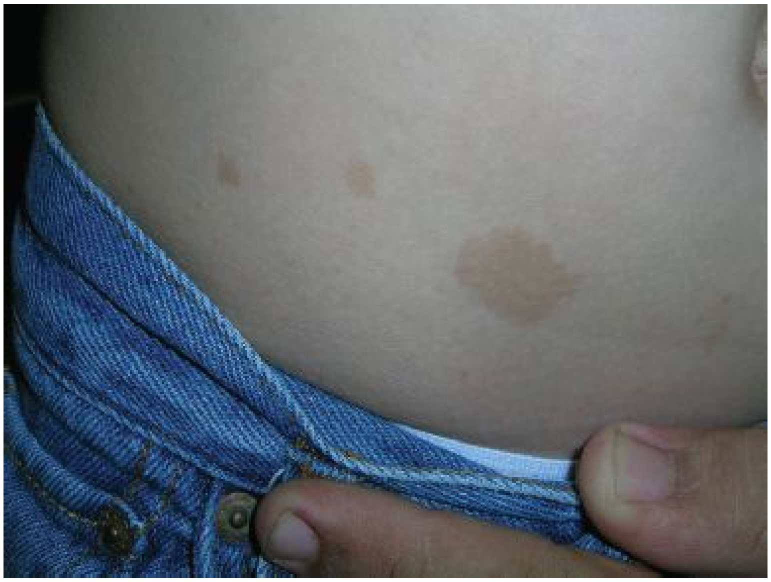

FIGURE 168-14 Cafe au lait macule in a child with neurofibromatosis. (Used with permission from Richard P. Usatine, MD.)

- Dermal Melanocytosis (Mongolian Spot) is a blue-gray hyperpigmented patch that can vary in size, but is most commonly found on the gluteal region of newborns and infants (**Figure 168-15**).[22] It is most prevalent in individuals of Asian and African ancestry, but it can occur in individuals of any race. The lesion is benign, has no known association with other congenital abnormalities, and will disappear in most children by the age of 4 but sometimes persists.[22] Given the likelihood of spontaneous regression, there is no need for treatment.

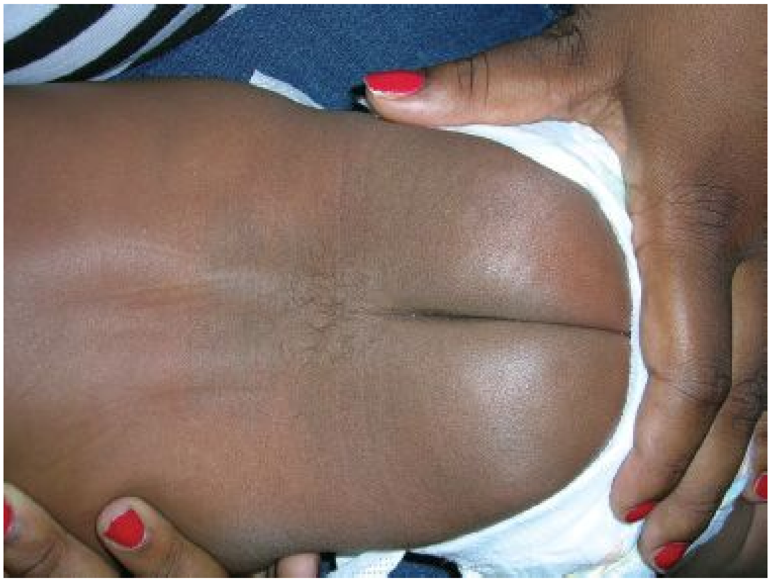

FIGURE 168-15 Dermal melanocytosis (Mongolian spot) in a black infant. (Used with permission from Richard P. Usatine, MD.)

- Ashy Dermatosis (Erythema Dyschromicum Perstans [EDP]) is characterized by blue-gray macules that may have a raised erythematous border.[23] They are most often found on the trunk, extremities, and neck (**Figures 168-16** and **168-17**). These lesions of unknown etiology are chronic and may grow larger and multiply over time. The prevalence is highest among Latin Americans though other races can be affected. EDP most commonly presents between the ages of 10 and 30, but can occur at any age.[23] The treatment of EDP is limited and lesions are often permanent. Many therapies have been attempted but none are very effective.[24]

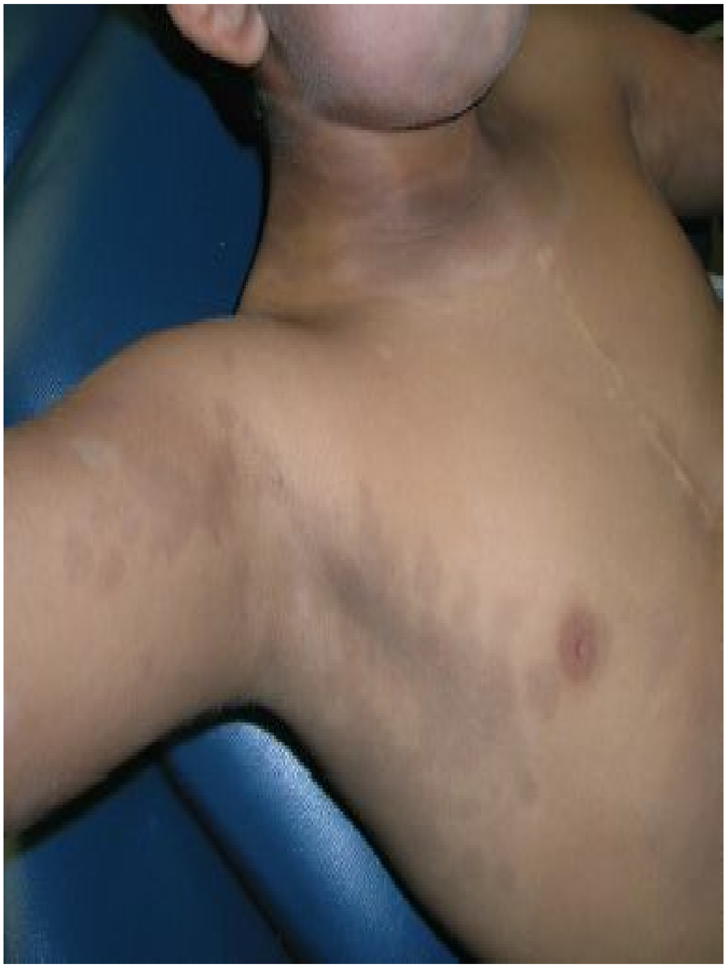

FIGURE 168-16 Ashy dermatosis (erythema dyschromicum perstans) in an 8-year-old boy that was confirmed by a punch biopsy. (Used with permission from Richard P. Usatine, MD.)

- Nevus of Ota (oculodermal melanocytosis) is a speckled blue-gray or brown macular lesion that follows a dermatomal distribution usually unilaterally within the distribution of the ophthalmic and maxillary branches of the trigeminal nerve. In addition to skin, it may involve ocular and oral mucosal surfaces (**Figure 168-18**).[25] These lesions represent a hamartoma of dermal melanocytes. Nevus Of Ito is the same process on the body and usually found on the shoulder. These lesions are often present at birth and tend to darken and expand with age. It is more commonly seen in Asian children, but can occur in any race and shows no gender predilection. The risk of malignant transformation in Nevus of Ota/Ito is extremely rare but there is up to 10 percent risk of glaucoma if the eye is involved. Nevus of Ota have also been associated with Sturge-

Weber, Klippel-Trenaunay-Weber, and neurodevelopmental abnormalities.[25] These risks make close follow-up important in pediatric patients. This dermal pigmentation responds well to laser therapy with the Q-switched ruby, Q-switched alexandrite, or Q-switched Nd:YAG lasers for cosmesis but they do not require treatment.[26–28]

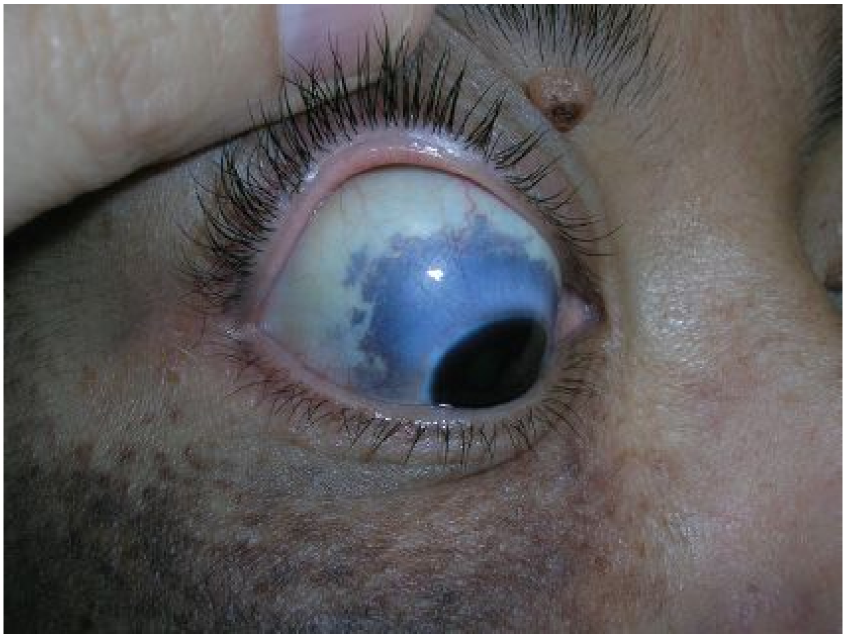

FIGURE 168-18 Nevus of Ota around the eye with blue-gray scleral hyperpigmentation. (Used with permission from Richard P. Usatine, MD.)

- In children with pigmented lesions, it is especially important to consider and rule out child abuse as a possibly cause.[12] Bruising or PIH that is linear or geometric in nature should raise concern for abuse. Also, lesions of abuse on the back or buttocks in a child can mimic EDP or dermal melanocytosis (**Figure 168-19**); however, traumatic lesions will fade quickly compared to the latter.

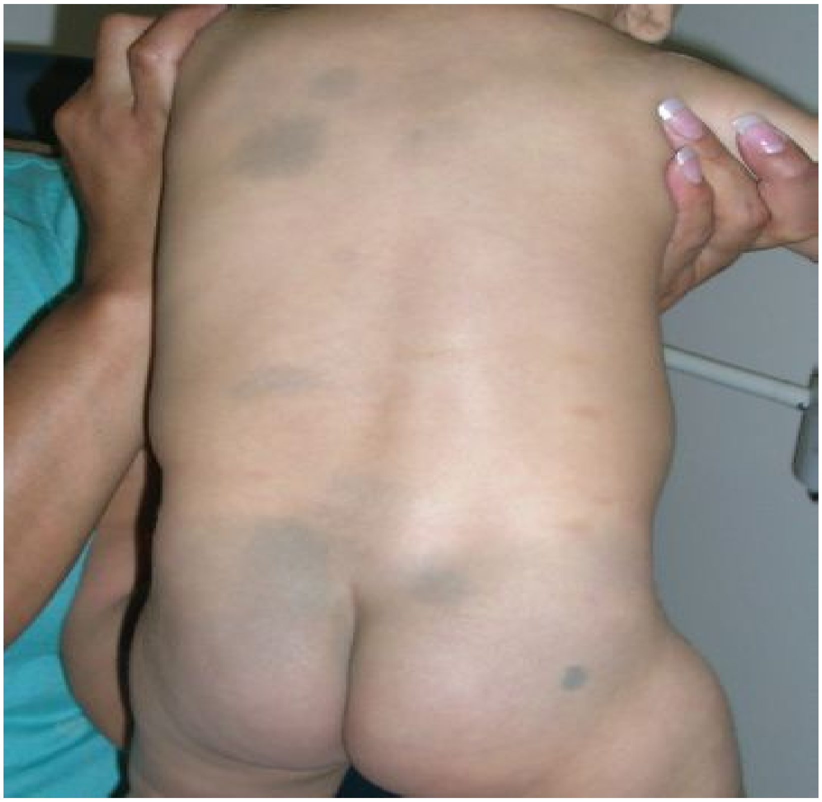

FIGURE 168-19 Multiple patches of dermal melanocytosis (Mongolian spots) on the back and buttocks of a young black child. (Used with permission from Richard P. Usatine, MD.)

MANAGEMENT

The first step in the management of PIH is to ascertain the underlying cause of cutaneous inflammation or trauma and rule out other causes of pigmented lesions.

The shape and distribution of the lesions should mirror the pattern of the underlying disorder and most patients with PIH will have a history of chronic skin disease or trauma. When there is no history of a chronic skin condition it is important to consider congenital diseases or other causes of hyperpigmentation, see differential diagnoses, which was previously discussed.

If the underlying cause is a treatable condition then prompt treatment is essential. Decreasing the development of additional PIH requires controlling the source of cutaneous inflammation.[12]

NONPHARMACOLOGIC

- The first line of therapy for PIH is *daily* sunscreen use. Daily use of sunscreen with an SPF of 30 or greater has been shown to decrease the duration of postinflammatory hyperpigmentation and to prevent darkening of existing lesions.[1] Any gains made with topical or other therapies can quickly be undone by short exposures to ultraviolet light. Behavior modification often requires additional patient/parent education. While darker skin types are more prone to pigmentary disorder they may not be as familiar sun protection behaviors given that they have a lower propensity for sunburn. “Physical sunscreens” (ones that are zinc or titanium based) are preferred, however, on darkly pigmented skin they may leave a gray or violaceous hue when applied and therefore an aesthetically acceptable product may be tricky. Sun protection should also include avoidance of peak sun hours (10 am to 4 pm), the use of wide brimmed hats, and long sleeves or pants depending on the body part affected.

TOPICAL TREATMENTS

- Various topical skin-lightening agents have been used to treat PIH and other disorders of hyperpigmentation. The treatments include topical medication such as hydroquinone, retinoids, mequinol, azelaic acid, kojic acid, and licorice extract, ascorbic acid, niacinamide, N-acetyl glucosamine, and soy.[1,12,29] In general, topical skin-lightening agents are most effective on epidermal pigmentation and less effective for dermal hyperpigmentation.[12]
- The first line in topical treatment for PIH is hydroquinone, which can be used at various concentrations though there is no increase in efficacy at concentrations higher than 5 percent.[13,30] Controlled trials have shown a decrease in skin hyperpigmentation as compared to baseline by 4 weeks after beginning therapy.[31] The potential side effects include allergic dermatitis (most common), the development of a ring of

hypopigmentation around the lesions, and rarely paradoxical darkening of the lesions (exogenous ochronosis).[32]

- Combination therapies with hydroquinone show additional efficacy. Small trials of 4 percent hydroquinone and 0.15 percent retinol have shown significant improvement in the degree of pigmentation and the lesion size.[31] Triple therapies combining 4 percent hydroquinone, 0.1 percent tretinoin, or 0.5 percent ascorbic acid, and topical steroids (dexamethasone or fluocinolone acetonide) resulted in higher rates of complete skin clearing of melasma than either hydroquinone monotherapy or dual therapy, but there is no such trial on the use of triple therapy in PIH.[33]

- There is some evidence for the efficacy of tretinoin (retinoic acid) as monotherapy in the treatment of PIH. In one randomized control trial, 91 percent of the participants in the treatment group had significant lightening of their lesions compared to 57 percent in the control group based on clinical evaluation.[34]

- There is some limited clinical evidence for the efficacy of such compounds as kojic acid, arbutin, niacinamide, n-acetyl glucosamine, ascorbic acid, licorice extract, and soy in treating hyperpigmentation. Most of the evidence for the efficacy of these naturally occurring chemicals is from trials for the treatment of melasma.[29] Of the agents listed, topical soy extract is the only agent with significant evidence in PIH.[13] Many of these compounds are marketed in over-the-counter products and may also contain derivatives of retinoic acid such as retinol or retinyl.

PROCEDURES

- The most common procedures used in the treatment of hyperpigmented lesions are chemical peels and laser therapy. Both have been shown to be efficacious in randomized controlled trials, but they remain second-line treatments and are generally only indicated in combination with or after treatment with topical agents have failed.[21]

- Chemical peels are used to treat hyperpigmentation.[13] The chemical agents used for these procedures include glycolic acid (GA), salicylic acid, and trichloracetic acid.[35,36] In general, superficial peels are recommended for people with skin of color to decrease the risk of additional postinflammatory hyperpigmentation. Side effects of chemical peels include erythema, burning/stinging, hypo/hyperpigmentation, ulceration, scarring, reactivation of HSV, and superficial desquamation. Repeated peels (5 or more) are often needed to achieve results.

- A few randomized controlled trials have indicated that the use of GA chemical peels in addition to hydroquinone therapy was as effective in PIH as hydroquinone therapy and tended to work more quickly with more dramatic results.[37] There is little data in the current literature assessing the safety of these therapies in children, though there are a few case reports of good outcomes in children with xeroderma pigmentosum and congenital melanocytic nevi.[38,39]
- Lasers are used in the treatment of hyperpigmentation. Q-switch alexandrite, Q-switch ruby, Q-switch Nd:YAG, and nonablative fractional protolysis laser treatments have been effective in treatment of many hyperpigmented lesions including PIH, Mongolian Spots, Nevus of Ota, and Café Au Lait Macules.[21,40,41] The wavelength of the system should be correctly matched to the depth of the lesion, and epidermal hyperpigmentation tends to respond best to shorter wavelengths, whereas dermal hyperpigmentation tends to respond best to longer wavelengths.[41] Great care must also be taken to avoid increasing the pigmentation of the lesion or inducing postinflammatory hyperpigmentation, as both of these are known potential side effects of laser therapy.[40] A review of laser use in children concluded that laser therapies are safe in children and in some cases are more efficacious than in adults.[41]

PROGNOSIS

- The course of postinflammatory hyperpigmentation is strongly dependent on controlling the underlying inflammatory disease. Once the underlying disease is treated most epidermal hyperpigmentation will resolve in 6 to 12 months, and with treatment the lesions may resolve as quickly as 4 weeks.[5,31] Dermal hyperpigmentation has a comparatively prolonged course, and lesions can persist for years or be permanent despite treatment.[5]

FOLLOW-UP

- The first step for children with PIH is to treat the underlying cause. Once the cause is treated simple reassurance and regular follow-up may be sufficient. More aggressive treatment should be considered for lesions in aesthetically sensitive areas such as the face, or, if the child experiences significant psychological distress.
- In children with congenital hyperpigmented lesions that may lead to psychological distress, consider initiating treatment early but to give parents realistic expectations. Most congenital or persistent lesions, if responsive, will do so to more invasive treatments such as laser therapy.

PATIENT EDUCATION

- PIH will generally resolve spontaneously over time, and the primary objective is to identify and eliminate the cause of inflammation in the skin.
- Strict sun protection may prevent worsening of PIH and can help it fade more quickly.
- If PIH persists, there are other treatment options but they have variable effectiveness and side effects and should be reserved for cases that have not resolved with watchful waiting.

SECTION 16 GENETIC SKIN DISORDERS

169 GENODERMATOSES

Olvia Revelo, MD
Michael Babcock, MD
Richard P. Usatine, MD

INTRODUCTION

There are more than 100 genetic syndromes with cutaneous manifestations that are referred to as genodermatoses. There are disorders of: pigmentation (e.g., albinism), cornification (e.g., the ichthyoses and Darier disease), vascularization (e.g., Sturge-Weber syndrome), connective tissue (e.g., Ehlers-Danlos syndrome), metabolism (e.g., phenylketonuria), immune system (e.g., Wiskott-Aldrich syndrome), and DNA repair (e.g., xeroderma pigmentosa). Some textbooks are dedicated to the topic of genodermatoses alone.[1] This chapter introduces the topic and illustrates several genodermatoses. We will focus our discussion on Darier disease and pachyonychia congenita as an introduction to the genodermatoses.

DARIER DISEASE

PATIENT STORY

A 12-year-old girl presents to her pediatrician with a scaling rash around her neck. A family history reveals that her mother, maternal grandmother, maternal aunt, and uncle all have Darier's disease. Because this genodermatosis is inherited as an autosomal dominant trait, the pediatrician states that this is likely to be the onset of her Darier disease. The pediatrician prescribes a low potency steroid cream to help the occasional itching that occurs with this new rash. She suggests that the patient also see a local dermatologist. Years later, the young woman returns and her rash is much worse. Upon examination she had red greasy scale around the neck and over the anterior chest (**Figures 169-1** to **169-3**). The patient states that she was given the diagnosis of Darier disease by the dermatologist but was unable to get an appointment during this acute flare-up. She asked the pediatrician if she could prescribe some 0.1 percent triamcinolone cream because that is what has helped her in the past and she ran out of it 1 month ago. The pediatrician agrees to give her a prescription but encourages her to make an appointment with her dermatologist to see what else can be done. She also notes that the nails have the distinctive red-and-white striping seen in Darier disease (**Figure 169-4**).

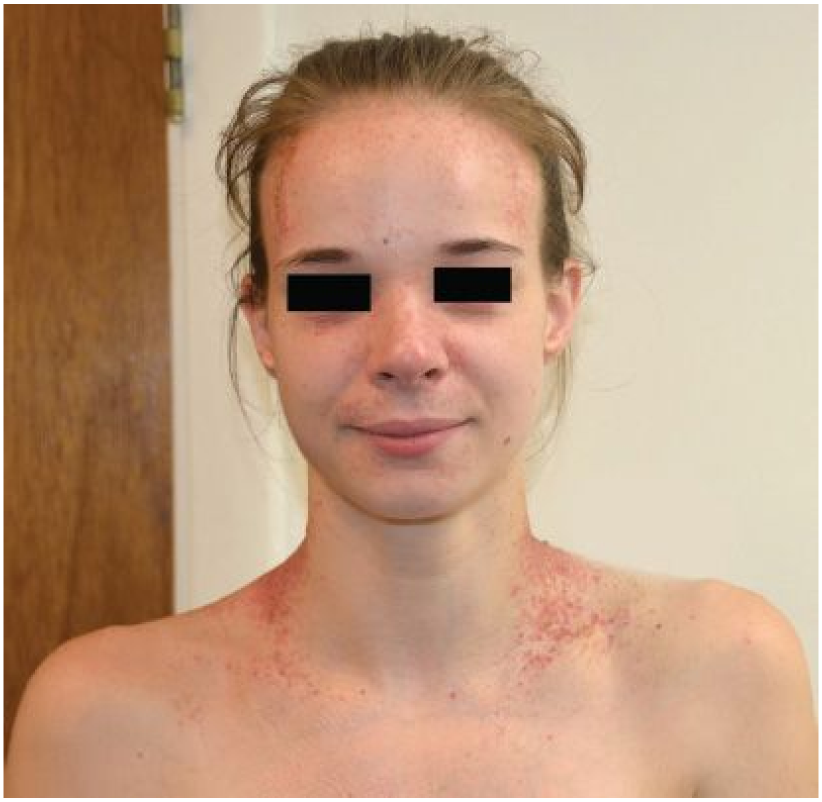

FIGURE 169-1 Darier disease with greasy hyperkeratotic scale in a seborrheic distribution involving the face, neck, and chest. As this is an autosomal dominant genodermatosis, many members of her mother’s family have this condition. (*Used with permission from Yoon Cohen, MD.*)

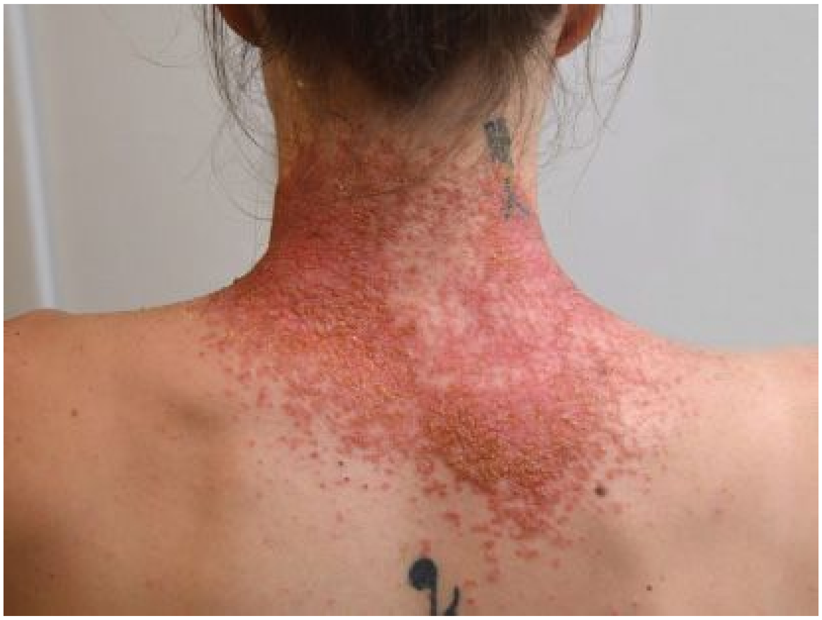

FIGURE 169-2 Darier disease flared up on the posterior neck and upper back in the same patient from Figure 169-1. Note the erythema and greasy yellow hyperkeratotic scale in the seborrheic area. (*Used with permission from Yoon Cohen, MD*.)

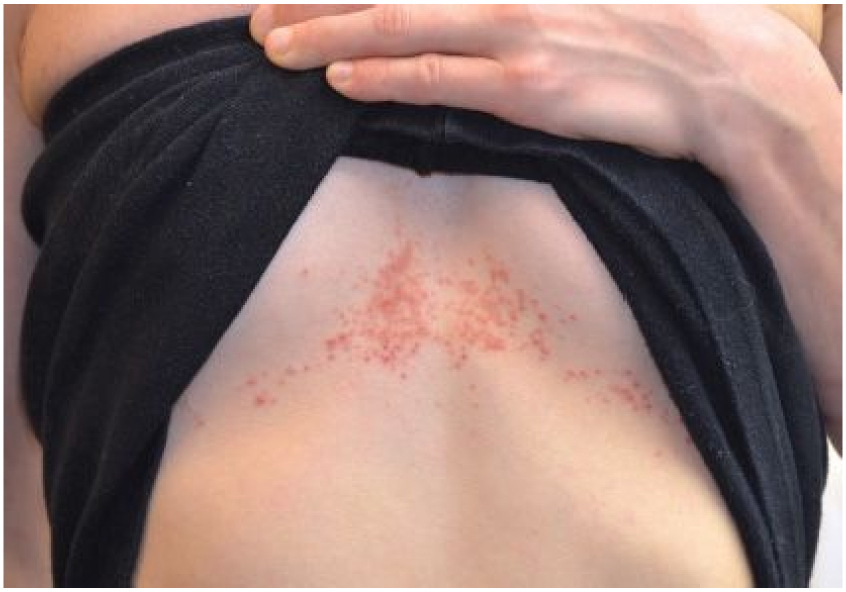

FIGURE 169-3 Darier disease on the chest in any seborrheic distribution over the sternum and around the breasts in the same patient from Figure 169-1. (*Used with permission from Yoon Cohen, MD*.)

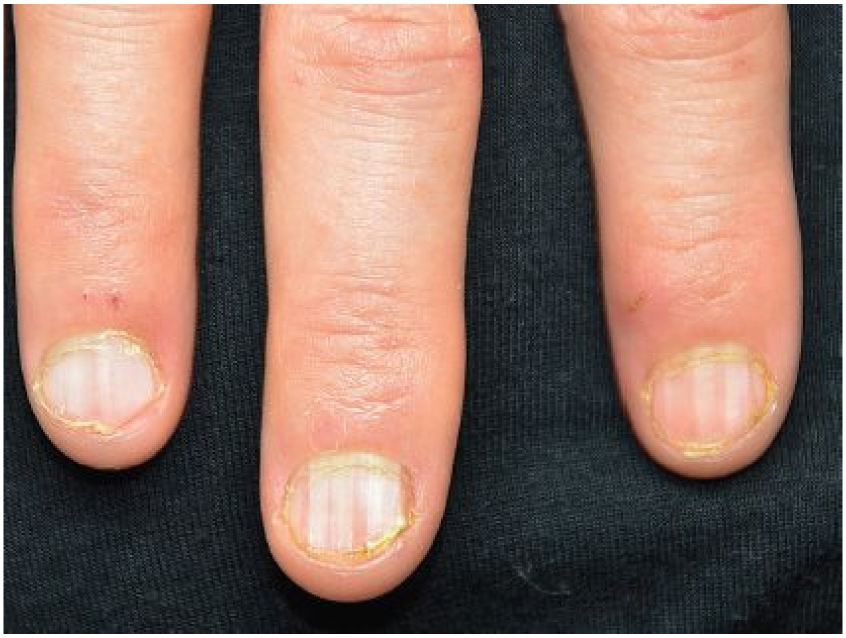

FIGURE 169-4 Darier disease of the fingernails with the typical red and white striping in the same patient from Figure 169-1. (*Used with permission from Yoon Cohen, MD.*)

EPIDEMIOLOGY

- Darier disease, also known as keratosis follicularis, has been reported in approximately 1:30,000 to 1:100,000 people.
- Males and females are equally affected as this occurs through autosomal dominant inheritance.
- Clinically it becomes apparent near puberty.

ETIOLOGY AND PATHOPHYSIOLOGY

- In Darier disease, a gene mutation in the ATP2A2 gene in chromosome 12q23-24.1 results in production of an abnormal calcium pump in the sarcoendoplasmic reticulum, SERCA2. How this mutation affects the way the cells interact together is still unknown, but it results in abnormal epidermal differentiation.[2] It is inherited in an autosomal-dominant fashion.

DIAGNOSIS

- Clinical features—Greasy, hyperkeratotic, yellowish-brown papules and plaques with scale in a seborrheic distribution (**Figures 169-1** to **169-3**). The feet can be covered with hyperkeratotic plaques. The palms may have pits or keratotic papules, and the nails can have V-shaped nicking and alternating longitudinal red and white bands (**Figures 169-4** and **169-5**). The keratotic papules can be intensely malodorous such that it can interfere with normal social situations (**Figure 169-6**).

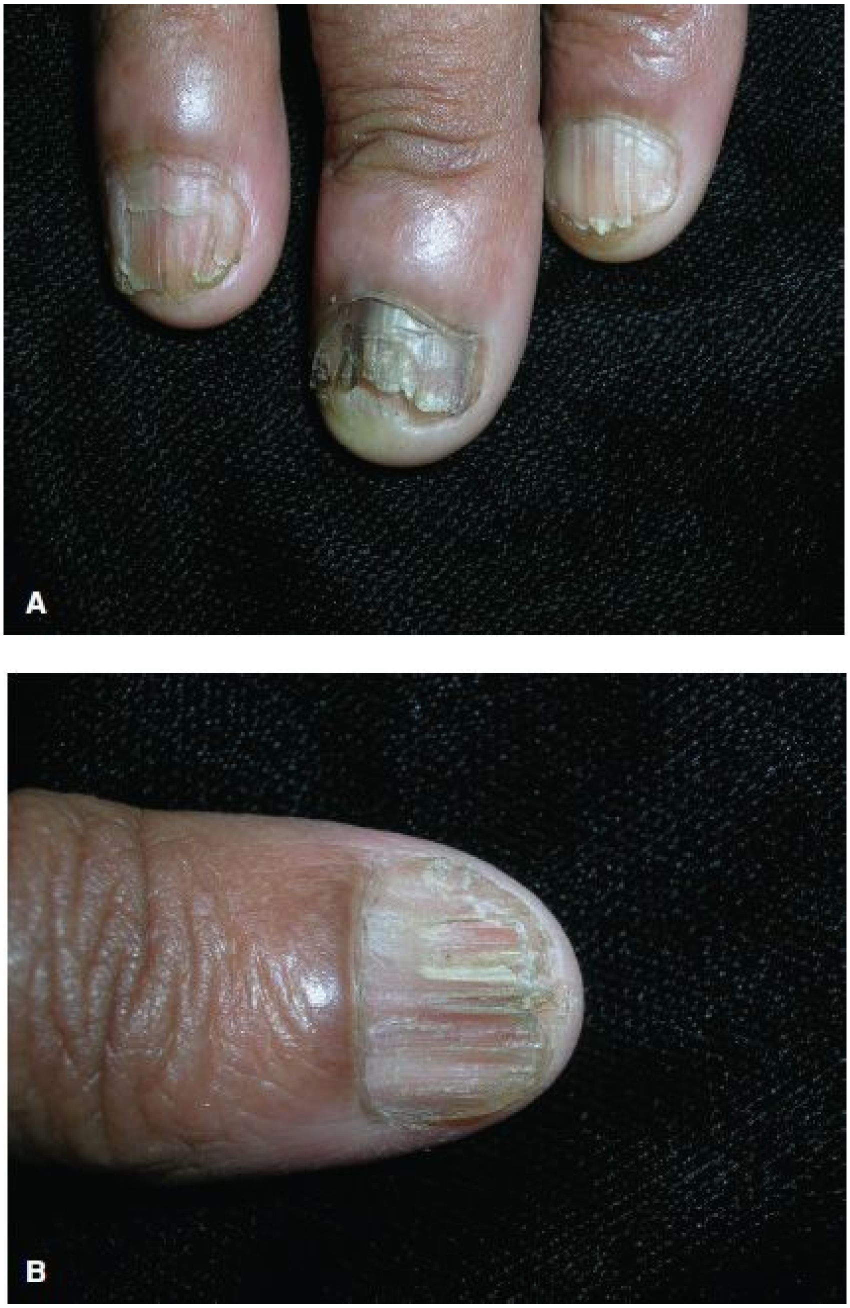

FIGURE 169-5 A. Typical nail findings in Darier disease showing longitudinal bands and longitudinal splitting. B. V-shaped nick at the free margin of the fingernail–the most pathognomonic nail finding in Darier disease. (*Used with permission from Richard P. Usatine, MD.*)

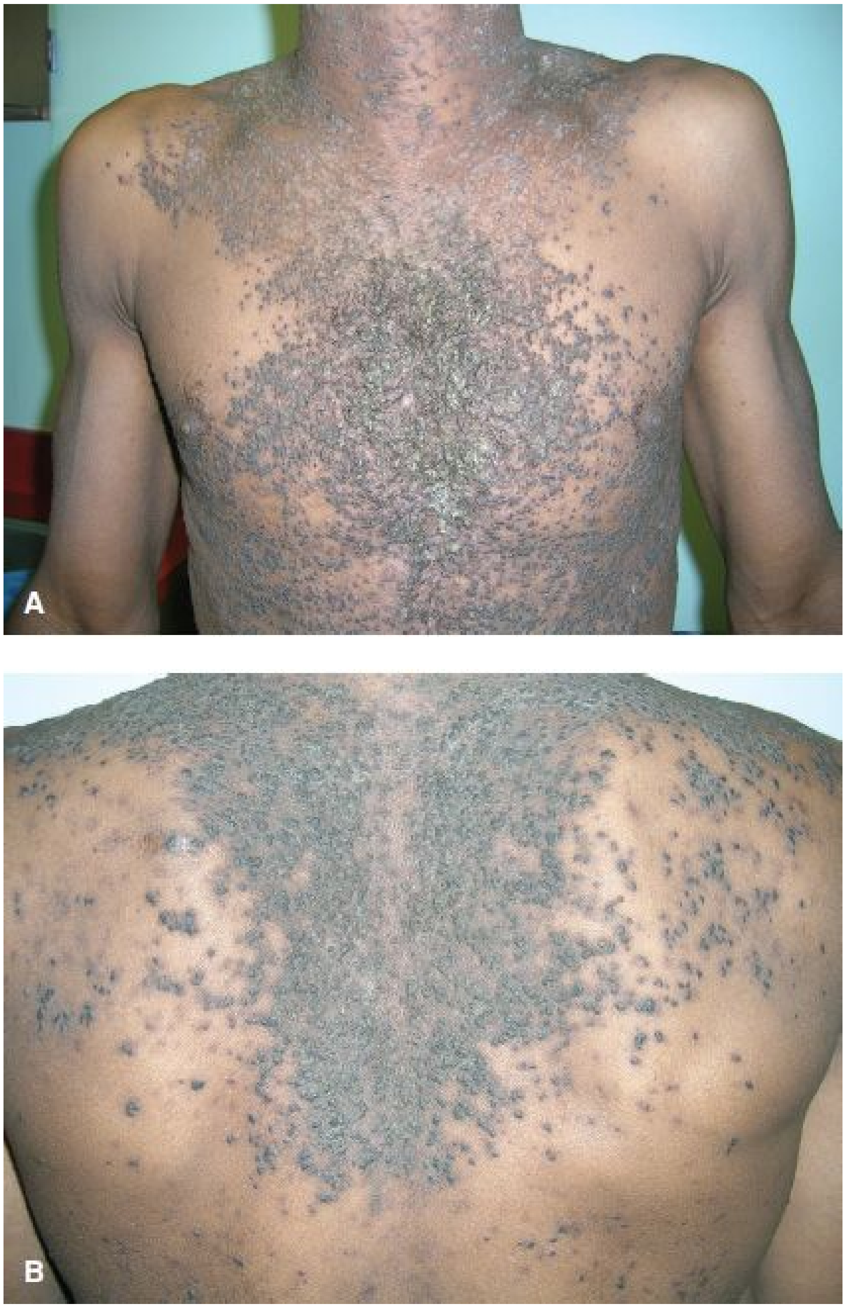

FIGURE 169-6 Darier disease in a more advanced stage. A. Central chest and neck are completely covered with hyperkeratotic greasy scale. B. The central back is also covered with hyperpigmented hyperkeratotic greasy scale. The patient states that warm weather worsens the rash and causes increased itching and an unpleasant odor. (*Used with permission from Richard P. Usatine, MD.*)

- Typical distribution—The clinical lesions involve skin in the seborrheic distribution (face, ears, scalp, upper chest, upper back, and groin; **Figures 169-1** to **169-3** and **169-6**). The axilla and inframammary areas may be involved (**Figure 169-3**). In early, mild, or partially treated disease, only the skin behind the ears may be affected.[3]The nails are characteristically involved (**Figures 169-4** and **169-5**).
- Laboratories—Skin biopsy reveals the characteristic histopathology. A test for the ATP2A2 gene mutation can be performed.

DIFFERENTIAL DIAGNOSIS

- Hailey-Hailey disease (aka benign familial pemphigus)—Another genodermatosis with crusted erosions and flaccid vesicles distributed in the intertriginous areas as opposed to the greasy keratotic papules in the seborrheic distribution. A 4-mm punch biopsy is adequate to make this diagnosis.
- Seborrheic dermatitis—Erythematous patches and thin plaques with yellow greasy scale on the scalp, central face, and chest. This is rarely as severe as Darier disease (see Chapter 135, Seborrheic Dermatitis).

MANAGEMENT

- Darier disease is so rare that there are no randomized controlled trials to guide treatment.
- Mild-to-moderate disease can be treated by avoiding exacerbating factors (sunlight, heat, and occlusion) and with topical medications, SOR Ⓒ but severe disease is best treated with oral retinoids. SOR Ⓒ
- Frequent application of emollients, humectants, and keratolytics are the mainstay of therapy. SOR Ⓒ There are many effective nonprescription and prescription products that contain propylene glycol, urea, or lactic acid.

Ammonium lactate can be obtained in a 6 percent lotion OTC and can be prescribed in a 12 percent lotion.

- Topical retinoids (adapalene, tretinoin, or tazarotene) are effective in some patients, but their main limitation is irritation. Adapalene use may be effective in localized variants.[4] SOR Ⓒ All retinoids are contraindicated in pregnancy.
- Topical corticosteroids may be of some help. Lower-potency topical corticosteroids should be used on the face, groin, and axillae to minimize side effects in these areas. SOR Ⓒ
- Topical calcineurin inhibitors (pimecrolimus and tacrolimus) may also be helpful as noted in some case reports.[5,6] SOR Ⓒ These do not have a risk of skin atrophy like steroids, but are generally more expensive and have the controversial black box warning related to the rare risk of skin malignancy and lymphoma.
- Systemic retinoids (acitretin initial 10 to 20 mg/day or isotretinoin 0.5 to 1mg/kg/day) are the most potent treatment and treatment of choice for severe disease.[2] SOR Ⓒ They should only be prescribed by physicians who have experience with these medications. Patients on systemic retinoids require close monitoring and careful selection, as they are teratogenic (category X) and can cause hyperlipidemia, hypertriglyceridemia, mucous membrane dryness, alopecia, hepatotoxicity, and possible mood disturbances. Females must not get pregnant for at least 1 month after stopping isotretinoin and at least 3 years after stopping acitretin.
- Topical or oral antibiotics may be necessary for flares as they often are secondarily infected with bacteria. SOR Ⓒ
- Laser, radiation, photodynamic, and gene therapy are newer treatment modalities that are being investigated.
- Refer to an urologist or ophthalmologist if testicular abnormality or corneal opacities are detected. SOR Ⓒ
- Gene therapy has also been studied but has not yet become a viable treatment option.
- The malodor that accompanies the disease, as well as the facial involvement, often adversely affects the patient’s quality of life; thus,

treatment is often warranted.

FOLLOW-UP

- Follow-up is needed if patients are on oral retinoids to monitor patients' lipid panel and liver function tests approximately every 3 months. Patients should also be monitored for signs of secondary bacterial infection.

PATIENT EDUCATION

- Avoid direct sunlight, heat, occlusion, and people acutely infected with herpes simplex virus (HSV) or varicella-zoster virus.
- Watch for signs of secondary cutaneous bacterial or viral infections.

PATIENT RESOURCES

- There are patient advocacy groups for several genetic skin conditions. A quick search online can obtain their websites and contact information.
- The American Academy of Dermatology has a summer camp that is free of charge for children with skin conditions called Camp Discovery—**www.campdiscovery.org/**.

PROVIDER RESOURCES

- A helpful free online resource for the genodermatoses, or any genetic disease, is the Online Mendelian Inheritance of Man website—**www.omim.org**.
- For information on laboratories that perform rare genetic tests and clinics that perform prenatal diagnostic testing for certain conditions—**www.genetests.org**.

- Skin Advocate is a free application for mobile devices that is provided by the Society of Investigative Dermatology. Patient advocacy groups—**www.skinadvocateapp.com**.

PACHYONYCHIA CONGENITA (PC)

PATIENT STORY

A college student comes to the pediatrician's office for a school physical exam and his influenza vaccine. He is aware that he was born with pachyonychia congenita (type-1) and has been dealing with the ramifications of this condition since he was 9 years old. He has come to accept the nail abnormalities (**Figure 169-7**) but finds that the hyperkeratotic lesions on his hands, feet, and elbows can be painful (**Figures 169-8** to **169-10**). The thick calluses on his feet cause him the most pain and he describes this problem to be like walking with pebbles in your shoes. His dermatologist has given him 12 percent ammonium lactate to help dissolve some of the thickened hyperkeratoses. He also uses a pumice stone after bathing to sand down the callus on the feet and the papules on the hands and elbows. He wonders if there is anything else that can be done to help him. As this is a rare genodermatosis, the pediatrician refers the young student to his dermatologist.

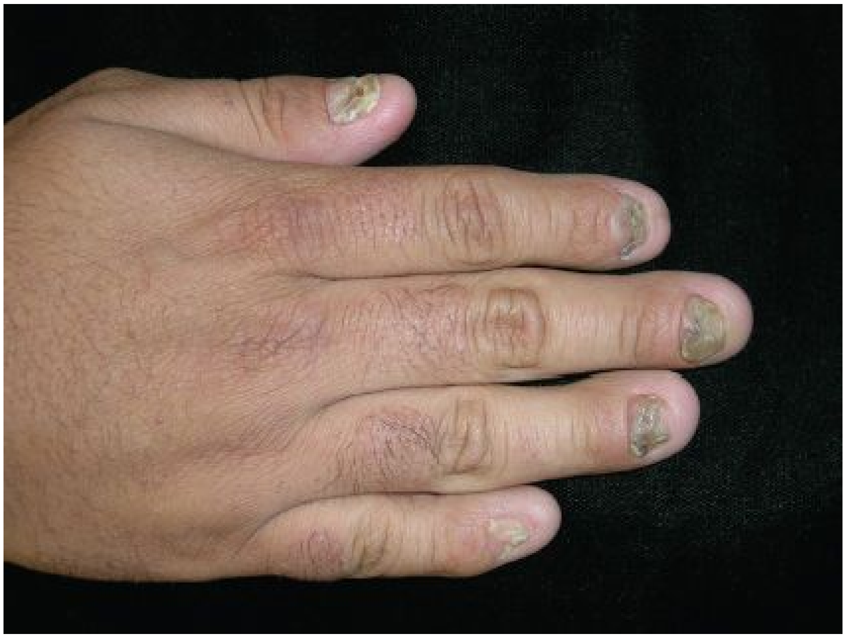

FIGURE 169-7 Pachyonychia congenita (type 1) showing the hyperkeratotic nail dystrophy. (*Used with permission from Richard P. Usatine, MD.*)

EPIDEMIOLOGY

- Rare disorder with unknown prevalence. Mutations in individuals from at least 227 families have been published.[7] Increasing data is currently being analyzed since the initiation of the International Pachyonychia Research Registry.
- Increased in Slavic and Jewish populations. Increased incidence in males that in females.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Pachyonychia congenita is considered a spectrum of clinical manifestations of ectodermal dysplasia associated with abnormal keratin proteins involved in normal intermediate filament assembly.[7] This defect disrupts the integrity of epithelial cells especially when frictional stressors are applied.

- About half of all cases are inherited in an autosomal dominant manner, the rest arise from spontaneous mutations.[1,2]
- Historically, the disorder had 2 variants called Jadassohn-Lewandsowsky (PC Type-1) and Jackson-Lawler (PC Type-2) based on clinical presentation. There has been an international effort in data collection registry that has led to a new classification system proposed at the 2010 International Pachyonychia Congenita Symposium based on the link between 4 genetic mutations and clinical presentation.[7]
- The four genetic mutations carry the name of the protein and the chromosome number associated with the keratin gene abnormality: KRT6A, KRT6B, KRT16, KRT17. Therefore the new nomenclature used to classify PC is as follows: PC-K6a, PC-K6b, PC-K16, PC-K17, and PC-U when the genetic mutation is unknown.[7]

DIAGNOSIS

- Diagnosis is made by clinical findings and molecular genetic testing of the four known keratin genes. The most common clinical finding is hypertrophic nail dystrophy (**Figure 169-7**). It is associated with painful focal keratoderma typically found on palms and soles or on pressure points or areas under recurrent friction stress (**Figures 169-8** to **169-10**).[2,7]

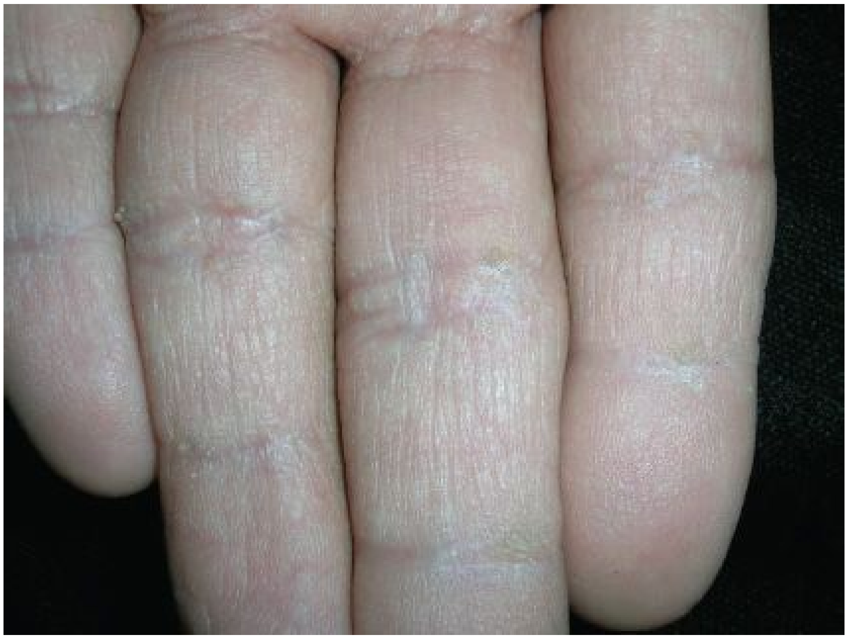

FIGURE 169-8 Pachyonychia congenita showing the small keratotic papules on the palmar side of the fingers. (*Used with permission from Richard P. Usatine, MD.*)

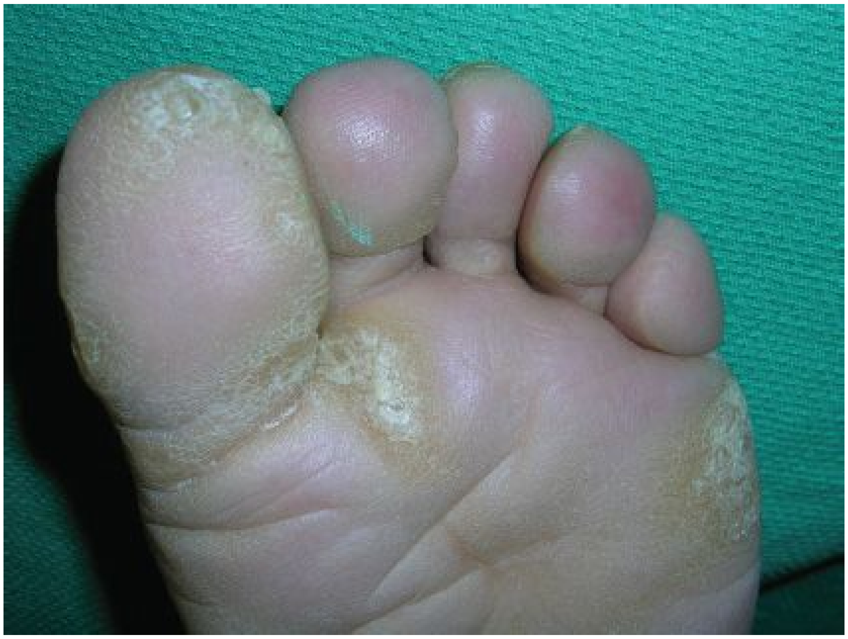

FIGURE 169-9 Pachyonychia congenita demonstrating the hypertrophic callus found on the soles of the feet. This patient religiously uses keratolytic topical medications to keep the callus under control. At one time he was

using a wheelchair because it was too painful to walk on his feet. (*Used with permission from Richard P. Usatine, MD.*)

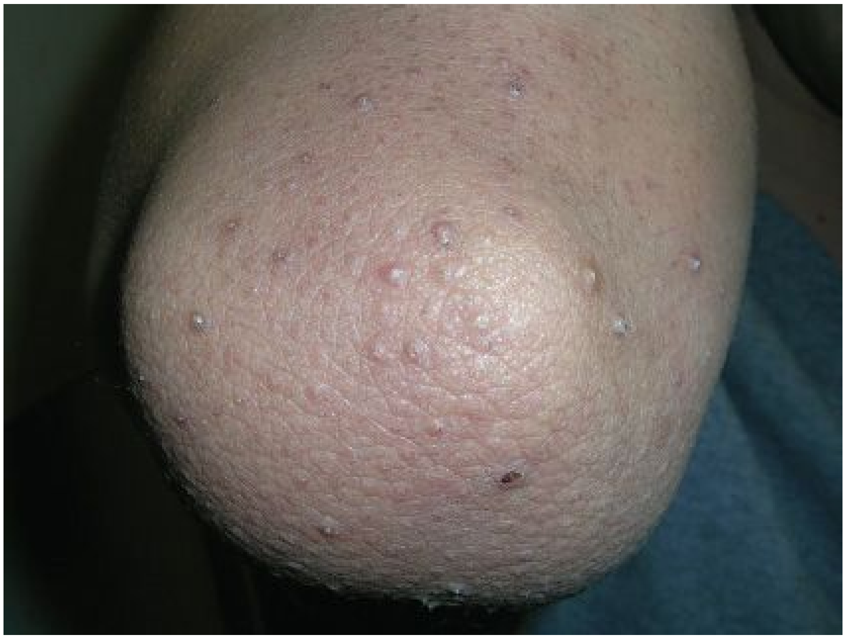

FIGURE 169-10 Pachyonychia congenita showing hyperkeratotic papules on the elbows. This patient also gets these on the buttocks, which can make it painful to sit. (*Used with permission from Richard P. Usatine, MD.*)

- First sign that may be appreciated during infancy is erythema of the nail bed prior to typical nail changes.
- Nails—Subungual hyperkeratosis with increased transverse curvature, “pincer nail effect,” and elevation of distal nail plate (**Figure 169-11**). Typically involves all 20 nails, with fingernails being affected more often than toenails. Nail plates may also be darkened, thickened and friable with increased risk of shedding the entire nail plate. May be associated with paronychial infection with Staphylococcus or Candida.

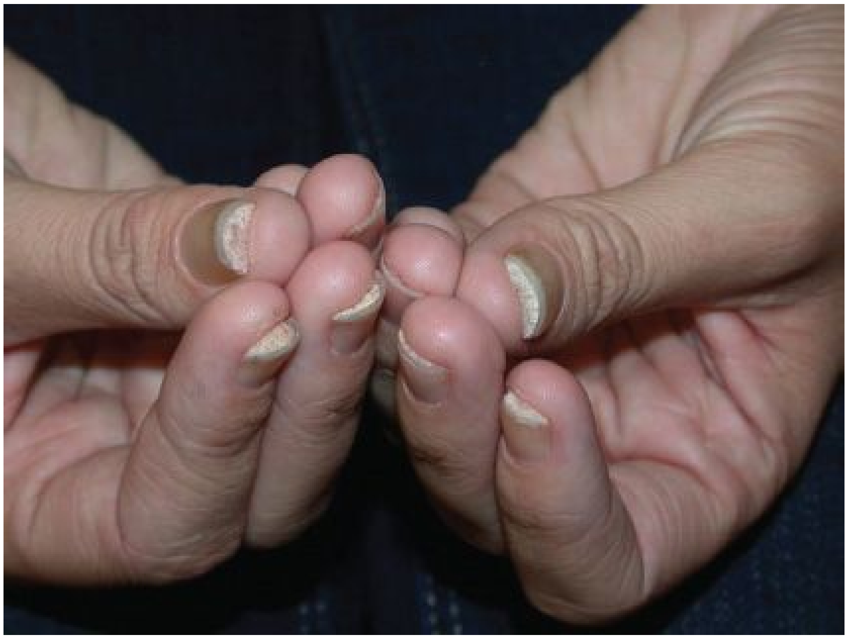

FIGURE 169-11 Pachyonychia congenita involving all 10 fingernails with subungual hyperkeratosis elevating the distal nail plate and causing some pincer-like deformities. (*Used with permission from Eric Kraus, MD*.)

- Skin—Focal symmetric palmoplantar keratoderma, follicular hyperkeratosis of elbows, knees, extensor extremities. May be associated with hyperhydrosis, steatocystoma multiplex, or epidermoid cysts. Steatocystoma multiplex is a condition in which there are many superficial cutaneous cysts filled with a fatty substance. It is frequently located on the back and chest (**Figure 169-12**). Hair may be coarse and brittle (pili torti).

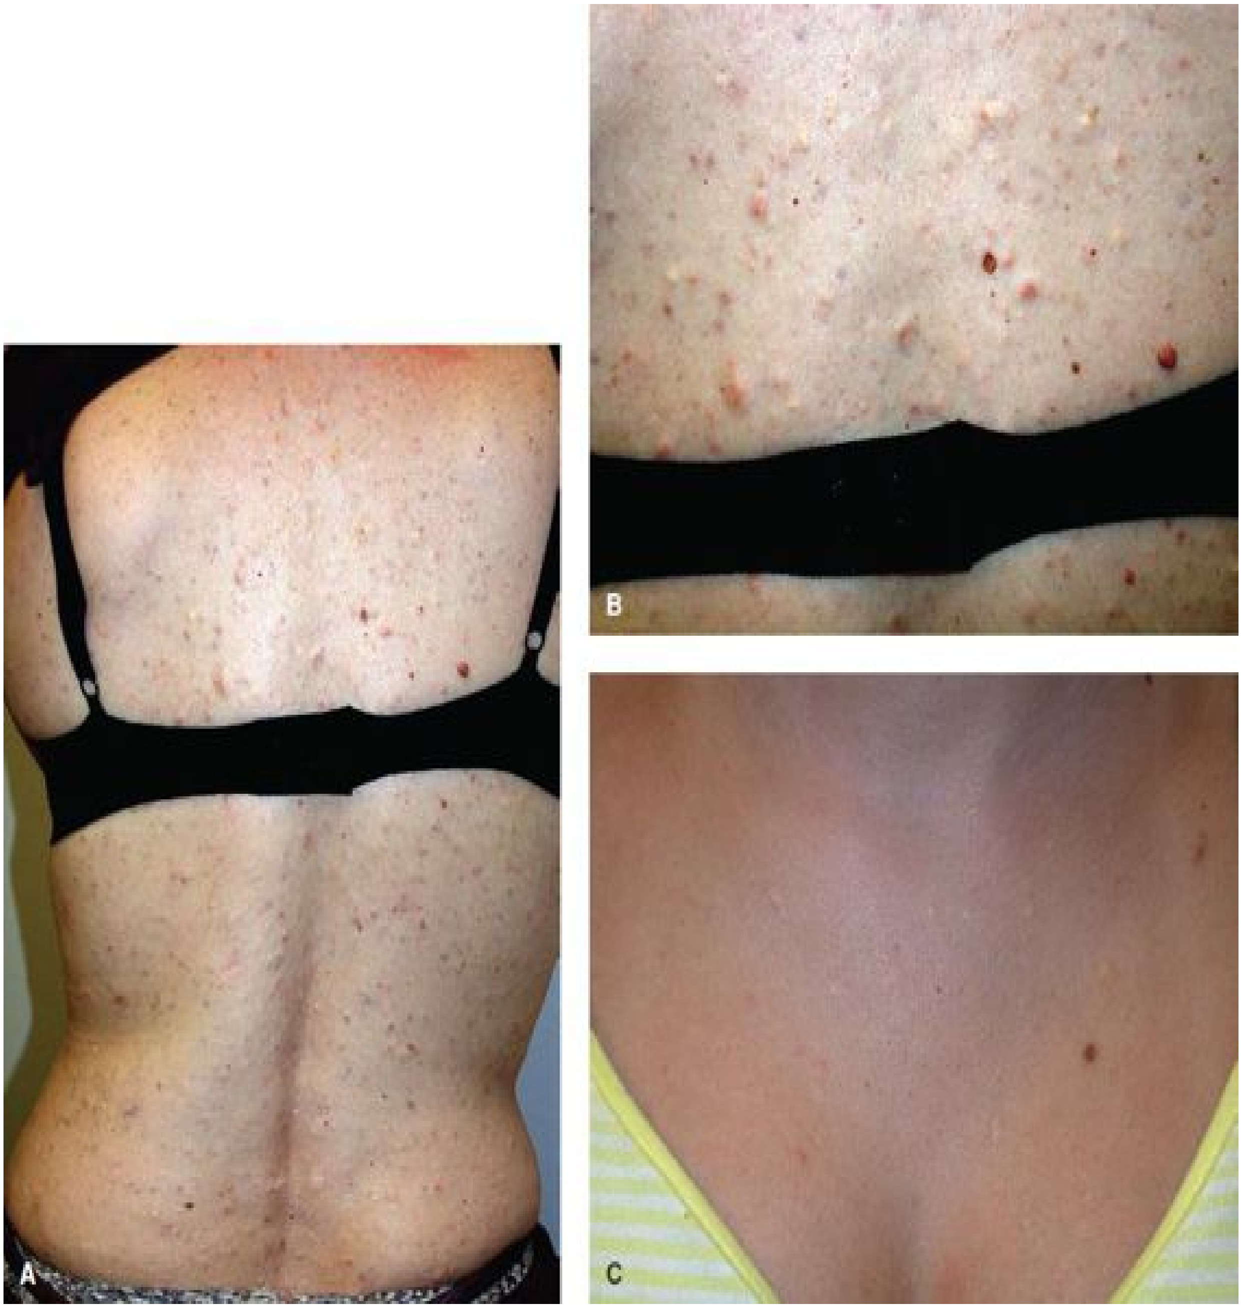

FIGURE 169-12 A. pachyonychia congenita type 2 with extensive steatocystoma multiplex on the back. B. Close-up of steatocystoma multiplex. C. The daughter is beginning to develop steatocystoma multiplex on the chest. (*Used with permission from Eric Kraus, MD*.)

- Oropharynx—May be associated with oral leukokeratosis, angular cheilitis, and hoarseness. Natal teeth have most frequently been associated with KRT17 mutation.

- Eyes/Ears—Rarely associated with corneal dystrophy, cataracts, and excessive cerumen accumulation.
- Phenotypes associated with genetic mutations are as follows:
    - KRT6A and KRT6B exist as the classic painful nail dystrophy and palmoplantar keratoderma typically not associated with other phenotypes.[2]
    - KRT16 is a focal nonepidermolytic palmoplantar keratoderma, defined as keratoderma of varying severity that may occur on the palms and soles with absent or mild nail dystrophy.[2]
    - KRT17 is associated with steatocystoma multiplex (**Figure 169-12**), and can have absent or only mild nail dystrophy and palmoplantar keratoderma.[2]

DIFFERENTIAL DIAGNOSIS

- Dyskeratosis congenita—May be difficult to differentiate from PC since both may show nail dystrophy, palmoplantar keratoderma, hyperhidrosis, and oral leukoplakia. However, reticulate hyperpigmentation, skin tumors, and hematologic manifestations are more specific to dyskeratosis congenita.
- Onychomycosis—Typically does not involve all 20 nails and is not associated with painful palmoplantar keratoderma or other PC findings. May perform a KOH preparation or culture the affected nail plate.
- Twenty nail dystrophy—May occur without keratoderma or other findings associated with PC. Genetic testing may be necessary to differentiate these entities.
- Palmoplantar psoriasis—Psoriasis is usually associated with mahogany (red-brown) spots and pustules. Also look for other signs of psoriasis such as plaques elsewhere or nail findings such as nail pitting or oil spots. Punch biopsy of plaque shows typical histopathologic changes.
- Other palmoplantar keratodermas—May present similarly and require syndromic phenotype clues or genetic testing to differentiate.

MANAGEMENT

- Treatment is mainly supportive and tailored to each patient according to age and severity of symptoms. Often there is need to treat overlying skin infection. Education about grooming practices is imperative.
- Topical therapies useful for ameliorating hyperkeratosis include lactic acid and urea based creams and lotions. Ammonium lactate can be obtained in a 6 percent lotion OTC and can be prescribed in a 12 percent lotion. SOR Ⓒ
- Mechanical nail paring with electric file, dental drill, or blade can be attempted. Avulsion of the nail plate with matrix destruction can be used in severe, symptomatic cases. SOR Ⓒ
- Systemic antibiotics or antifungals may be needed to treat underlying infection. SOR Ⓒ
- Pain can be reduced by limiting friction and trauma to the feet. Attempting to minimize prolonged walking or standing may be helpful. Patients should select comfortable, ventilated footwear and attempt to maintain an ideal body weight. SOR Ⓒ
- Routine grooming of the feet is essential and includes paring down the hyperkeratotic areas to avoid painful buildup that can add further friction and trauma to the foot. Soaking the feet in warm water prior to the paring is helpful when plaques are hard. The surface of the skin and the instruments used should be clean to avoid infection. If blisters develop, they can be drained with a sterile needle. SOR Ⓒ
- Treatments currently under investigation include use of genetic modulators, rapamycin, simvastatin, anti-TNF biologics, and even botulinum toxin.[1]

FOLLOW UP

- Referral to dermatology and podiatry as needed for management and supportive treatment of complications from skin excess. Genetic referral should be considered for reproductive counseling and assessment of at-risk family members.

PATIENT EDUCATION

- Lesions persist throughout life. Reduction of trauma, friction, and sheer forces to the skin and nails improves the condition. Heat or perspiration may worsen the condition and should be avoided.
- Molecular genetic testing of at-risk relatives in a family with PC is not indicated because the phenotype is readily observed from a young age and no interventions can prevent the development of manifestations or reduce their severity.
- It is rarely associated with blindness secondary to corneal dystrophy. There are no other known associated systemic risks or conditions.

Additional Examples

XERODERMA PIGMENTOSA

- Xeroderma pigmentosa (XP) is an autosomal recessive genetic repair disorder resulting in early predisposition to malignancy mainly secondary to UV-light damage (**Figure 169-13**). The condition affects approximately 1 in 1 million people in the US, but there seems to be an increased incidence in Japan.[8] The earliest sign is increased sun sensitivity with easy sun burning in infancy. Dyschromic macules and telangiectasias start to develop in a sun-exposed distribution within the first few years of life. After some time actinic keratosis followed by various forms of skin cancer start to appear depending on the amount of sun exposure. Ophthalmologic and neurologic manifestations are associated. Treatment includes extreme sun avoidance (only out early morning and evening) as well as protective barriers, cancer screening, excision of skin cancers, and referral to dermatology, ophthalmology, or neurology accordingly.

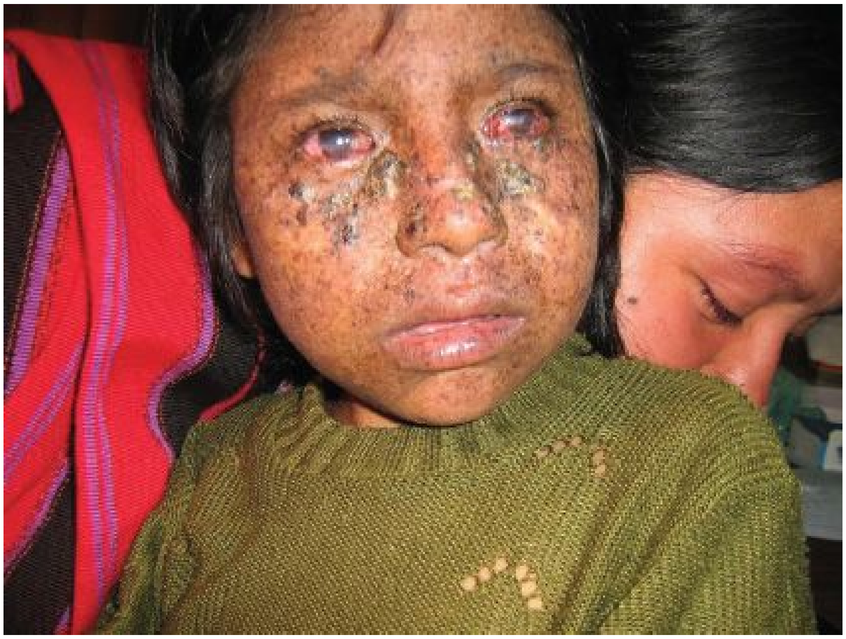

FIGURE 169-13 Xeroderma pigmentosum in an 8-year-old girl from Guatemala showing large hyperkeratotic lesions with some induration suspicious of actinic keratosis and early squamous cell carcinoma. There are also numerous hyperpigmented solar lentigines. Marked corneal scarring and conjunctival injection is present. (*Used with permission from James Halpern, Bryan Hopping, Joshua M Brostoff and Wikimedia Commons*.)

PSEUDOXANTHOMA ELASTICUM

- Pseudoxanthoma elasticum (PXE) is considered a genetic disorder of connective tissue. There is a rare mutation in a transmembrane transporter gene that in some way leads to the clinical manifestations observed. Incidence is approximately 1 in 100,000, affecting both sexes equally.[9] Some key clinical features include yellow papules/plaques over redundant, lax, soft skin folds on the sides of neck (**Figure 169-14**), axillae, antecubital fossae, abdomen, groin, and thighs as well as mucous membranes. Eyes exhibit angioid streaks, retinal pigmentation alteration, and may be associated with macular degeneration and retinal hemorrhages causing blindness. Other systems involved are the cardiovascular system (gastric artery hemorrhage) and reproductive system (first trimester miscarriage). Diagnosis is clinical or with biopsy if needed. Treatment is supportive with appropriate referrals as complications arise.

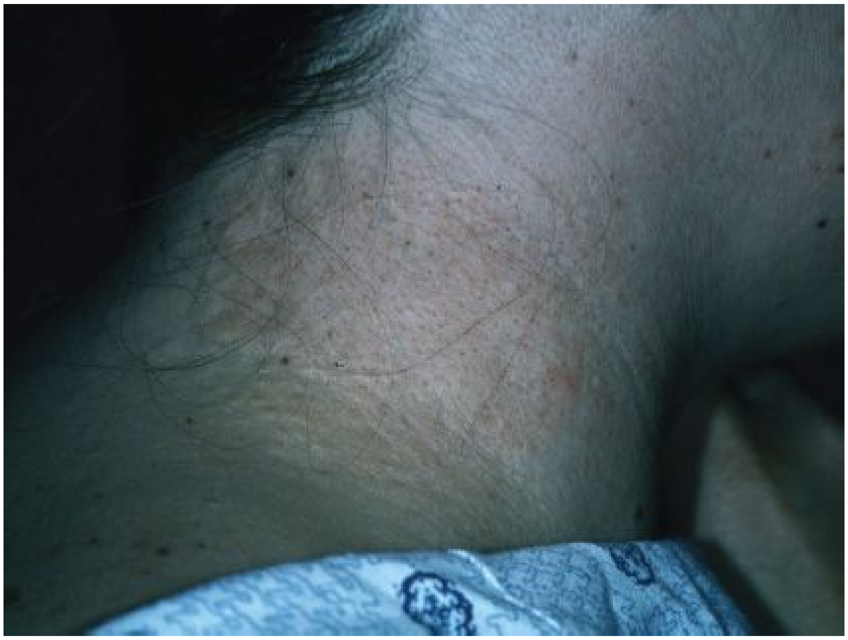

FIGURE 169-14 Pseudoxanthoma elasticum with a typical patch of soft thickened pink skin on the neck. This young woman went on to have early coronary artery disease. (*Used with permission from Richard P. Usatine, MD*.)

170 VASCULAR AND LYMPHATIC MALFORMATIONS

Richard P. Usatine, MD
Nathan Hitzeman, MD

PATIENT STORY

A 6-month-old African American boy is brought to his pediatrician for his six-month well-baby exam and immunizations. The mother asks whether the red mark on the forehead and right eyebrow from birth will ever go away (**Figure 170-1**). The pediatrician refers the child to a dermatologist that explains that this is a capillary malformation called a port-wine stain and that it will remain there for the rest of the child’s life. He also notes that it is less likely but still possible for this to be a salmon patch that could resolve spontaneously (although most salmon patches are lighter and midline). He states that it is not necessary to perform a biopsy because either way it is a capillary malformation that will not cause the child any physical harm. As it only involves part of V1 and none of V2, it is extremely unlikely to be part of the neurocutaneous syndrome known as Sturge-Weber syndrome. The pediatrician decides to not even bring up Sturge-Weber to avoid making the mother anxious but will continue to follow the child’s development over time. The dermatologist also explained that the child may choose to have laser treatment in the future if the capillary malformation is causing psychological distress.

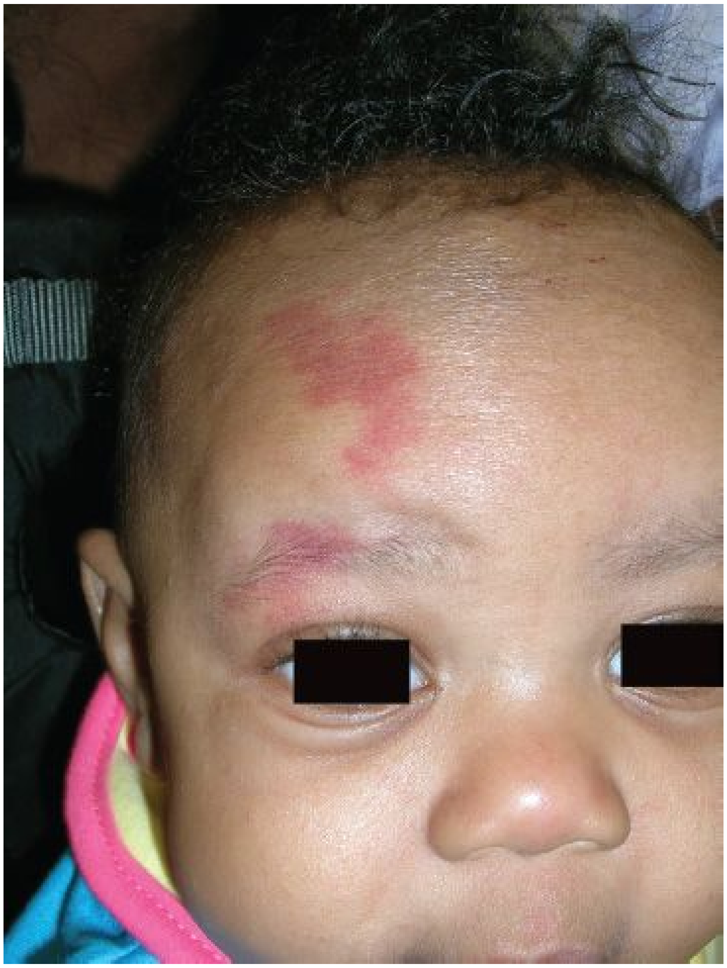

FIGURE 170-1 Capillary malformation since birth on the forehead and right eyebrow of this 6-month-old infant. This is likely to be a port-wine stain since it is not midline and it is darker than most salmon patches. As it only involves part of V1 and none of V2 it is extremely unlikely to be part of the Sturge-Weber syndrome. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Vascular malformations at birth range from the very common and benign salmon patch to rare but serious neurocutaneous syndromes (Sturge-Weber syndrome). Cutaneous lymphatic malformations are seen in a relatively rare condition called lymphangioma circumscripta. Osler-Weber-Rendu syndrome (hereditary hemorrhagic telangiectasia) is a rare vascular disorder that is inherited an autosomal dominant manner. Childhood hemangiomas are covered separately in Chapter 93, Childhood Hemangiomas.

SYNONYMS

There are two major types of capillary malformations present at birth:

- Salmon patch (stork bite, angel kiss, capillary stain, nuchal nevus, nevus simplex, telangiectatic nevus, and nevus flammeus nuchae) is a superficial capillary malformation and is likely to resolve spontaneously (**Figure 170-2**). Using the term capillary stain is one-way to denote how superficial it is.

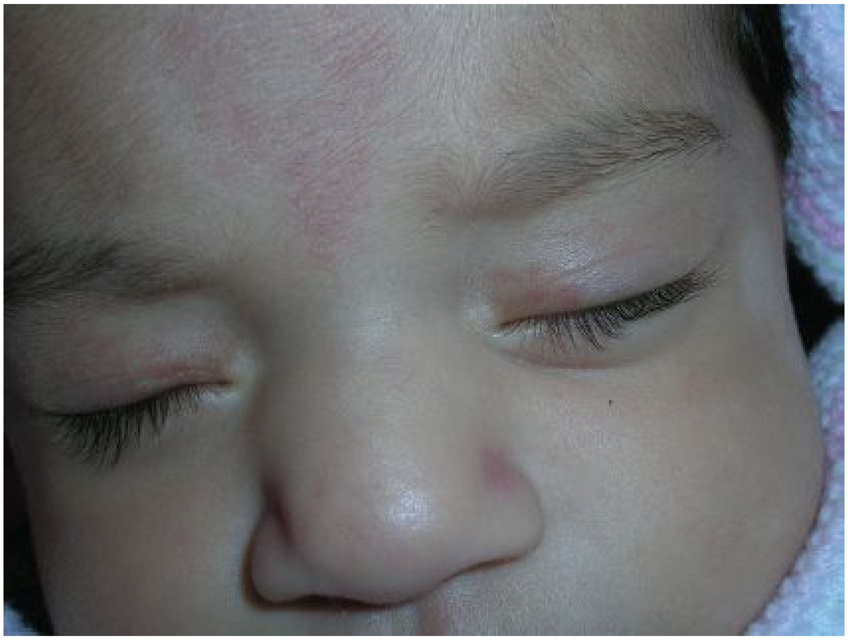

FIGURE 170-2 Salmon patches on the eyelids (angel kisses), glabella, forehead and nose in this healthy 2-month-old infant. Note how the pink color is faint and the forehead involvement is midline. (*Used with permission from Richard P. Usatine, MD.*)

- Port-wine stain (nevus flammeus) is deeper capillary malformation in the dermis and does not involute over time (**Figure 170-3**). In fact, it may increase in size, thickness, and become more nodular over time. It is this type of capillary malformation that may be associated with Sturge-Weber syndrome or Klippel-Trenaunay syndrome.

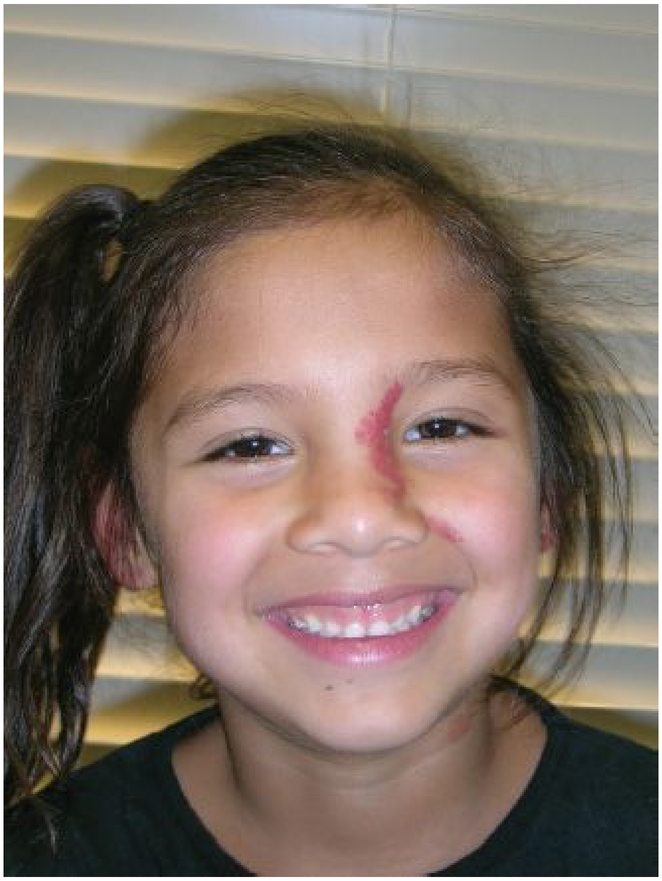

FIGURE 170-3 Port-wine stain on the face of this 6-year-old happy and healthy girl. While her mother would like to see the port-wine stain removed she understands that her daughter is too young for laser therapy. (*Used with permission from Richard P. Usatine, MD.*)

- Microcystic lymphatic malformations are called lymphangioma circumscriptum or cutaneous lymphangioma circumscriptum (**Figure 170-4**).

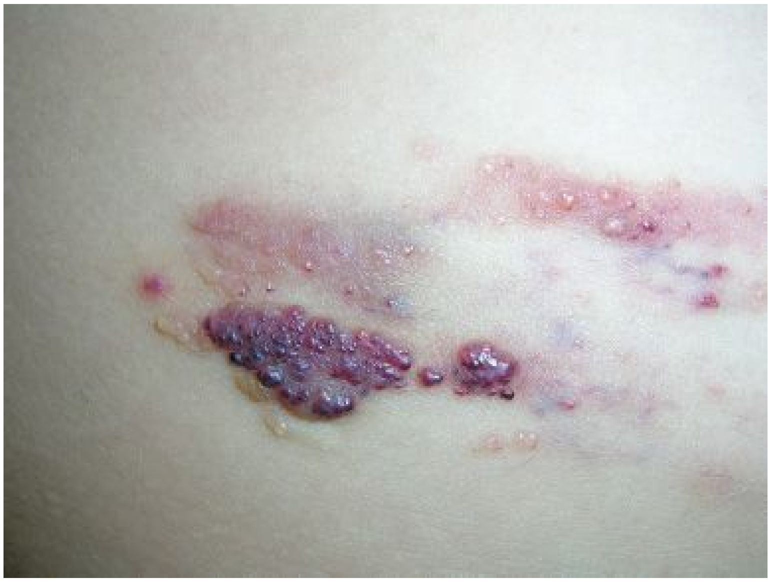

FIGURE 170-4 Close-up of lymphangioma circumscriptum present from birth on the trunk of this 7-year-old girl. The vesicles vary in color from yellow to pink and red. The red color is due to blood within the dilated lymphatic vessels. Note how this pattern resembles frog spawn. (*Used with permission from Richard P. Usatine, MD*.)

EPIDEMIOLOGY

- Salmon patches, also known as "stork bites" or "angel kisses" are present in 26 to 64 percent of newborns.[1–4] The angel kisses over the face tend to fade with time but the stork bites on the nape of the neck often persist (**Figure 170-2**).
- Port-wine stains are congenital vascular malformations that occur in 0.6 to 2.8 percent of infants as developmental anomalies.[3,4] They persist into adulthood. They may be associated with rare syndromes such as Klippel-Trenaunay and Sturge-Weber syndromes (see Chapter 207, Sturge-Weber Syndrome).
- Hereditary hemorrhagic telangiectasia (HHT) is an autosomal-dominant vascular disorder that affects one in several thousands of people (**Figure**

170-5). Certain populations in Europe and the US have a higher prevalence of this disease.[5]

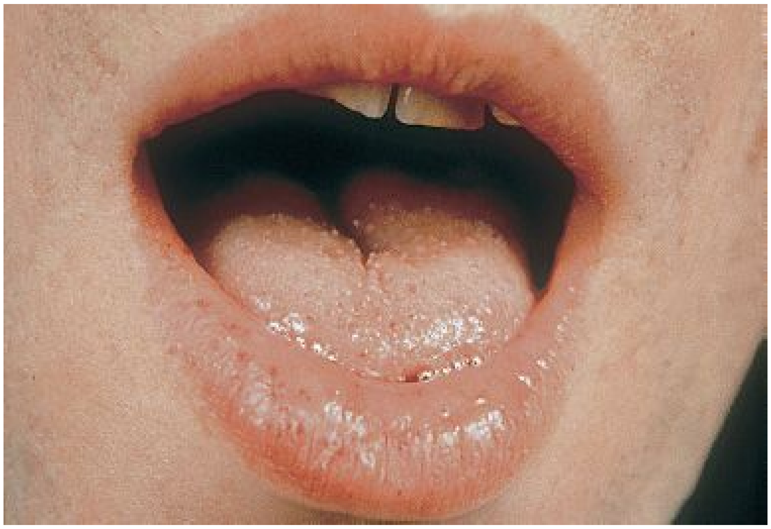

FIGURE 170-5 Hereditary hemorrhagic telangiectasias (Osler-Weber-Rendu syndrome) in a teen with recurrent nosebleeds and visible telangiectasias on the lips and tongue. (*Used with permission from Kane KS, Lio P, Stratigos AJ, Johnson RA. Color Atlas and Synopsis of Pediatric Dermatology, 2nd edition, Figure 8-10b, New York, NY: McGraw-Hill, 2009.*)

- Lymphangioma circumscriptum consists of dilated cutaneous lymphatic tissue and is rare.

ETIOLOGY AND PATHOPHYSIOLOGY

- Port-wine stains are vascular ectasias or dilations thought to arise from a deficiency of sympathetic nervous innervation to the blood vessels. Dilated capillaries are present throughout the dermis layer of the skin.
- HHT is associated with mutations in two genes: endoglin on chromosome 9 (HHT type 1) and activin receptor-like kinase-1 on chromosome 12 (HHT type 2). These genes are involved in vascular development and repair. With the mutations, arterioles become dilated and connect directly

with venules without a capillary in between. Although manifestations are not present at birth, telangiectasias later develop on the skin, mucous membranes, and GI tract. In addition, AVMs often develop in the hepatic (up to 70% of patients), pulmonary (5% to 300%), and cerebral circulations (10% to 15%). Any of these lesions may become fragile and prone to bleeding.[5]

- Congenital malformations of the lymphatic system may involve the skin, subcutaneous tissues and intestines.[6] These lymphangiomas are hamartomatous in nature with the most superficial version being lymphangioma circumscriptum. Deeper versions are called cavernous lymphangiomas and cystic hygromas. The dilated ectopic lymph vessels protrude from the skin forming vesicles.

DIAGNOSIS

CLINICAL FEATURES

- Salmon patches present with fine pink to salmon-colored dilated superficial capillaries over the eyelids, glabella, forehead and posterior neck (**Figures 170-2** and **170-6**). These may be so faint that they are only visible when the baby is crying. Most salmon patches on the forehead are midline.

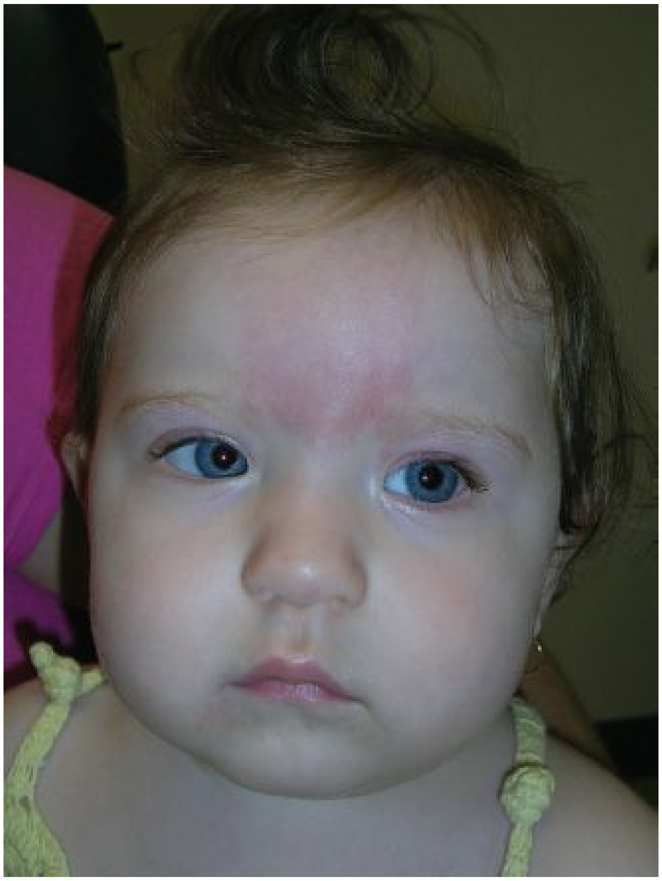

FIGURE 170-6 Salmon patch on the forehead and glabella of this otherwise healthy infant. This will spontaneously fade over time. Note how the pink color is faint and the forehead involvement is midline. (*Used with permission from Richard P. Usatine, MD.*)

- Port-wine stains are irregular red-to-purple patches that start out smooth in infancy but may hypertrophy and develop a cobblestone texture with age (**Figures 170-1** and **170-3**).
- Klippel-Trenaunay syndrome is characterized by vascular malformations, venous varicosities, and soft-tissue hyperplasia over an entire limb or another part of the body. This may cause hemihypertrophy of a single extremity such as the leg (**Figure 170-7**).

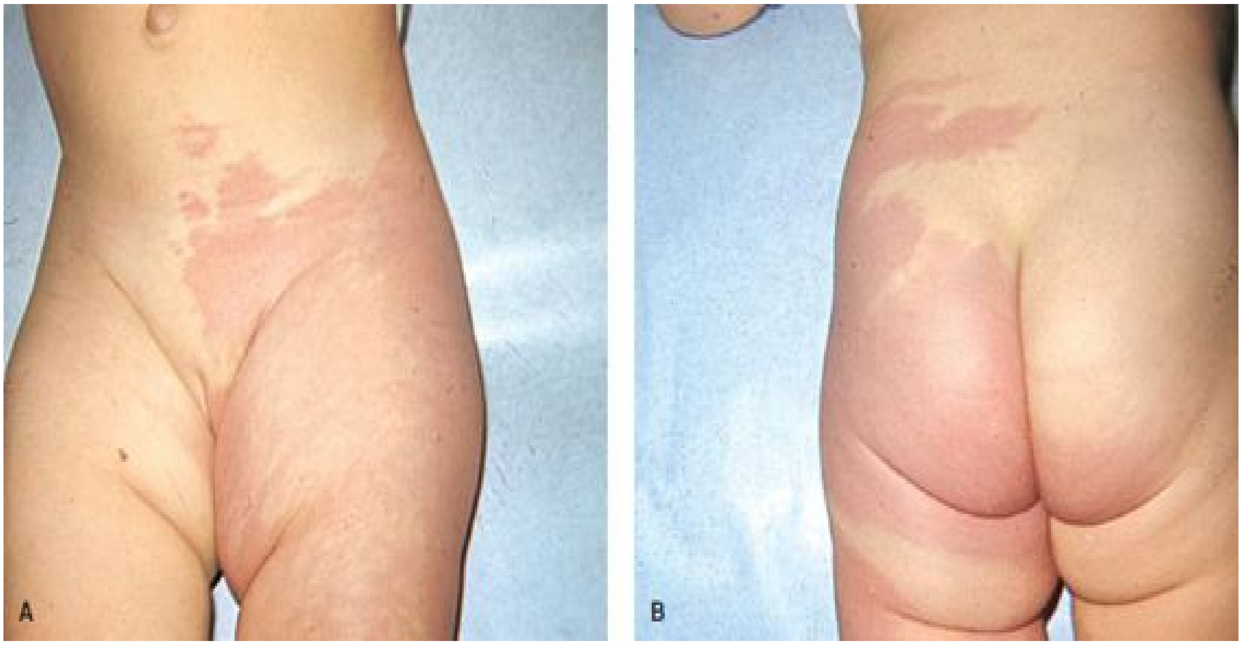

FIGURE 170-7 Klippel-Trenaunay syndrome with a port-wine stain over the left thigh. Over time, more massive vascularization and enlargement of the limb will develop. A. Anterior left thigh. B. Buttocks and posterior thigh. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figures 20-35 and 20-36, New York, NY: McGraw-Hill, 2008.*)

- Patients with Sturge-Weber syndrome often have developmental delays, epilepsy, and ophthalmology problems (see Chapter 207, Sturge-Weber Syndrome).
- HHT is diagnosed if three of the following four Curaçao criteria are met (and suspected if two are present):
  1. Recurrent spontaneous nosebleeds (the presenting sign in more than 90 percent of patients, often during childhood);
  2. Mucocutaneous telangiectasia (**Figure 170-5**; typically develops in the third decade of life);
  3. Visceral involvement (lungs, brain, liver, and colon); and/or
  4. An affected first-degree relative.[7]
- Lymphangioma circumscriptum appears as fluid-filled vesicles in groups are clusters on the skin. These can be clear, pink or red depending upon

the amount of blood within them (**Figures 170-8** and **170-9**). These vesicles can resemble frog spawn (**Figure 170-10**).

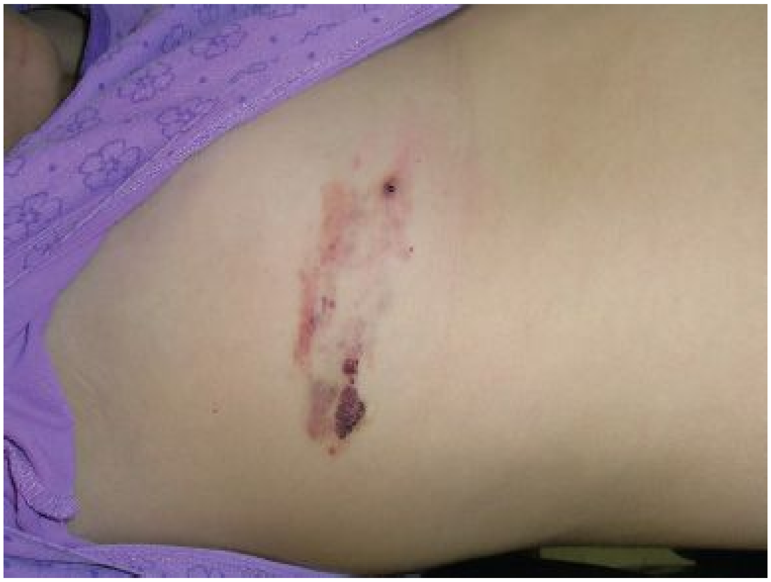

FIGURE 170-8 Lymphangioma circumscriptum since birth on the trunk of this 7-year-old girl. It is asymptomatic but the parents would like to know if it can be removed. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

- Salmon patches are presents over the eyelids, glabella, forehead and posterior neck (**Figures 170-2** and **170-6**). Most salmon patches on the forehead are midline.
- Port-wine stains tend to affect the face and neck, although lesions may affect any body surface, including mucous membranes (**Figures 170-1** and **170-3**). Lesions of Klippel-Trenaunay syndrome tend to affect the lower extremities (**Figure 170-7**). A diagnosis of Sturge-Weber syndrome requires that a port-wine stain be present in the trigeminal nerve distribution (see Chapter 207, Sturge-Weber Syndrome).
- HHT skin manifestations are few to numerous lesions on the tongue, lips, nasal mucosa, hands, and feet (**Figure 170-5**). However, any skin area or internal organ may be involved.

- Common locations for lymphangioma circumscriptum include the trunk (**Figures 170-8** to **170-10**), extremities, tongue, vulva, and genitalia.

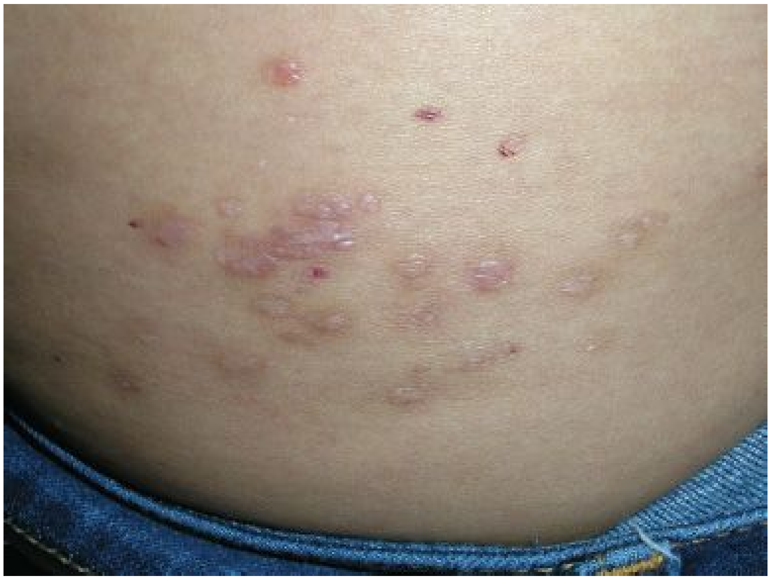

FIGURE 170-9 Lymphangioma circumscriptum near the waist of this 18-year-old female after sclerotherapy was partially effective. She is hoping that additional therapy will remove this from her skin. (*Used with permission from Richard P. Usatine, MD*.)

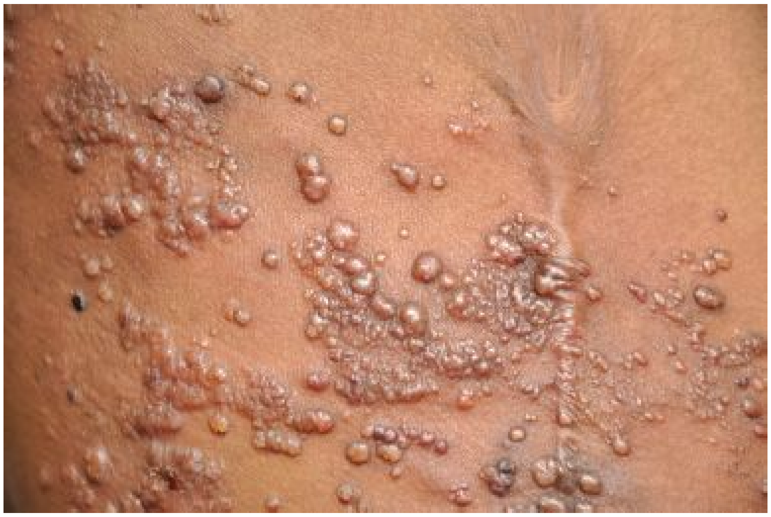

FIGURE 170-10 Lymphangioma circumscriptum on the trunk of teenager that occurred after surgery. Not all lymphangioma circumscriptum is congenital. Note how this pattern resembles frog spawn. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY STUDIES

- Patients with benign-appearing salmon patches, port-wine stains, lymphangiomas who lack other concerning symptoms, do not require laboratory testing.
- Check an annual complete blood count (CBC) and fecal occult blood in patients with HHT. They are at higher risk for iron-deficiency anemia because of recurrent nosebleeds and/or GI bleeding.
- If Sturge-Weber syndrome is suspected, perform neuroimaging and glaucoma testing. Neuroimaging may reveal leptomeningeal malformations ipsilateral to the port-wine stain. An electroencephalogram may reveal epilepsy. Elevated ocular pressures or visual field deficits may indicate glaucoma (see Chapter 207, Sturge-Weber Syndrome).

DIFFERENTIAL DIAGNOSIS

- Childhood hemangiomas are most likely to be confused with capillary malformations, especially if they are relatively flat. These are very different pathophysiologically as these hemangiomas are actually benign vascular tumors rather than malformations. Hemangiomas are usually raised and will involute over time (see Chapter 93, Childhood Hemangiomas).
- Childhood hemangiomas on the face may be part of the PHACES syndrome (see Chapter 227, PHACES Syndrome). As these may be segmental, they can be confused with the port-wine stain following a dermatomal distribution of the trigeminal nerve (**Figures 170-11** and **170-12**).

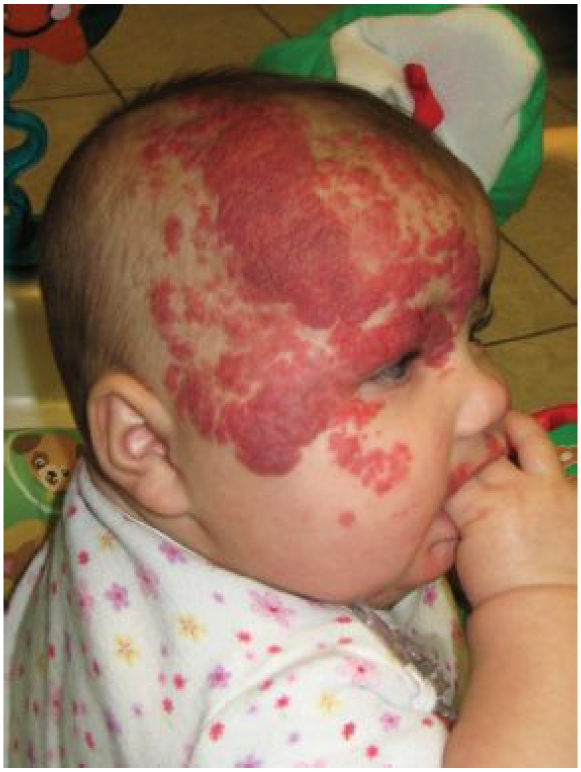

FIGURE 170-11 Infant with PHACE syndrome and a large segmental hemangioma over the face. The child also has a congenital coloboma of the right eye. (*Used with permission from angel face.com*.)

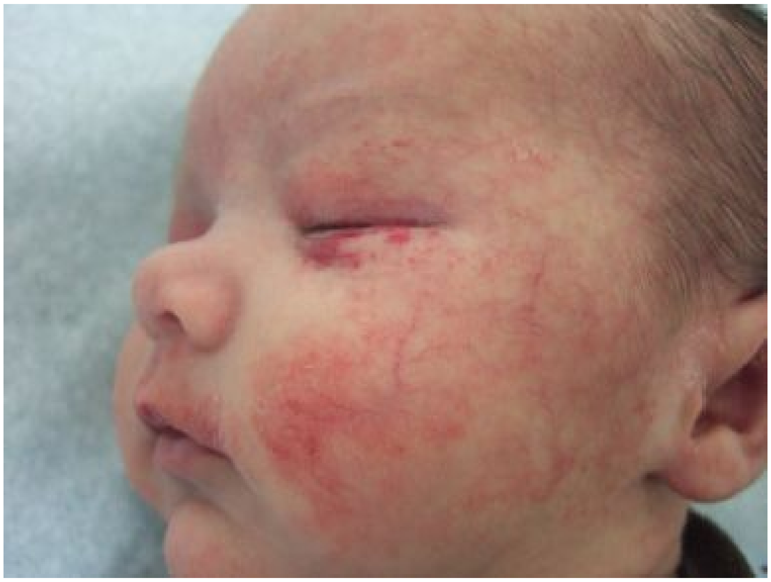

FIGURE 170-12 Infant with PHACE syndrome. In this case the hemangioma is flat with many telangiectasias and resembles a port-wine

stain. (*Used with permission from John Browning, MD*.)

- Cutis marmorata is found in infants and presents with a reticulated mottling of the skin with a pink, red or bluish coloration when the infant is exposed to cold temperatures. It usually occurs on the lower extremities and is evanescent (**Figure 170-13**).

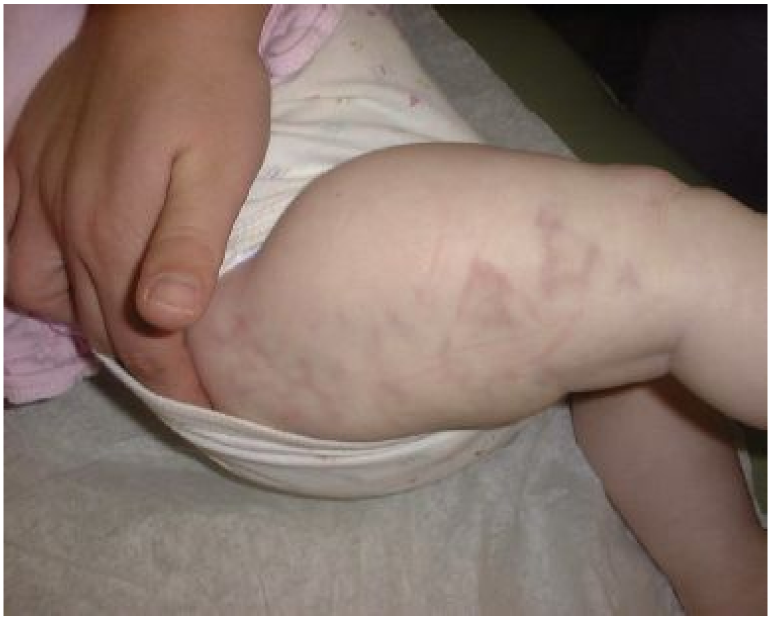

FIGURE 170-13 Infant with cutis marmorata showing a reticular pink network that occurs when the child is cold. (*Image used with permission from Robert Brodell, MD*.)A B

- Acquired capillary malformations seen in pyogenic granulomas (lobulated capillary hemangioma) could be mistaken for a congenital capillary or lymphatic malformation but a good history should prevent this confusion. Pyogenic granulomas are not present at birth and often follow local trauma to the area. They are often friable and bleed easily (see Chapter 142, Pyogenic Granuloma).
- CREST (calcinosis, Raynaud phenomenon, esophageal involvement, sclerodactyly, and telangiectasia) syndrome and scleroderma usually have multiple telangiectasias as in HHT. Other clinical features and laboratory tests such as the antinuclear antibody (ANA) can differentiate between these rheumatologic conditions and HHT (see Chapter 178, Scleroderma and Morphea).

MANAGEMENT

- Port-wine stains may be treated with makeup (see the “Patient Resources” section at the end of this chapter). Pulsed-dye laser treatment is another cosmetic option available to teens and adults able to tolerate this procedure. Laser treatments blanch most port-wine lesions to some degree, but complete resolution is difficult to achieve and the recurrence rate is high.[8] SOR Ⓑ In a Cochrane systematic review of the literature, pulse dye laser resulted in a 25 percent reduction in redness over 1 to 3 treatments.[9]
- HHT has no cure. Oral iron supplementation and transfusions are sometimes needed as a result of bleeding. Few randomized controlled trials exist regarding treatment of bleeding. Estrogen/progesterone supplementation for heavily transfusion-dependent female patients decreases recurrent bleeding.[10] SOR Ⓑ Case reports and uncontrolled studies regarding epistaxis treatment show some benefit from laser treatment, surgery, embolization, and topical therapy. SOR Ⓒ Cauterization is not recommended because of complications from local tissue damage. Embolization procedures have been described for AVMs in the liver, lungs, and brain. Surgical resection of AVMs is sometimes done as a last resort when other measures fail.[5] In short, it is often best to do as little intervention as possible with HHT and, if any intervention is done, it is done by specialists experienced with this disease, as complications and recurrence are frequently encountered.
- There are many treatments that have been tried for lymphangioma circumscriptum including surgery, electrosurgery, cryosurgery, sclerotherapy, topical imiquimod, and carbon dioxide laser.[11–15] In a systematic review of carbon dioxide laser for lymphangioma circumscriptum, 11 case reports and 5 case series with a total of 28 separate patients were identified. Eight patients remained disease free from 4 months to 3 years, 10 experienced partial recurrence, and two experienced complete recurrence.[16]
- In a case report of a 16-year-old female with a life-long history of a weeping, hemorrhagic, and painful lymphangioma on her right buttock, the authors attempted therapeutic treatment with pulsed dye laser.[15] The

lesion appeared unchanged after two trials and so three sessions of electrodessication were applied to the aberrant lymphatic vessels. The lesion largely resolved without complications and was no longer causing pain or emotional distress.[15]

- In one series, 10 patients were treated with the combination technique of radiofrequency ablation (RFA) and sclerotherapy for their lymphangioma circumscriptum.[11] The sessions were repeated at monthly intervals until complete clearance. Nine of 10 patients who were treated with the combination technique achieved near-complete clearance. RFA ablates the lesions and achieves hemostasis while the sclerosant injected in and around the lesion reaches the deeper vascular lesions, preventing recurrence.[11]

FOLLOW-UP

- The need for follow-up varies from not at all to regular follow-up for patients with HHT and Sturge-Weber syndrome.
- Patients with Sturge-Weber syndrome should have yearly eye examinations that include testing of intraocular pressures SOR C (see Chapter 207, Sturge-Weber Syndrome).

PATIENT EDUCATION

- Whatever the vascular condition is, patients can benefit from reliable information about the current and future outlook for their condition.

171 ICHTHYOSIS

William A. Miller, MD, MPH, MSc
Richard P. Usatine, MD

PATIENT STORY

Two brothers are seen during a medical mission in Africa for their dry skin. The clinician recognizes the pattern of X-linked ichthyosis sparing the antecubital fossae of the arms amidst the heavy scales (**Figure 171-1**). With the help of a translator, the condition is explained to the mother and her boys. It turns out the mother's father also had the same condition but never received a diagnosis or had any medical care. The suggested treatment is daily emollients and keratolytics.

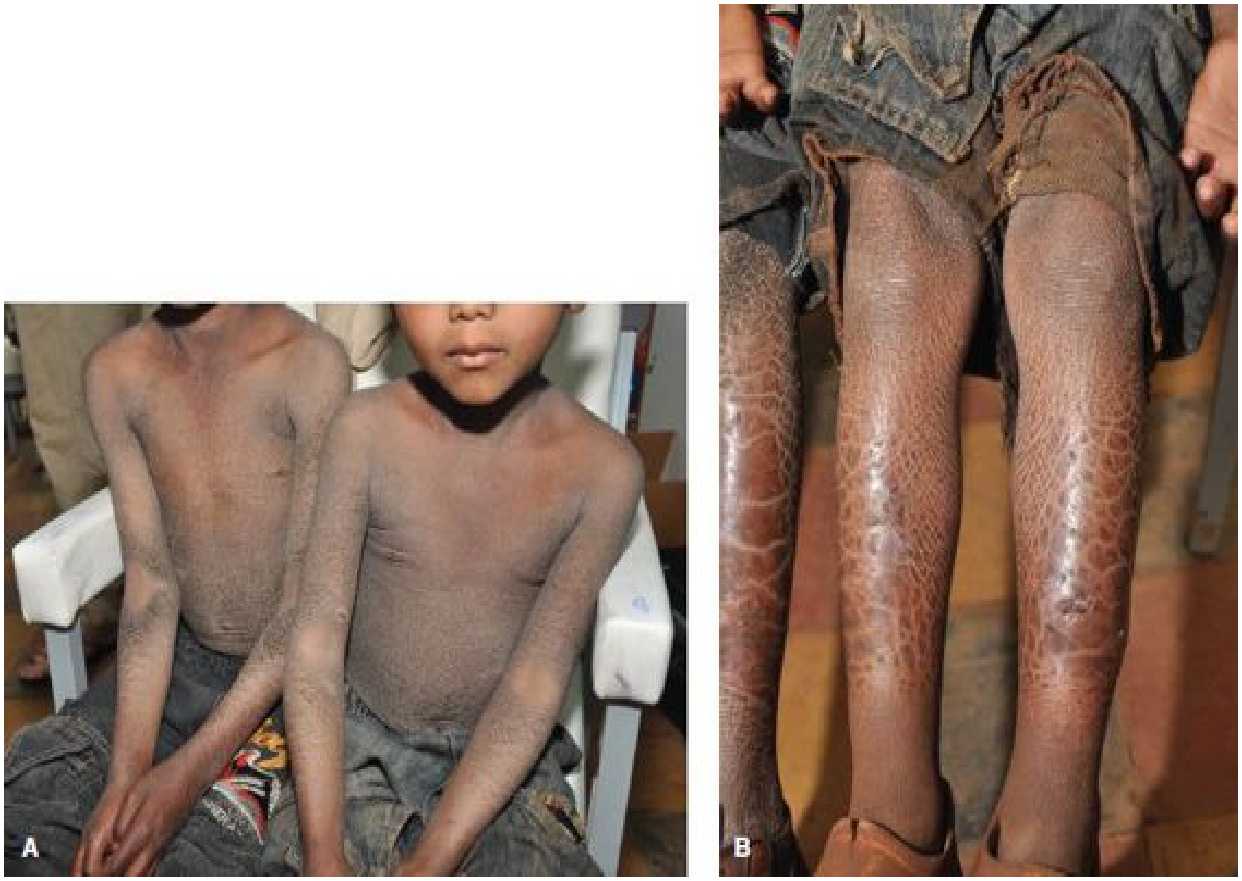

FIGURE 171-1 A. X-linked ichthyosis in two brothers showing sparing of the antecubital fossae of the arms amid the heavy scales. B. Heavy fish scale of X-linked ichthyosis on the legs of the same two affected brothers. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Ichthyoses were recently reclassified by consensus with respect to nomenclature and whether they involved organs in addition to the skin (syndromic).[1] This chapter addresses four relatively more common ichthyoses pediatricians may encounter: ichthyosis vulgaris, X-linked recessive ichthyosis, epidermolytic ichthyosis, and lamellar ichthyosis. Common features of the ichthyoses include thick, dry skin, various forms and degrees of scaling, cutaneous inflammation, hypohidrosis, and skin fragility. Management is typically symptomatic, attempting to reduce morbidity, and often involves coordinated care with a dermatologist.

SYNONYMS

Epidermolytic ichthyosis (EI)—Formerly known as epidermolytic hyperkeratosis (EHK) or bullous ichthyosiform erythroderma (BIE), nonbullous congenital ichthyosiform erythroderma (NBIE) or congenital ichthyosiform erythroderma (CIE).

Lamellar ichthyosis—Also known as nonbullous congenital ichthyosis, one of the autosomal recessive congenital ichthyoses (ARCI).

EPIDEMIOLOGY

- Ichthyosis vulgaris—A common ichthyosis (**Figure 171-2**), with approximately 1 in 250 individuals affected.[2] Males and females are affected equally.

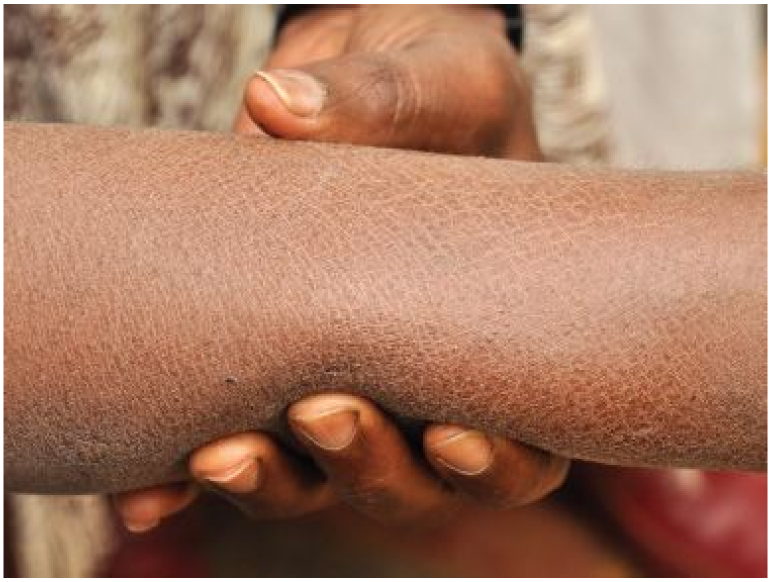

FIGURE 171-2 Ichthyosis vulgaris starts in childhood and has a fine scale. (*Used with permission from Richard P. Usatine, MD*.)

- X-linked recessive ichthyosis—Occurs in approximately 1 in 2000 to 6000 males.[3] Because of its frequent occurrence, steroid sulfatase deficiency accounts for most cases of X-linked ichthyosis, but a normal steroid sulfatase level in a male with ichthyosis does not rule out an X-linked pattern of inheritance.[4]
- Epidermolytic ichthyosis (bullous ichthyosiform erythroderma)—Prevalence of approximately 1 in 200,000 to 300,000 persons.[5]
- Lamellar ichthyosis (non-bullous ichthyosiform erythroderma)—The most common form of autosomal recessive congenital ichthyosis (**Figure 171-3**).[6,7]

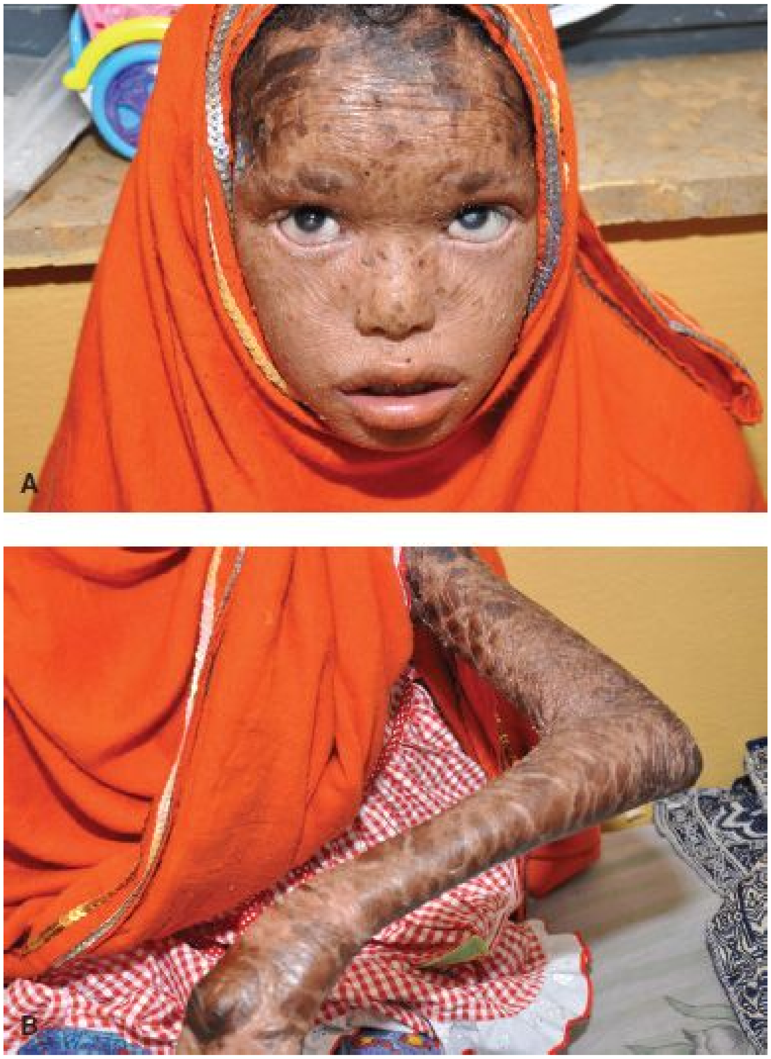

FIGURE 171-3 Lamellar ichthyosis is more rare and severe than X-linked ichthyosis. A. Note the deep lines and severe dryness of the skin on the face of this girl with lamellar ichthyosis. B. Her arm is severely affected so that she cannot extend her elbow fully. (*Used with permission from Richard P. Usatine, MD.*)

ETIOLOGY AND PATHOPHYSIOLOGY

- Ichthyosis vulgaris—A relatively common condition caused by loss of function mutations in the filaggrin gene.[2,8] It is inherited in an autosomal dominant manner and presents in childhood with a fine adherent scale in similar distribution to X-linked ichthyosis (**Figure 171-2**). Patients frequently have hyperlinear palms, keratosis pilaris, and atopic dermatitis, which are not commonly associated with X-linked ichthyosis.

- X-linked ichthyosis—A deletion of the steroid sulfatase gene results in keratinocyte retention by inhibiting desmosome degradation.[9] It is inherited in an X-linked recessive manner (**Figure 171-4**).

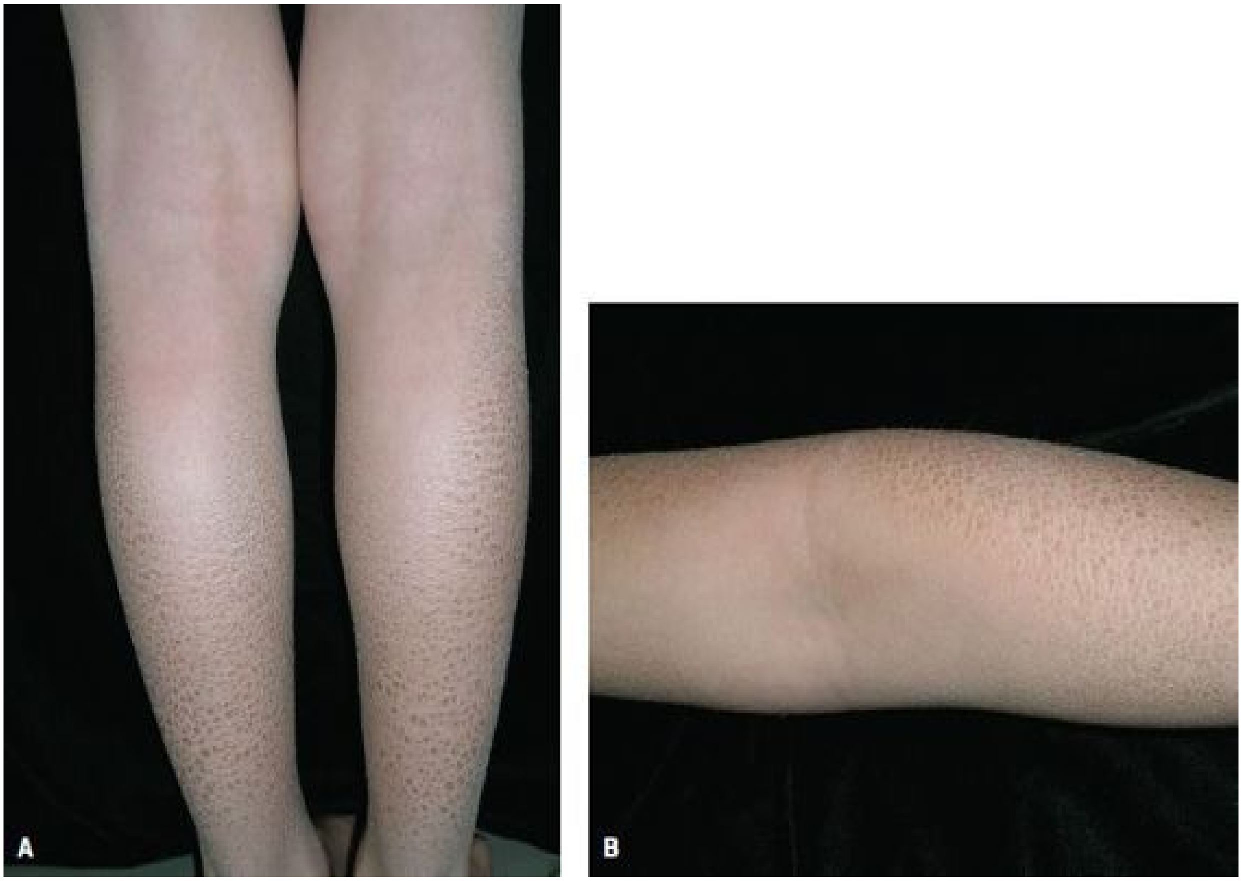

FIGURE 171-4 X-linked ichthyosis in a 9-year-old boy whose maternal uncle is also affected. A. Ichthyosis showing sparing of the popliteal fossa. B. Ichthyosis sparing antecubital fossa. (*Used with permission from Richard P. Usatine, MD.*)

- Epidermolytic ichthyosis—Inherited in an autosomal dominant manner and is due mutations leading to production of faulty keratin proteins that function poorly.[10]
- Lamellar ichthyosis—A more severe and rare disorder resulting from mutations in the transglutaminase 1 gene.[11] Manifests with plate-like

scales involving most of the body, including the face and flexures (**Figure 171-3**). Patients are typically born as a collodion baby (a thin translucent membrane that surrounds the baby at birth).[12]

DIAGNOSIS

ICHTHYOSIS VULGARIS

- Clinical features—Onset is usually between ages 3 and 12 months, presenting with fine scale, sometimes centrally tacked-down with superficial fissuring, varying degrees of dry skin, and hyperlinear palms and soles.[2] Some patients improve with age and especially with warm weather. However, it typically does not clear completely.
- Typical distribution—Scaling is most prominent on legs, buttocks, abdomen, and trunk, while flexural areas are typically spared.
- Other findings—Can be associated with atopic eczema and keratosis pilaris.
- Laboratories—Appropriate genetic testing.

X-LINKED ICHTHYOSIS

- Clinical features—Firm, adherent, fish-like brown scale noted early in the life of young affected boys whose mothers were carriers of the gene on their X chromosome (**Figures 171-1** and **171-4**). Extracutaneous involvement may include ocular and testicular manifestations. Patients have an increased incidence of cryptorchidism and are at an increased risk of testicular cancer, independent of the risk from cryptorchidism alone.[2,3] These patients may have corneal opacities which do not affect their vision.[9,13] Often, they are delivered by caesarean section because a placental sulfatase deficiency results in failure of labor progression.[14,15]

- Typical distribution—Most of the body is involved, except for the typical sparing of the flexures, face, palms, and soles. The antecubital fossae are notably spared (**Figures 171-1** and **171-4**). There is an accentuation noted on the neck, giving these patients a characteristic “dirty neck” appearance (**Figure 171-5**).

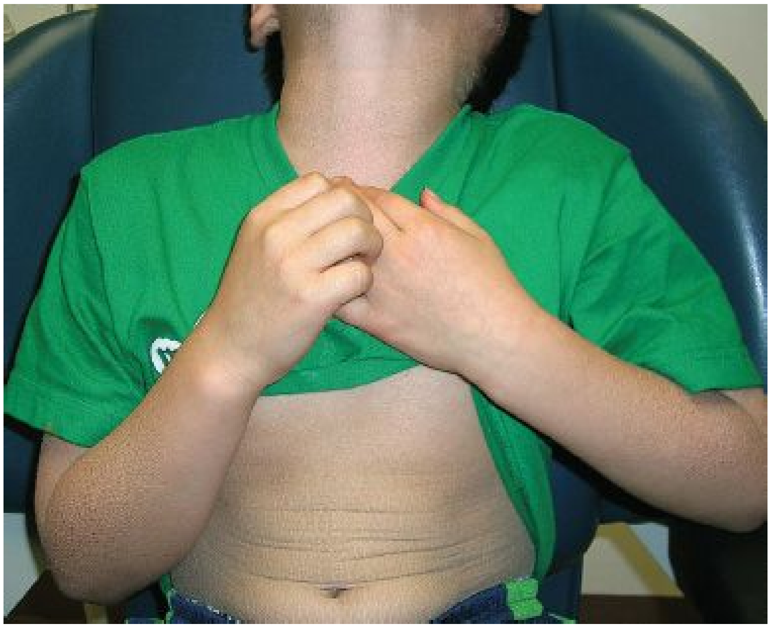

FIGURE 171-5 X-linked ichthyosis in a 9-year-old boy. His mother states that she could never get his neck clean. This is the “dirty neck appearance” of X-linked ichthyosis. Of course the neck is not dirty—this is the scale of ichthyosis which is also readily seen on the arms and abdomen. (*Used with permission from Richard P. Usatine, MD*.)

- Laboratories—Increased levels of serum cholesterol sulfate levels (steroid sulfatase hydrolyses cholesterol sulfate). Steroid sulfatase activity can also be measured directly. Appropriate genetic testing.

EPIDERMOLYTIC ICHTHYOSIS

- Clinical features—Patients present with fragile skin that eventually progresses to ichthyosis. Within hours after birth, minor trauma may cause blisters, superficial erosions, and peeling.[16]

- Typical distribution—Presents as a bullous disease shortly after birth with blistering resulting from even minor trauma. Only focal areas of hyperkeratosis and signs of skin weakness at sites of minor trauma may hint toward the diagnosis. Later in childhood, hyperkeratosis is noticeable on flexures, the abdominal wall, and scalp.
- Other findings—Skin colonization by staphylococcus, other bacteria, and possibly yeast creates an unwanted body odor.
- Laboratories—Appropriate genetic testing.

LAMELLAR ICHTHYOSIS

- Clinical features—Usually seen at birth presenting with collodion membrane (**Figure 171-6**).[12] After shedding membrane, patients demonstrate flushing and large, rough, dark-brown scales.[17]

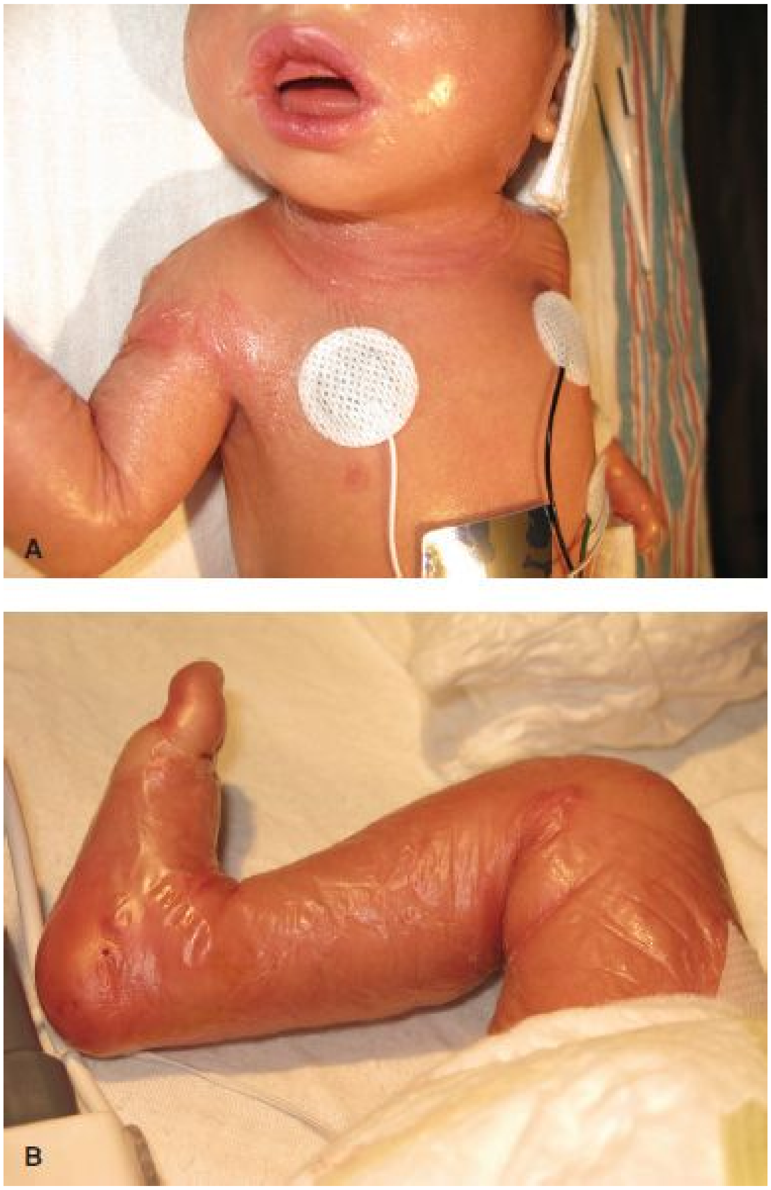

FIGURE 171-6 A. Collodion baby just after birth. Note the shiny skin covered with a thin membrane and the turning out of the lips (eclabium). This baby also had eversion of the eyelids (ectropion). B. The shiny skin is very prominent on the foot. (*Used with permission from Jeffrey Meffert, MD*.)

- Typical distribution—Typically the whole body is affected, however some patients may experience partial resolution resulting in a bathing suit-pattern ichthyosis.

- Other findings—Ectropion improves during growth, but may persist into adulthood in many patients. Nail findings may include ridging, subungual hyperkeratosis, or hypoplasia. Patients typically cope with decreased sweat gland function. Bacterial and viral cutaneous infections are rare, however, fungal infections are common. Severe lamellar ichthyosis may affect growth and nutritional deficiencies may be present, including vitamin D deficiency. Possible vitamin D deficiency imparts an increased risk of rickets.[18-20]
- Laboratories—Vitamin D levels and appropriate genetic testing.

DIFFERENTIAL DIAGNOSIS

- Atopic dermatitis (eczema)—Much more common than the ichthyoses and typically presents with generalized dry skin (xerosis) resulting in pruritus that manifests the infamous itch-scratch cycle of atopic dermatitis. Repetitive scratching leads to skin thickening (lichenification) and accentuation in skin markings. Notably, atopic dermatitis is frequently the first condition to present in the “atopic march” of atopic dermatitis, food allergy, asthma, and allergic rhinitis (Chapter 130, Atopic Dermatitis).[21]
- Acquired ichthyosis—Does not occur until adulthood. It is not inherited and may be associated with some systemic disease. The time of onset is the key to diagnosis. The legs are often are most involved and the skin appears similar to fish-scales (**Figure 171-7**).

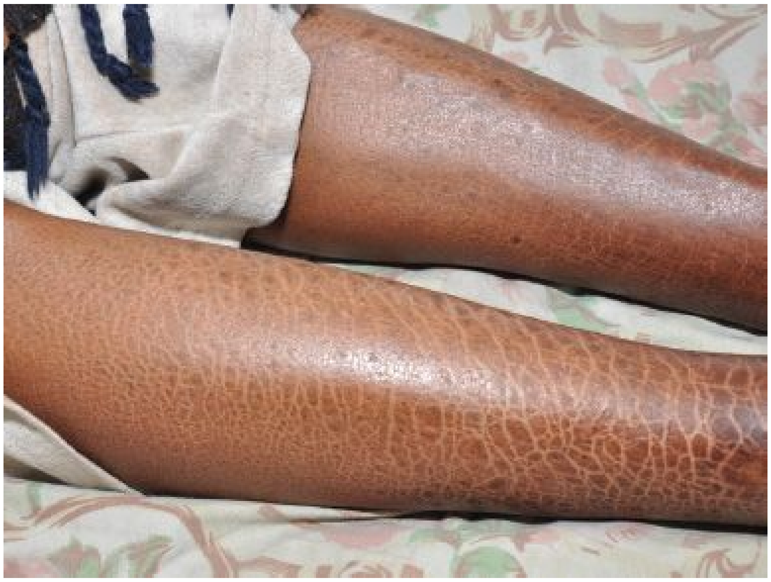

FIGURE 171-7 Acquired ichthyosis starts in adulthood and is especially prominent on the legs. (*Used with permission from Richard P. Usatine, MD.*)

MANAGEMENT

- Generally, frequent application of emollients and keratolytics are the mainstay of therapy.[22] There are many effective nonprescription and prescription products that contain petrolatum, propylene glycol, urea, or lactic acid.[22] Good choices for emollients include petrolatum, Aquaphor, and Eucerin. Ammonium lactate is an effective keratolytic available as a 6 percent OTC product or a 12 percent prescription. SOR Ⓒ
- Topical salicylic acid products used for their keratolytic properties to remove scale should be applied only on a limited area, as systemic absorption has led to salicylate toxicity in some patients.
- Epidermolytic ichthyosis tends to improve with age. If manifested in newborns as denuded skin, it may necessitate treatment in an intensive care unit due to increased risk of electrolyte irregularities and infectious complications. Further, patients should be handled carefully to avoid new trauma. Symptomatic care for blistering and use of emollients are particularly helpful in newborns. Moisturization and topical emollients

continue to be the foundation of management as children age. Keratolytics may be avoided if they irritate the skin. Special diet and activity restrictions are not necessary.

- Systemic retinoids such as acitretin may be used in boys for severe lamellar ichthyosis by physicians experienced in their use (**Figure 171-8**). These agents are strong teratogens and should be avoided in any female of childbearing potential (including up to 3 years before menarche). SOR C

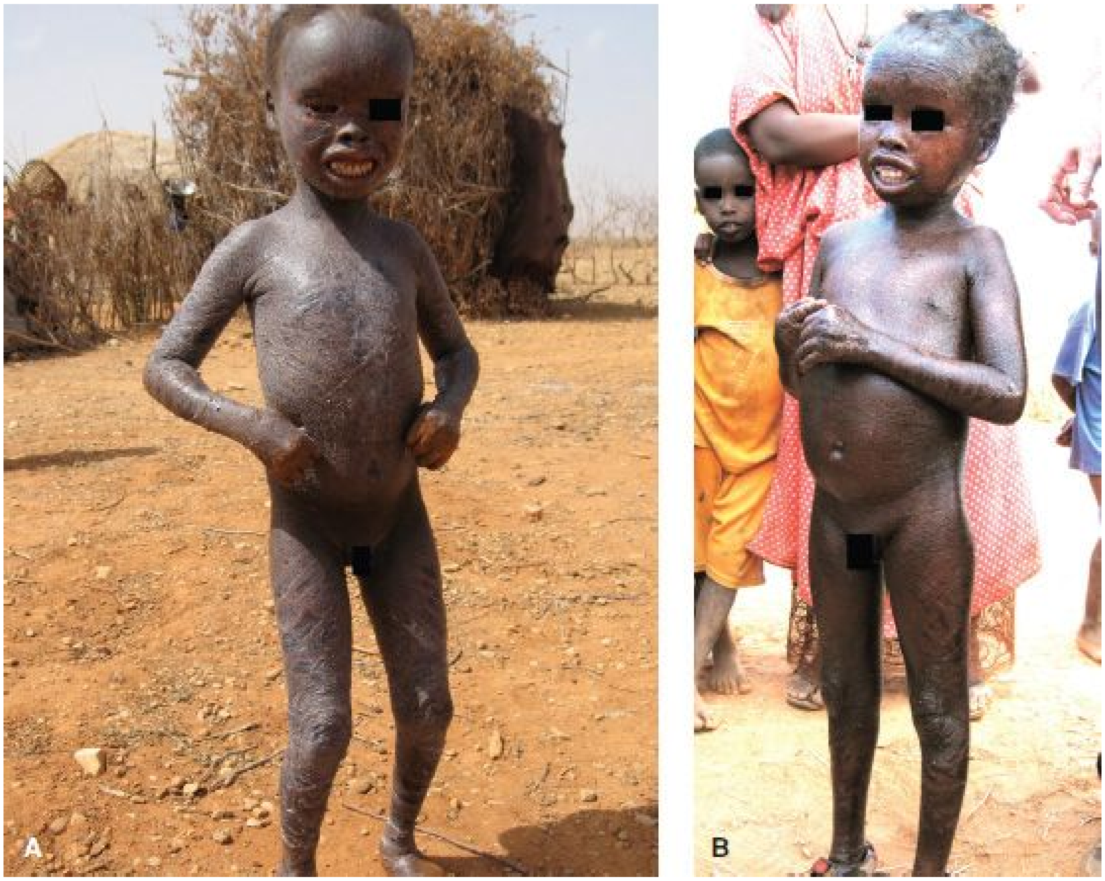

FIGURE 171-8 A. Lamellar ichthyosis in a young boy in Ethiopia. B. Great improvement in the ichthyosis after systemic retinoids (acitretin). (*Used with permission from Rick Hodes, MD and Richard Lord*.)

- Gene therapy is an active area of research but is not yet a viable treatment option.

REFERRAL

- Refer to a urologist or ophthalmologist if testicular abnormality or corneal opacities are detected.

FOLLOW-UP

- Ichthyosis vulgaris—The prognosis is excellent, however, infection can result from fissured skin that has been refractory to management.
- X-linked ichthyosis—Adolescent males may experience cosmetic morbidity. Further, regular physical exams monitoring for corneal opacities and for testicular cancer in males should be performed at follow-up visits.
- Epidermolytic ichthyosis—Requires lifelong management but symptoms may improve with age.
- Lamellar ichthyosis—Specialist care by a dermatologist is recommended for skin assessment and treatment. Patients with ectropion should be referred to an ophthalmologist.

PATIENT EDUCATION

- Consider genetic counseling for all families that have a child with a hereditary ichthyosis.
- Ichthyosis vulgaris—For most patients, emphasis on regular and consistent treatment is important in achieving satisfactory management.
- X-linked ichthyosis—Use daily moisturizers, especially in dry climates and in the winter. Patients should understand the need for and should regularly conduct self-examination for testicular carcinoma.
- Lamellar ichthyosis—Patients should be informed of a higher risk of heat stroke.

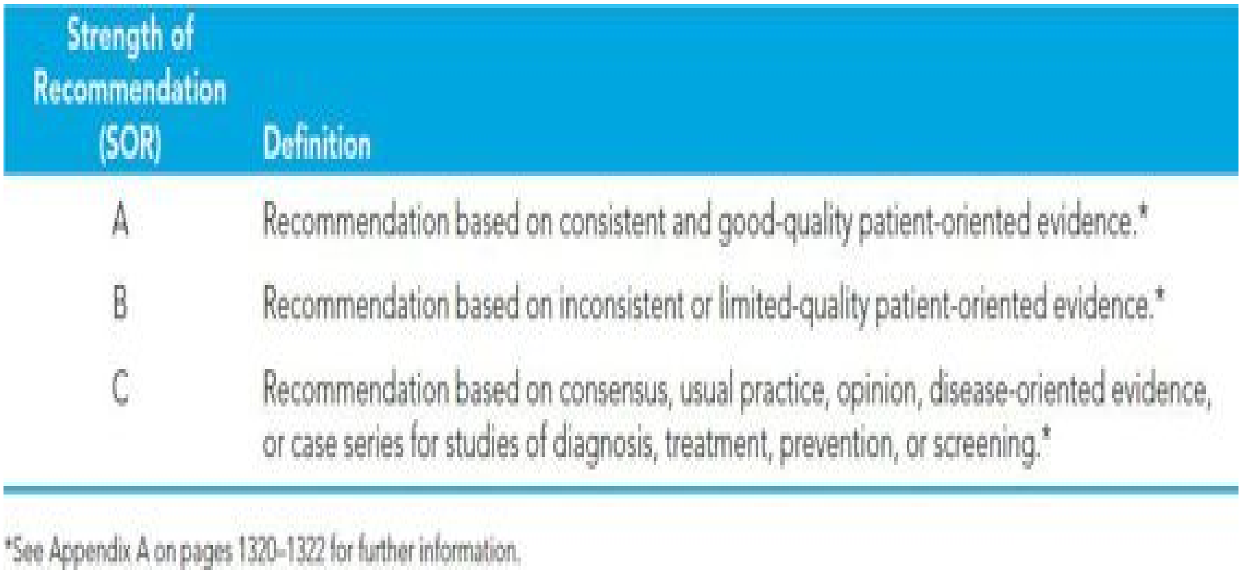
RHEUMATOLOGY



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

172 JUVENILE IDIOPATHIC ATHRITIS

Shoghik Akoghlanian, MD
Andrew Zeft, MD MPH

PATIENT STORY

A 2-year-old Caucasian girl has had left knee swelling for 2 months (**Figure 172-1**). On physical examination, she has a warm left knee with limited range of motion and an effusion. Her left leg is longer than her right, and she walks with an antalgic gait. She has no other systemic signs and symptoms. Her antinuclear antigen (ANA) test is positive (1:160, speckled pattern) and her erythrocyte sedimentation rate is normal. She is diagnosed with oligoarticular juvenile idiopathic arthritis (oligoJIA). After initially taking nonsteroidal antiinflammatory medication around the clock, she is given an intra-articular steroid injection to treat her synovitis followed by physical therapy. Six weeks later, her knee exhibits full range of motion and is free of swelling. Six months later, she is found to have anterior uveitis (**Figure 172-2**) on routine screening slit lamp ophthalmology exam. Her uveitis is treated with ocular steroid drops, but her eye disease remains active, and requires the disease modifying antirheumatic drug, methotrexate.

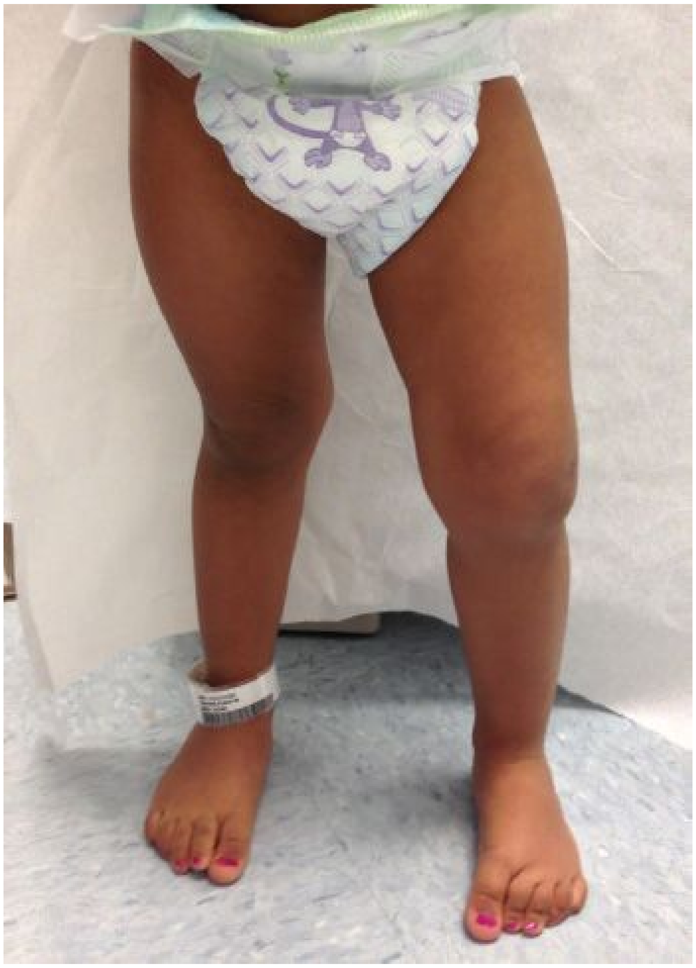


FIGURE 172-1 Swelling of the left knee in a 2-year-old girl with oligoarticular JIA. (*Used with permission from Vidya Raman, MD*.)

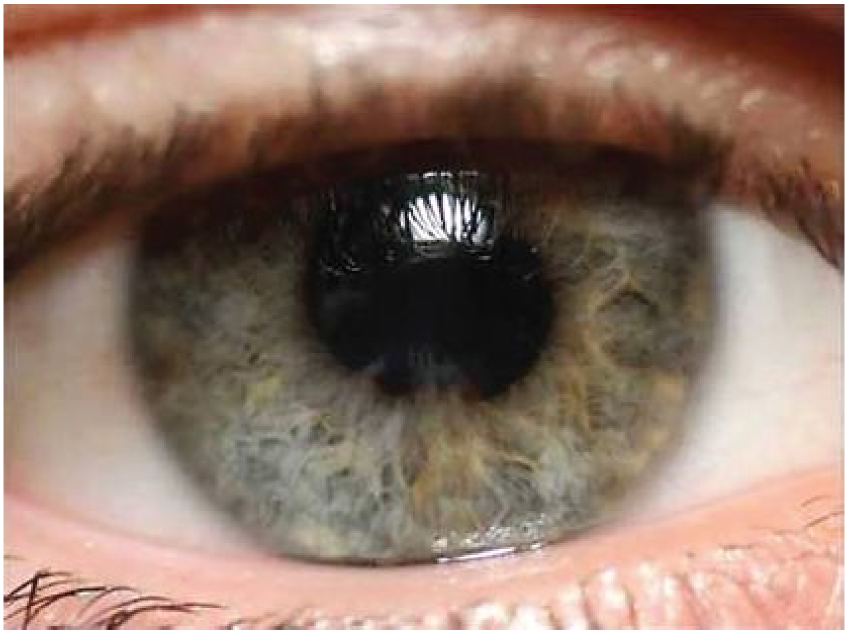

FIGURE 172-2 Synechiae complicating anterior nongranulomatous uveitis in a child with juvenile idiopathic arthritis. (*Used with permission from Carol A. Wallace, MD.*)

INTRODUCTION

Juvenile Idiopathic Arthritis (JIA), the most common chronic rheumatologic disease of childhood,[1] is defined by arthritis lasting greater than 6 weeks clinically beginning in a child before their 16th birthday after infection or other systemic etiologies have been ruled out. JIA is divided into 7 phenotypic subtypes which include: oligoarticular (persistent, extended), polyarticular (rheumatoid factor [RF] positive), polyarticular (RF negative), systemic onset, psoriatic, enthesitis related, and undifferentiated.[2]

SYNONYMS

Juvenile chronic arthritis (JCA) and juvenile rheumatoid arthritis (JRA).

EPIDEMIOLOGY

- JIA occurs worldwide.
- The prevalence is ~1 per 1,000 children, and the incidence is ~12 new cases per 100,000 children.[3]
- JIA appears to occur more commonly in children of Northern European ancestry.
- A striking age of onset peak in the oligoarticular type is noted between 1 to 2 years of age, in contrast to polyarticular JIA, which has a biphasic clinical onset with one peak between 1 to 3 years of age and another late in school age and into adolescence. Systemic onset JIA is more common in toddler-aged children, but otherwise onset is rather equally distributed amongst ages.
- In general, girls are affected more often than boys, but gender distribution varies with disease subtypes. The most common subtype, oligoJIA, occurs most commonly in toddler-aged girls (F: M, 3:1) and accounts for close to half of JIA diagnoses.
- Anterior nongranulomatous uveitis occurs in ~15 percent of ANA-positive patients with either the oligoJIA or RF-negative polyarticular subtype (**Figure 172-2**).

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology of JIA is related to both genetic and environment factors.
- Synovitis describes synovial hypertrophy and a proliferation of inflammatory pannus (abnormal fibrovascular tissue). The presence of synovitis is diagnostic in children with JIA. Pannus is composed partially of T and B-lymphocytes as well as macrophages and is accompanied by angiogenesis (**Figure 172-3**).

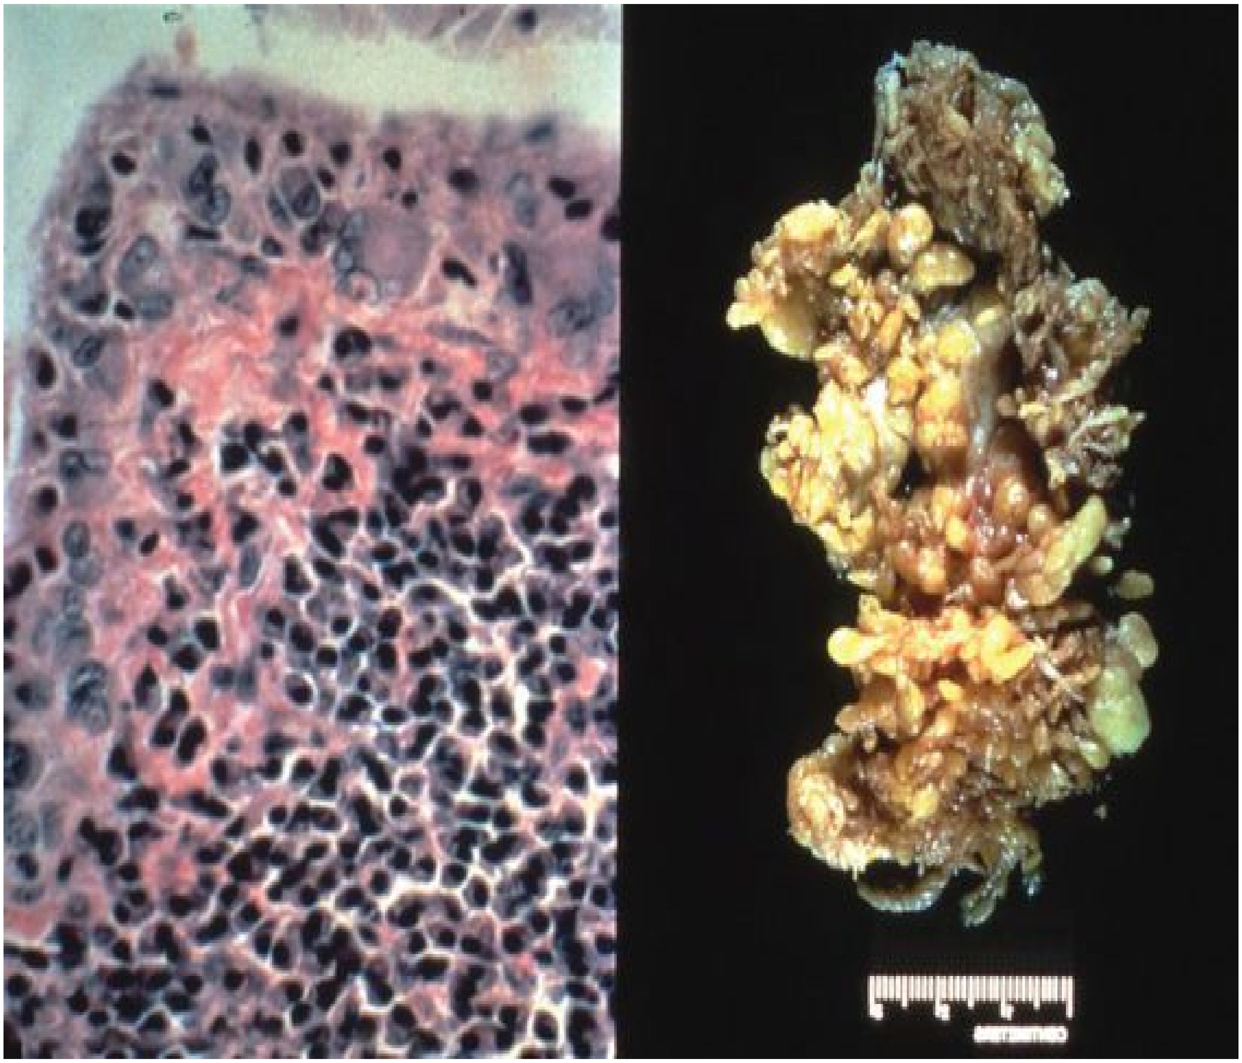

FIGURE 172-3 Pannus, composed of mixed lymphocytes and macrophages (left), seen after gross removal (right) from a joint of a patient with active juvenile idiopathic arthritis. (*Used with permission from Carol A. Wallace, MD*.)

- Contiguous cartilage and bone may be invaded and damaged.
- Cytokines released primarily by proinflammatory macrophages precipitate pannus formation and cartilage/osseus damage.

RISK FACTORS

- Genetic factors, aberrant immune responses, and putative environmental triggers play roles in JIA pathogenesis.
- Associations of HLA class I and II alleles with JIA are well established, further suggesting the involvement of T cells and antigen presentation in the pathogenesis of JIA.
- Hormonal influences may affect pathogenesis given the predominance of females with both oligoJIA and RF-positive polyJIA.

DIAGNOSIS

CLINICAL FEATURES[2]

- Arthritis is defined as:
  - Persistent joint swelling or effusion.
  - Presence of two or more of the following signs in one or more joints:
    - Limitation of range of motion.
    - Tenderness or pain on motion.
    - Increase in tactile heat.
- Enthesitis defined as inflammation where tendon, ligament, joint capsule, or fascia attach to bone.
- Specific JIA Subgroups and Definitions.
  - Systemic onset JIA (soJIA)—Presents with systemic symptoms such as fever, evanescent salmon-colored rash (typically truncal and nonpruritic; **Figure 172-4**), lymphadenopathy, and hepatosplenomegaly with or followed by arthritis. Macrophage activation syndrome can be a life-threatening presentation of undertreated soJIA.

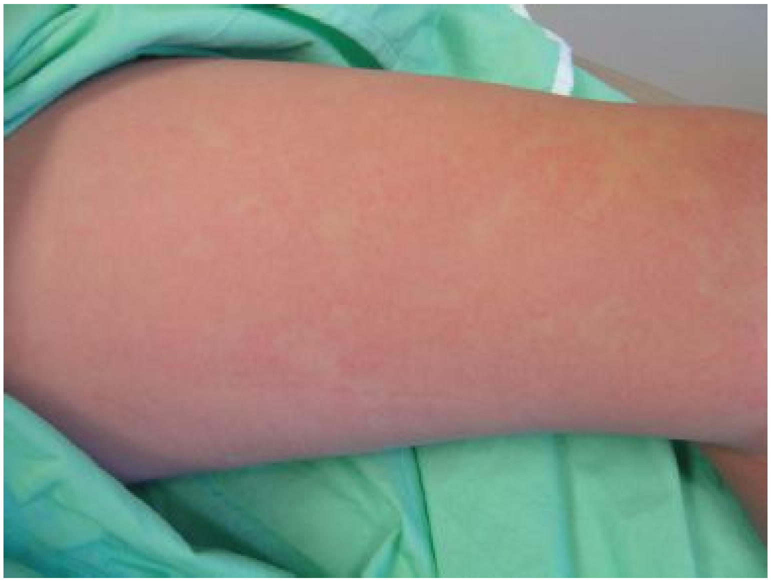

FIGURE 172-4 Salmon-colored, evanescent, macular eruption in a child diagnosed with systemic-onset juvenile idiopathic arthritis. (*Used with permission from Steven Spalding, MD*.)

- OligoJIA—Arthritis involving 4 or fewer joints in the first 6 months of disease (**Figures 172-1** and **172-5**). OligoJIA is described as persistent (or extended) if the joint involvement persists beyond 6 months. Disease in children with persistent oligoJIA often remits with therapy, but risk for flares remain.

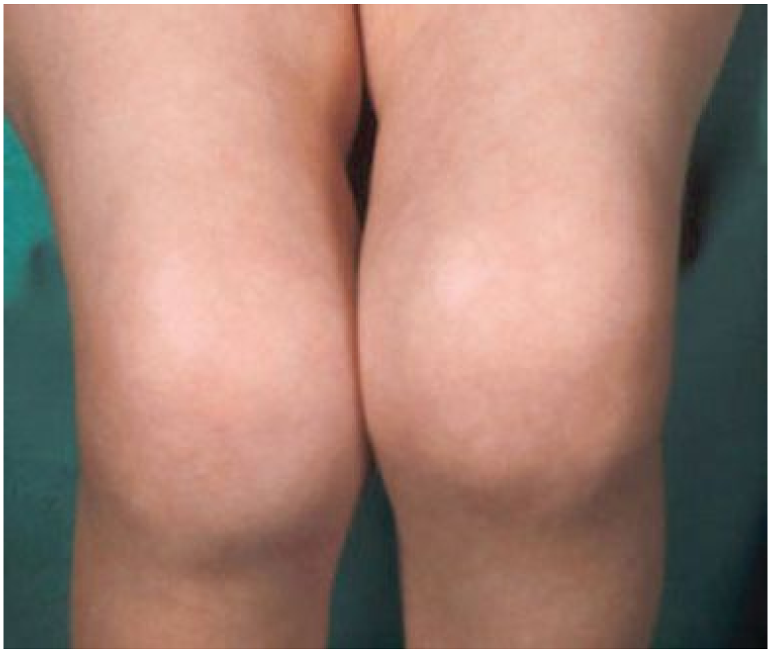

FIGURE 172-5 Left knee swelling in a young child with oligoarticular juvenile idiopathic arthritis. (*Used with permission from the Cleveland Clinic Children's Hospital Photo files*.)

- Polyarticular JIA (polyJIA)—Arthritis involving five or more joints, further divided by JIA International League Against Rheumatism criteria into seropositive and seronegative polyarticular subgroups based on the presence or absence of IgM RF (**Figure 172-6**). Children with seropositive polyJIA share clinical and immunologic features of adult patients with rheumatoid arthritis, including symmetric arthritis disease involving wrists and small joints of the hands and feet, with or without subcutaneous rheumatoid nodules and articular erosions. Unfortunately, many patients with polyJIA enter adulthood with active disease and require continued treatment on disease modifying or biologic therapy.

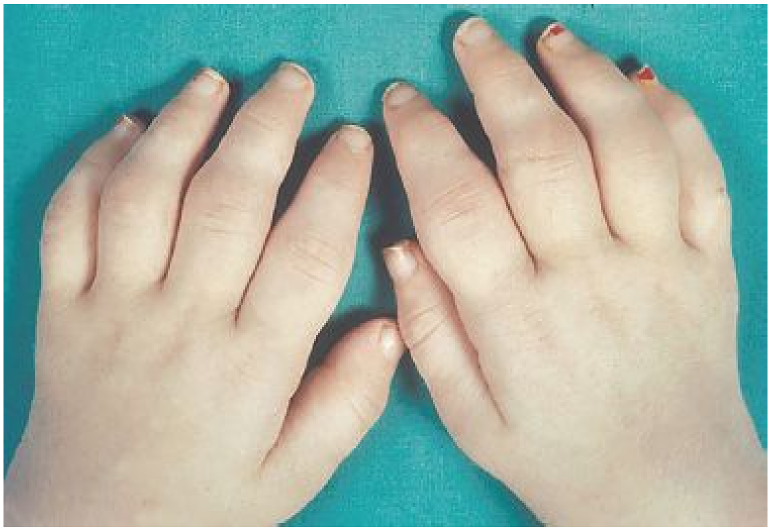

FIGURE 172-6 Small joint arthritis in a young child with polyarticular juvenile idiopathic arthritis. (*Used with permission from the Cleveland Clinic Children's Hospital Photo files*.)

- Psoriatic JIA (psJIA)—Either the presence of:
  - Arthritis and psoriasis.
  - Arthritis and 2 of 3 features including: dactylitis, nail changes ranging from mild nail pitting to onycholysis, and family history of a first degree relative having psoriasis or psoriatic arthritis.

  - Enthesitis related arthritis (ERA)—The presence of arthritis and enthesitis *or* arthritis or enthesitis with greater than or equal to 2 of the following: history of sacroiliac joint tenderness and/or inflammatory lumbosacral pain, HLA-B27+, onset in a male >8 years of age, acute (symptomatic) anterior uveitis, or family history in at least one first- or second-degree relative of medically confirmed HLA-B27 associated disease. Typically enthesitis involves the lower extremities at tendon insertions at the posterior and anterior iliac crest, femoral greater trochanter, patella, tibial tuberosity, Achilles tendon, and/or planter fascia.
  - Undifferentiated JIA—The patient's features of arthritis and other associated symptoms do not fit any other JIA category *or* fit more than one category.

LABORATORY TESTING

- No specific laboratory result is diagnostic for JIA.
- Hematological abnormalities may reflect the state of systemic inflammation (anemia of chronic disease, thrombocytosis, elevated ESR, as well as thrombocytopenia and dampened ESR in soJIA).
- ANA is associated with increased risk for chronic anterior uveitis in oligoJIA and seronegative polyJIA patients.
- Anticyclic citrullinated peptide (CCP) antibody is a specific but insensitive test for seropositive polyarticular arthritis.[4]
- Variable levels of synovial fluid cellularity, often (but not characteristically) <50,000 white blood cells per high power field.

DIFFERENTIAL DIAGNOSIS

- Infection—Lyme disease, bacterial (streptococcal or staphylococcus), brucella, and viral (influenza or parvovirus); mycoplasma, usually more acute in onset than JIA and have specific epidemiologic clues.

- Reactive arthritis in response to bacterial gastroenteritis (Yersinia, E. coli, salmonella, Shigella, or campylobacter) or genitourinary tract infection (gonococcal)—Preceding infection or specific symptoms help to differentiate these entities.
- Malignancy—Acute lymphoblastic leukemia (pre-B cell most common), metastatic bone, primary bone, cartilage, synovium, or soft tissue tumors can be distinguished from JIA by characteristic laboratory and radiographic features.
- Other pediatric autoimmune diseases involving arthritis, such as systemic lupus erythematosis and inflammatory bowel disease—Should be suspected when other organ systems are involved such as the renal and gastrointestinal systems (see Chapter 173, Lupus, Systemic and Cutaneous and Chapter 59, Inflammatory Bowel Disease).
- Metabolic.
    - Hurler's Syndrome—Bone and joint symptoms often occur in conjunction with other manifestations, such as growth delays, deafness, facial features, and heart valve abnormalities.

MANAGEMENT

NONPHARMACOLOGIC

- Physical and occupational therapy are recommended to restore and maintain function and prevent disability.
- Ophthalmology consultation in oligoarticular and polyarticular JIA patients to screen for intraocular signs of anterior uveitis and in psJIA or ERA patients, primarily for treatment of symptomatic scleritis, episcleritis.

MEDICATIONS

- Intra-articular glucocorticoid injection is first line therapy for oligoJIA and utilized for other JIA patients with persistent disease activity despite systemic therapy.[6,7] SOR Ⓑ

- Non-steroidal anti-inflammatory drugs.[8–12] Provide symptomatic pain relief, but do not modify disease. SOR Ⓐ
- Systemic corticosteroids.[5] Induction treatment or may be kept at a low daily dose. Limiting daily systemic steroids is essential to avoid unwarranted side effects in children. SOR Ⓒ
- Disease-modifying antirheumatic drugs: methotrexate (most commonly), leflunomide, or sulfasalazine.[5,13] SOR Ⓑ
- Biologic agents[14]—Inhibit the action of proinflammatory cytokines:
    - Tumor necrosis factor-α (TNF-α etanercept, adalimumab, and infliximab).[15,16] SOR Ⓐ for polyJIA
    - IL-1 (anakinra, canakinumab, or rilonacept).
    - IL-6 (tocilizumab).
    - Other medications target T-cell (abatacept) and B-cell (rituximab) function.
- Side effects of immune modulatory and biologic medications include increased risk of infection (tuberculosis dissemination with anti-TNF therapy). Screening for latent tuberculosis should be performed prior to treatment.
- Avoid administering live vaccines (MMR or varicella) while the patient is receiving chronic steroids, methotrexate, or biologic therapy.

SURGERY

- Synovectomy—Arthroscopic approach to remove chronic, persistent hypertrophic synovial tissue.
- Reconstructive surgeries and joint replacement for dysfunctional joints with long standing erosive arthritis, advanced secondary osteoarthritic changes, or to correct pronounced leg length discrepancy due to long-standing, unilateral disease.

PROGNOSIS

- Long-term functional limitations are common and often persist into adulthood.[17–19]
- Recent advances in therapy, especially the use of biologic agents, have improved the short- and medium-term outcomes.[15,16,20]

173 LUPUS—SYSTEMIC AND CUTANEOUS

Vidya Raman, MD
E.J. Mayeaux, Jr., MD

PATIENT STORY

A previously healthy 16-year-old African American girl presented to the clinic with alopecia and rash over her face and arms for 6 months (**Figures 173-1** and **173-2**). She reported pain in her knees and ankles for a year and an oral ulcer 3 months ago, which had healed. Laboratory evaluation was remarkable for a low white blood cell count at 2.4 × 1000/uL (normal 5.0–13.0 × 100/uL), hemoglobin of 10.8 g/dL (normal 11.8–16.0 g/dL), and platelet count of 109 × 1000/uL (normal 142–424 × 1000/uL). Erythrocyte sedimentation rate was elevated at 45 mm/hr (normal 0–15 mm/hr). Antinuclear antibody was positive at 1:640 with a strongly positive antidouble stranded DNA antibody confirming a diagnosis of systemic lupus erythematosus (SLE). Urinalysis did not show proteinuria to suggest renal involvement. She was treated with prednisone and hydroxychloroquine resulting in improvement in her problems.

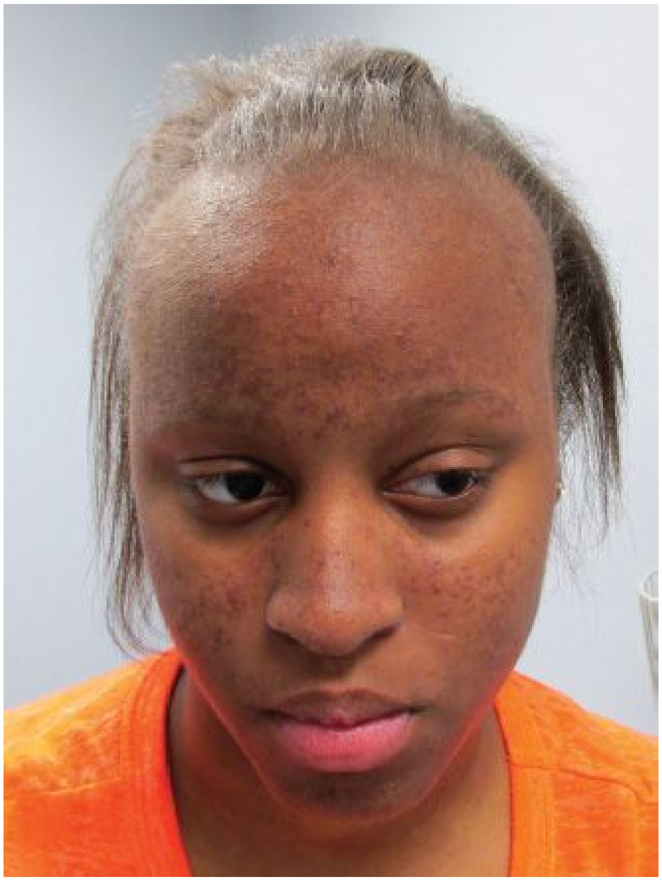

FIGURE 173-1 New onset systemic lupus erythematosus (SLE) presenting with 6 months of a facial rash and alopecia in a 16-year-old African American girl. She also had pain in her knees and oral ulcers. (*Used with permission from Vidya Raman, MD*.)

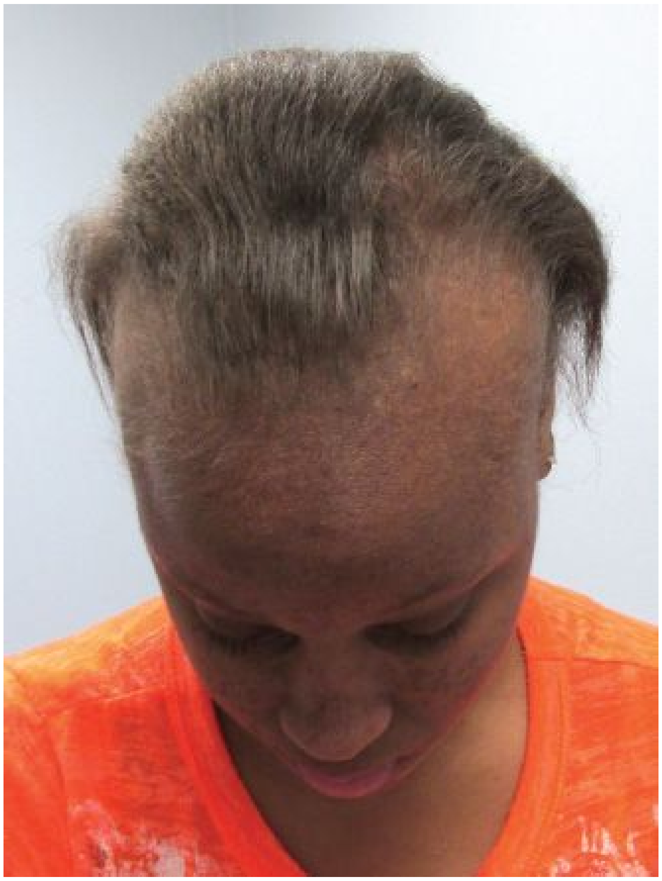

FIGURE 173-2 New onset SLE in a 16-year-old girl (as seen in Figure 173-1) demonstrating her alopecia. Her ANA was 1:640. (*Used with permission from Vidya Raman, MD*.)

INTRODUCTION

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease that can affect many organs of the body including the skin, joints, kidneys, lungs, nervous system, and mucus membranes.

SYNONYMS

- Chronic cutaneous lupus erythematosus = discoid lupus = DLE.

- Lupus profundus = lupus panniculitis.

EPIDEMIOLOGY

- The true incidence of pediatric SLE is difficult to estimate since there are very few studies in the pediatric population. It is believed that approximately 15 percent of patients with SLE have onset of disease in childhood. Childhood SLE occurs in 6 to 18.9 cases per 100,000 white females, with higher prevalence in African Americans and Hispanics.[1]
- The mean age of presentation of SLE in children is 12 to 13 years.
- Discoid lupus erythematosus (DLE), which develops in up to 25 percent of adults with SLE, is less common in children.[3] Patients with only DLE have a 5 to 10 percent risk of eventually developing SLE, which tends to follow a mild course.[4] DLE lesions usually slowly expand with active inflammation at the periphery, and then to heal, leaving depressed central scars, atrophy, telangiectasias, and hypopigmentation.[5] The female–male ratio of discoid lupus erythematosus (DLE) is 2:1.

ETIOLOGY AND PATHOPHYSIOLOGY

- SLE is a multisystem autoimmune disease with variable presentations. Based on current understanding, an environmental exposure, occurring in a genetically susceptible individual, results in activation of the innate and adaptive immune response resulting in production of auto-antibodies and loss of tolerance to self antigens.
- Recent studies in children have revealed a central role for type I interferon in the disease pathogenesis through an amplification loop activating T and B cells and may be useful in monitoring response to therapy.[6]
- Many of the signs and symptoms of SLE are caused by the circulating immune complexes or by the direct effects of antibodies to cells.

- A genetic predisposition for SLE exists. The concordance rate in monozygotic twins is between 25 percent and 70 percent. If a mother has SLE, her daughter's risk of developing the disease is 1:40 and her son's risk is 1:250.
- The course of SLE is one of intermittent remissions punctuated by disease flares. Organ damage often progresses over time.
- Rarely, neonates may develop a lupus rash and can have complete heart block from acquired antibodies through transplacental transmission from mother if she has active SLE (**Figures 173-3** and **173-4**).

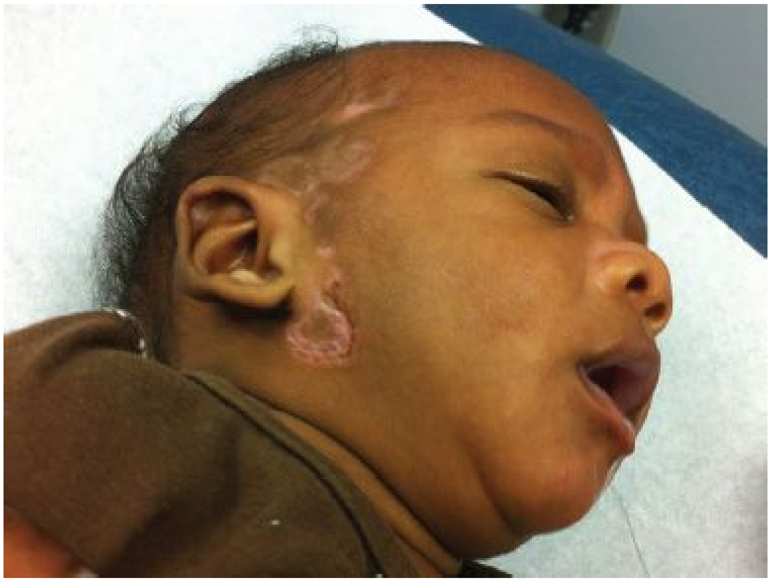

FIGURE 173-3 Neonatal lupus from acquired antibodies through transplacental transmission from the mother with positive SSA (Ro) and SSB (La) antibodies. (*Used with permission from Vidya Raman, MD*.)

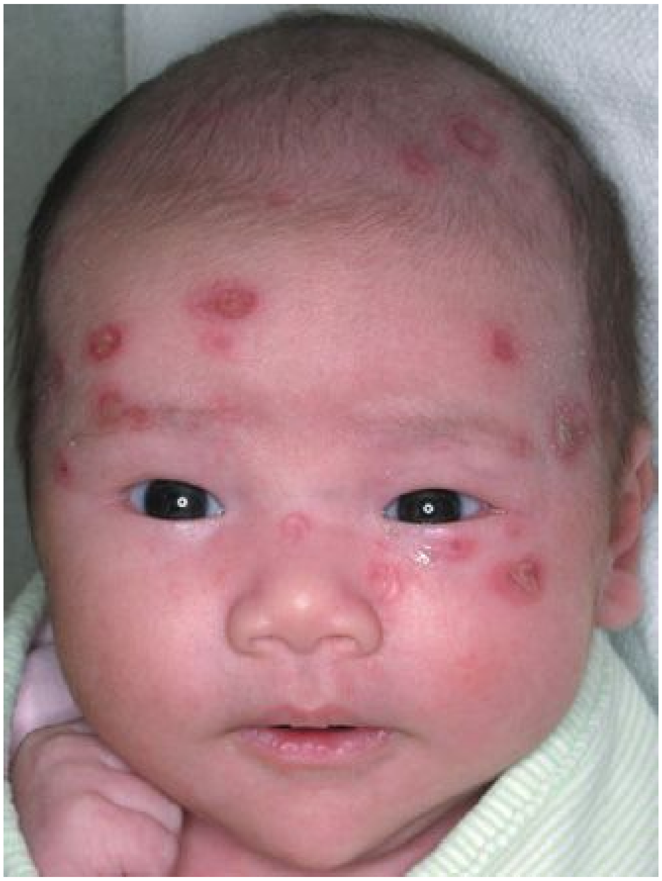

FIGURE 173-4 Neonatal lupus from acquired antibodies through transplacental transmission from the mother with active SLE. (*Used with permission from Warner AM, Frey KA, Connolly S. Annular rash on a newborn. J Fam Pract. 2006;55(2):127-129. Reproduced with permission from Frontline Medical Communications*.)

RISK FACTORS

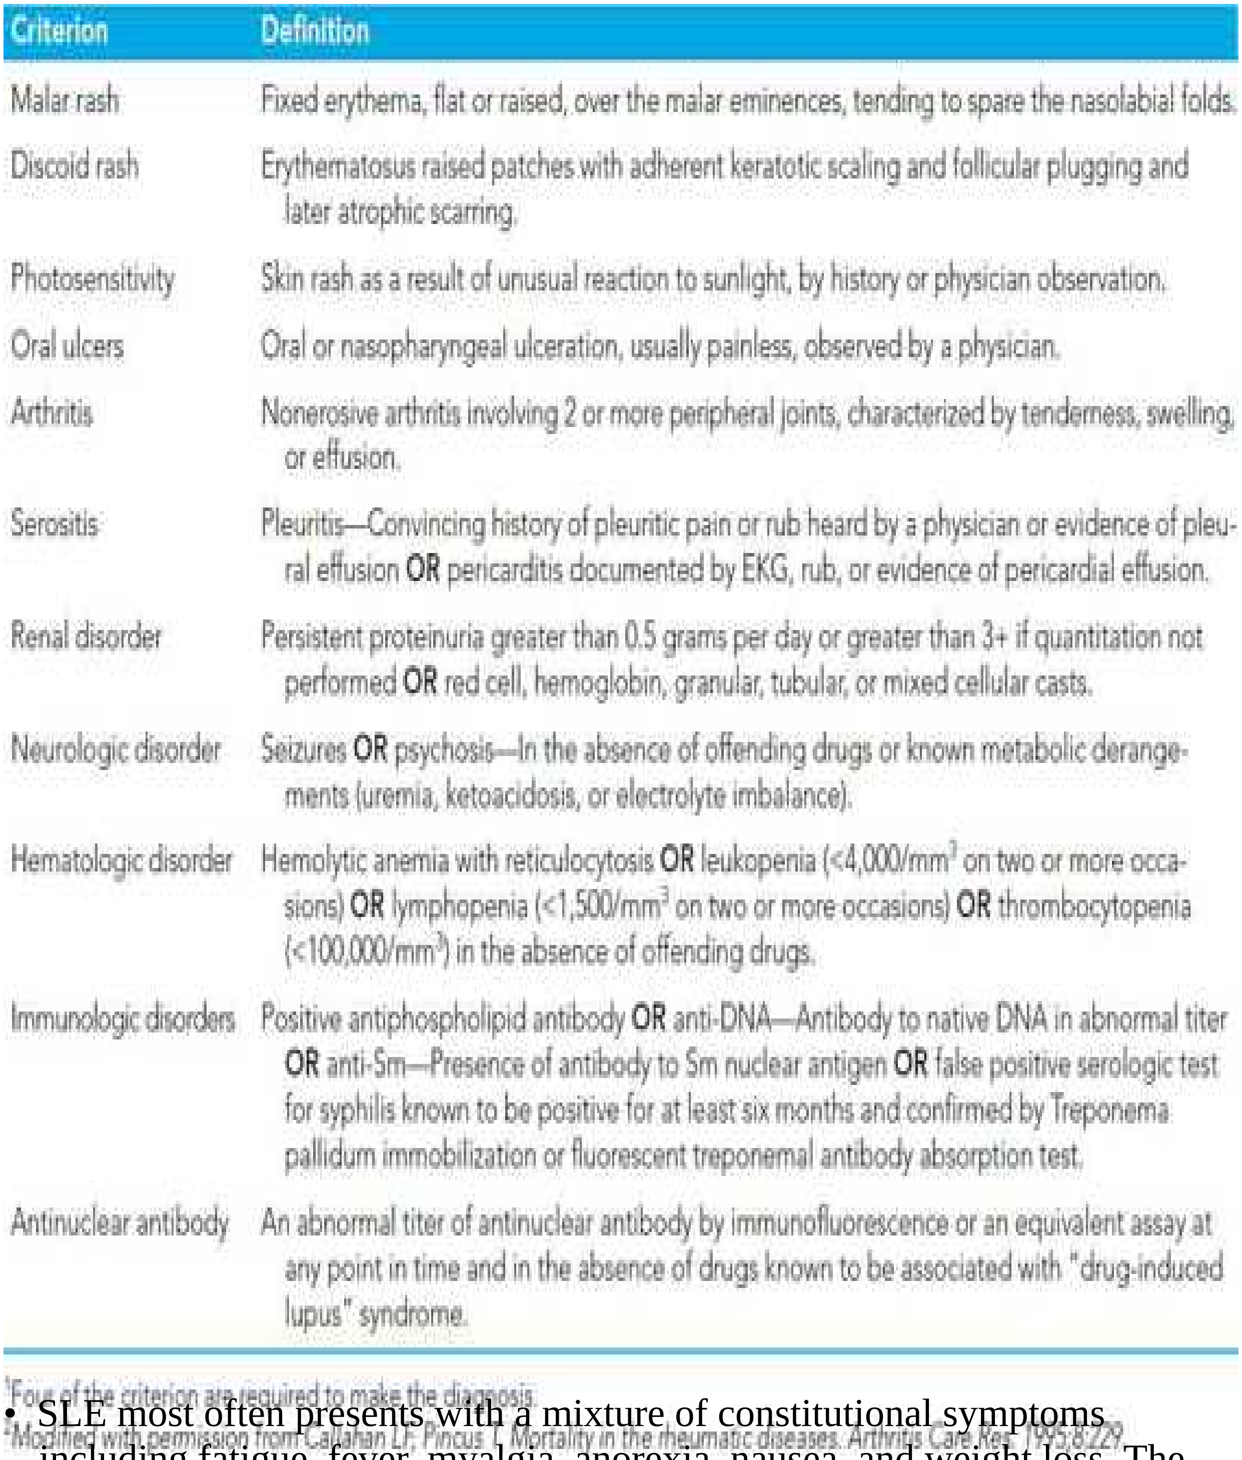
- Precipitating factors for SLE include:
    - Exposure to the sunlight (ultraviolet light, especially UVB).
    - Infections.
    - Stress.
    - Trauma or surgery.
    - Pregnancy (especially in the postpartum period).

DIAGNOSIS

CLINICAL FEATURES

- SLE is a chronic, recurrent, potentially fatal inflammatory disorder that can be difficult to diagnose. It is an autoimmune disease involving multiple organ systems that is defined clinically with associated autoantibodies directed against cell nuclei. The disease has no single diagnostic sign or marker (**Table 173-1**). Accurate diagnosis is important because treatment can reduce morbidity and mortality.[7]

TABLE 173-1 American College of Rheumatology Criteria for Diagnosis of Systemic Lupus Erythematosus[1,2]



Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds.
Discoid rash	Erythematosus raised patches with adherent keratotic scaling and follicular plugging and later atrophic scarring.
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by history or physician observation.
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician.
Arthritis	Nonerosive arthritis involving 2 or more peripheral joints, characterized by tenderness, swelling, or effusion.
Serositis	Pleuritis—Convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion **OR** pericarditis documented by EKG, rub, or evidence of pericardial effusion.
Renal disorder	Persistent proteinuria greater than 0.5 grams per day or greater than 3+ if quantitation not performed **OR** red cell, hemoglobin, granular, tubular, or mixed cellular casts.
Neurologic disorder	Seizures **OR** psychosis—In the absence of offending drugs or known metabolic derangements (uremia, ketoacidosis, or electrolyte imbalance).
Hematologic disorder	Hemolytic anemia with reticulocytosis **OR** leukopenia (<4,000/mm^3 on two or more occasions) **OR** lymphopenia (<1,500/mm^3 on two or more occasions) **OR** thrombocytopenia (<100,000/mm^3) in the absence of offending drugs.
Immunologic disorders	Positive antiphospholipid antibody **OR** anti-DNA—Antibody to native DNA in abnormal titer **OR** anti-Sm—Presence of antibody to Sm nuclear antigen **OR** false positive serologic test for syphilis known to be positive for at least six months and confirmed by Treponema pallidum immobilization or fluorescent treponemal antibody absorption test.
Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome.

[1] Four of the criterion are required to make the diagnosis.

[2] Modified with permission from Callahan LF, Pincus T. Mortality in the rheumatic diseases. Arthritis Care Res. 1995;8:229.

- SLE most often presents with a mixture of constitutional symptoms including fatigue, fever, myalgia, anorexia, nausea, and weight loss. The mean length of time between onset of symptoms and diagnosis is 5 years.
- The disease is characterized by exacerbations and remissions as well as symptoms. The diagnosis of SLE is made if four or more of the manifestations mentioned in the following are either present, serially or simultaneously, in the patient at the time of presentation or were present in

the past. Arthralgias, which are often the initial complaint, are usually out of proportion to physical findings. The polyarthritis is symmetric, nonerosive, and usually nondeforming. In longstanding disease, rheumatoid-like deformities with swan-neck fingers are commonly seen.

- A malar or butterfly rash is fixed erythema over the cheeks and bridge of the nose sparing the nasolabial folds (**Figures 173-5** and **173-6**). It may also involve the chin and ears. More severe malar rashes may cause severe atrophy, scarring, and hypopigmentation

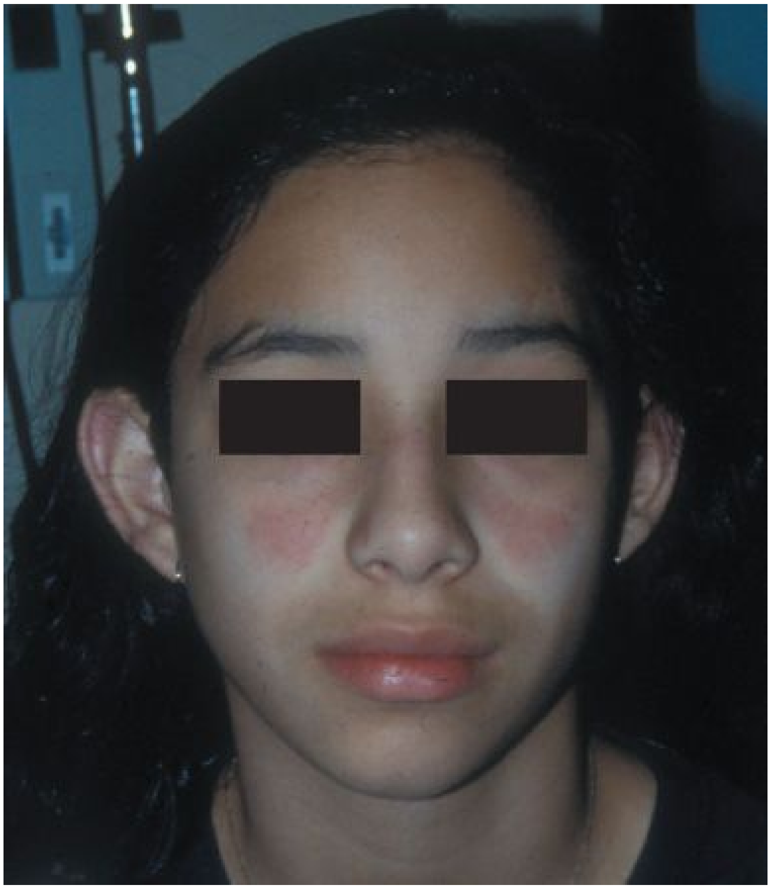


FIGURE 173-5 Malar rash in adolescent Hispanic girl with SLE. Note the relative sparing of the nasolabial fold. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

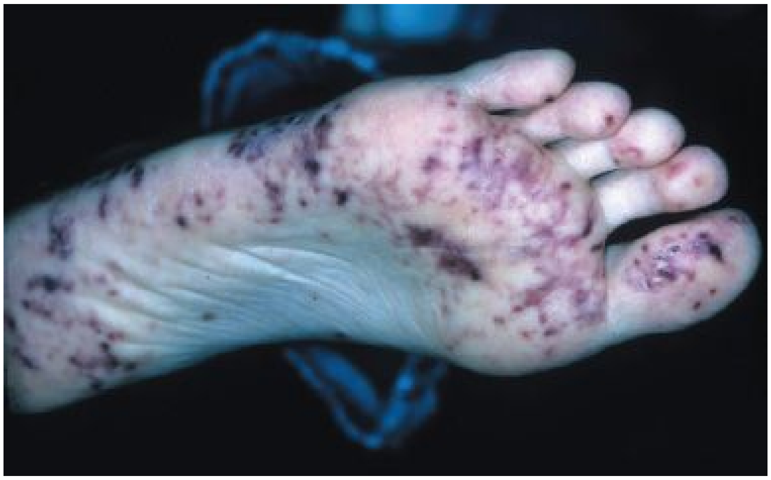

FIGURE 173-6 Necrotizing angiitis in a Japanese American patient with a severe lupus flare. Palpable purpura was evident on both feet and hands. (*Used with permission from Richard P. Usatine, MD.*)

- The rash is often associated with photosensitivity to ultraviolet (UV) light.
- A discoid rash consisting of erythematosus raised patches with adherent keratotic scaling and follicular plugging. Atrophic scarring may occur in older lesions.
- Ulcers (usually painless) in the nose, mouth, or vagina are frequent complaints.
- Pleuritis as evidenced by a convincing history of pleuritic pain or rub or evidence of pleural effusion.
- Pericarditis as documented by EKG, rub, or evidence of pericardial effusion.
- Renal disorder such as cellular casts or persistent proteinuria >0.5 g/d or >3+ if quantitation not performed.
- Central nervous system (CNS) symptoms ranging from mild cognitive dysfunction to psychosis or seizures. Any region of CNS can be involved. Intractable headaches and difficulties with memory and reasoning are the most common features of neurologic disease in lupus patients.
- Hematologic disorders such as hemolytic anemia, leukopenia (<4000/mm^3 total on two or more occasions), lymphopenia (<1500/mm^3 on two or

more occasions), or thrombocytopenia (<100,000/mm^3 in the absence of precipitating drugs).

- GI symptoms may include abdominal pain, diarrhea, and vomiting. Intestinal perforation and vasculitis are important diagnoses to exclude.
- Vasculitis (**Figures 173-6** and **173-7**) can be severe and can include retinal vasculitis.

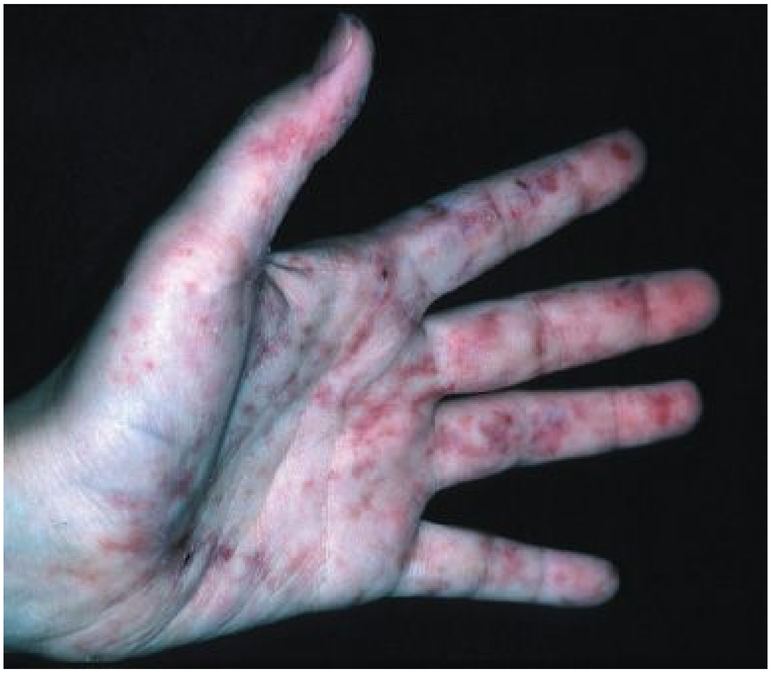

FIGURE 173-7 Necrotizing angiitis on the hand of the patient in **Figure 173-6** with lupus. (*Used with permission from Richard P. Usatine, MD.*)

- Immunologic disorders such as a positive antiphospholipid antibody, anti-DNA, anti-Sm, or a false positive serologic test for syphilis (known to be positive for at least 6 months and confirmed by a negative treponema specific test).
- An abnormal titer of antinuclear antibody at any point in time and in the absence of drugs associated with "drug-induced lupus."
- DLE (cutaneous lupus) lesions are characterized by discrete, erythematous, slightly infiltrated papule or plaques covered by a well-formed adherent scale (**Figures 173-8** to **173-11**). As the lesion progresses, the scale often thickens and becomes adherent.

Hypopigmentation develops in the central area and hyperpigmentation develops at the active border. Resolution of the active lesion results in atrophy and scarring. When they occur in the scalp, scarring alopecia often results (**Figure 173-12**). If the scale on the scalp is removed, it may leave a “carpet tack sign” from follicular plugging.

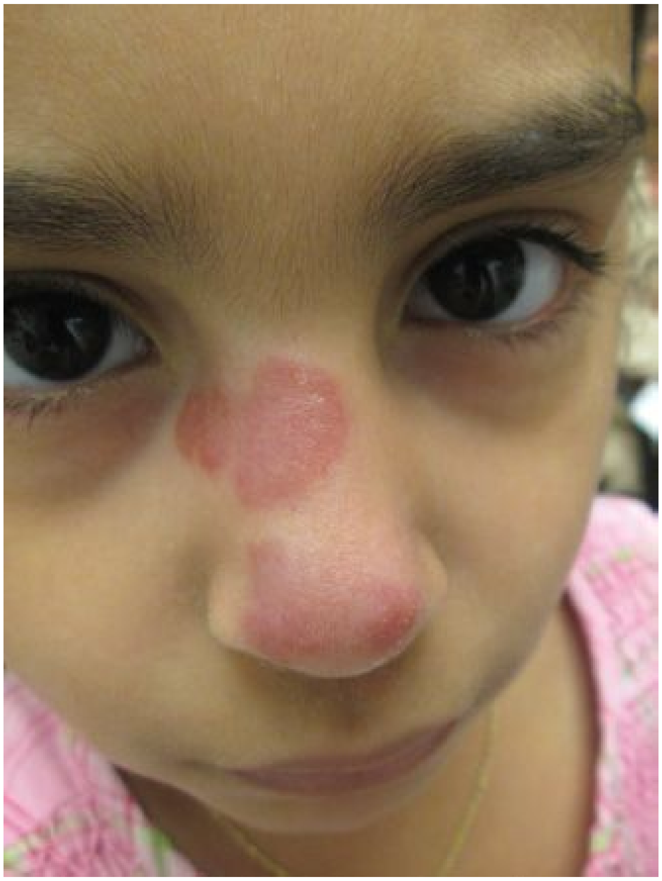

FIGURE 173-9 Cutaneous lupus on the face of a 5-year-old girl. She is responding to hydroxychloroquine with improvement in the facial lesions. (*Used with permission from Lewis Rose, MD*.)

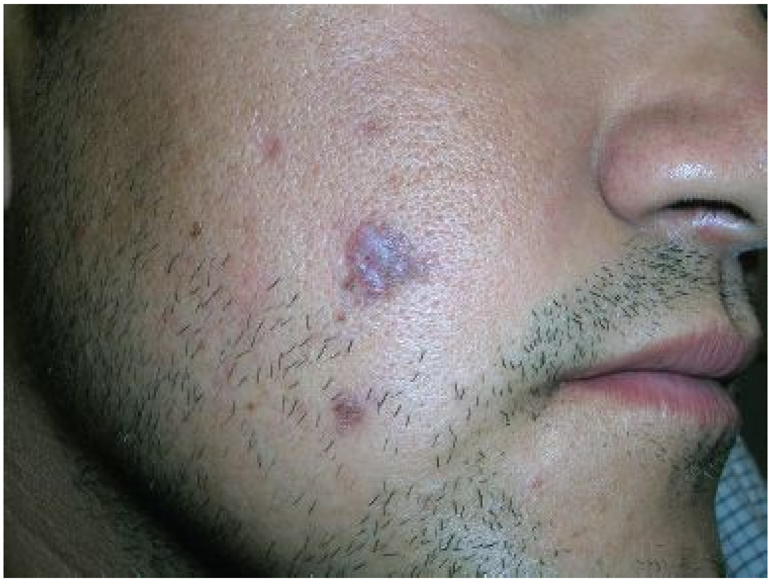

FIGURE 173-10 Discoid lupus with hyperpigmentation and scarring on the face of this young man.

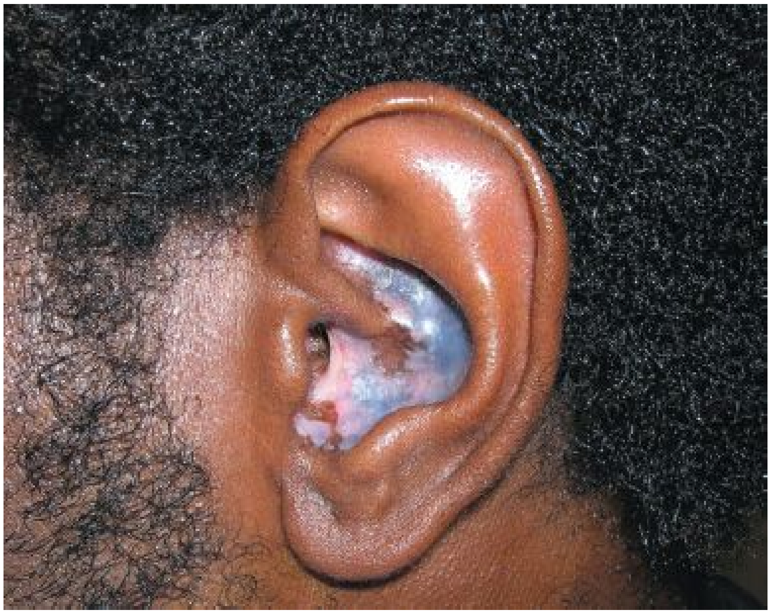

FIGURE 173-11 Discoid lupus with hypopigmentation and scarring inside the pinna. (*Used with permission from E.J. Mayeaux, Jr., MD*.)

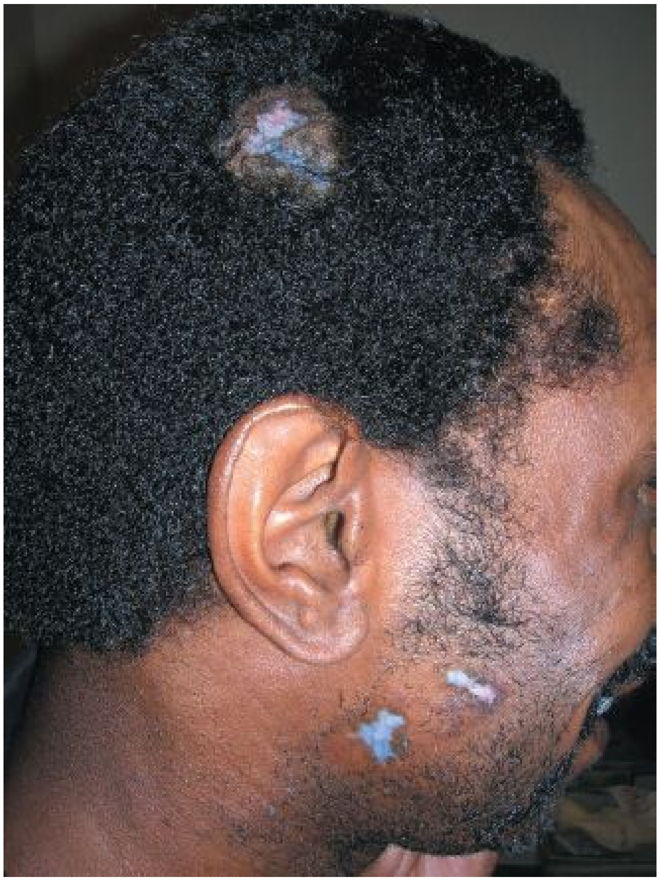

FIGURE 173-12 Discoid lupus with scarring alopecia and hypopigmentation on the scalp and face. (*Used with permission from E.J. Mayeaux, Jr., MD.*)

TYPICAL DISTRIBUTION

- SLE is known for its typical malar rash across the face like a butterfly (**Figures 173-5** and **173-13**).

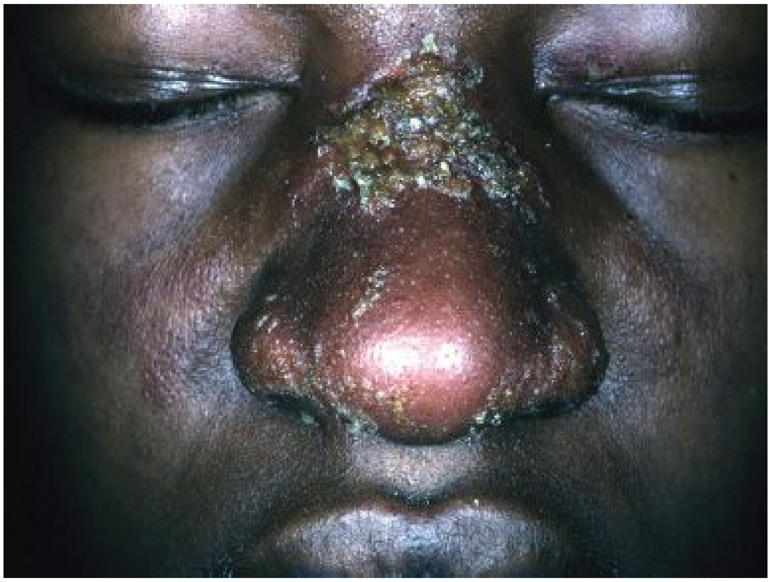

FIGURE 173-13 An 18-year-old girl presenting with crusted sores on her nose and malar rash. This was impetigo over the malar rash from new onset SLE. Months later she developed a severe lupus cerebritis. (*Used with permission from Richard P. Usatine, MD.*)

- Discoid lesions are most often seen on the face, neck, and scalp, but also occur on the ears, and infrequently on the upper torso.
- DLE lesions may be localized or widespread. Localized DLE occurs only in the head and neck area, while widespread DLE occurs anywhere. Patients with widespread involvement are more likely to develop SLE.
- Lupus panniculitis, or lupus profundus, is a variant of LE that primarily affects subcutaneous fat. It usually involves the proximal extremities, trunk, breasts, buttocks, and face (**Figure 173-14**).

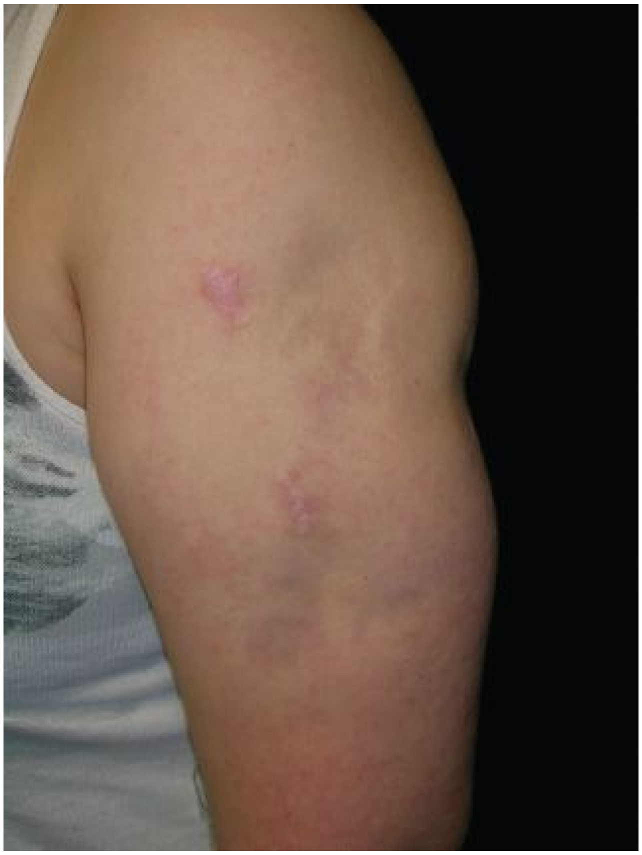

FIGURE 173-14 Lupus profundus showing localized atrophic changes of the arm secondary to the panniculitis. This teenager also has the lupus profundus on the face and other arm. The atrophy has been present for more than 1 year despite treatment. (*Used with permission from Richard P. Usatine, MD*.)

LABORATORY TESTING

- The American College of Rheumatology recommends ANA testing in patients who have two or more unexplained signs or symptoms that could be lupus. Elevation of the ANA titer to or above 1:80 is the most sensitive of the American College of Rheumatology diagnostic criteria. Although many patients may have a negative ANA titer early in the disease, more than 99 percent of SLE patients will eventually have an elevated ANA titer.[9] The ANA test is not specific for lupus, and the most common reason for a positive ANA test without SLE (usually at titers <1:80) is the presence of another connective tissue disease. ANA titer is useful in screening and diagnosis but not in monitoring disease activity. Specific antibodies used in confirming the diagnosis include anti-double stranded DNA (anti-DS DNA) and anti-Smith antibodies.

- Active SLE is often heralded by a rise in IgG anti-double-stranded DNA titers and/or a fall in complement levels.[10]
- Patients with only DLE generally have negative or low-titer ANA titers, and rarely have low titers of anti-Ro antibodies.[11]

DIFFERENTIAL DIAGNOSIS

- Drug-induced lupus is a lupus-like syndrome most strongly associated with procainamide, hydralazine, isoniazid, chlorpromazine, methyldopa, and quinidine.
- Scleroderma presents with thickening of the skin and multi-system sclerosis (see Chapter 178, Scleroderma and Morphea).
- Dermatomyositis presents with facial swelling, “heliotrope” rash around the eyes, Gottron’s papules, and periungual erythema in the hands, and proximal muscular limb girdle weakness (see Chapter 174, Juvenile Dermatomyositis).
- Psoriasis demonstrates silver-white plaques that cover the elbows, knees, scalp, back, or vulva. There may also be nail and scalp involvement (see Chapter 136, Psoriasis).
- Rosacea is associated with mid-facial skin erythema, papules, and pustules without the systemic symptoms of LE, and usually involves the nasolabial folds (see Chapter 97, Rosacea).
- Sarcoidosis may produce skin plaques but without the central clearing and atrophy of LE (see Chapter 150, Pediatric Sarcoidosis).
- Syphilis may produce a plaque like rash that can be confused with DLE. The short course of the disease and serologic testing can distinguish the diseases. However, lupus autoantibodies may produce a false-positive screening test for syphilis (see Chapter 181, Syphilis).

MANAGEMENT

NONPHARMACOLOGIC

- Since UV light can flare SLE, use of sunscreen, preferably those that block both UV-α and UV-B, should be encouraged. SOR Ⓒ

MEDICATIONS

- Conservative management for SLE with nonsteroidal anti-inflammatory drugs or cyclooxygenase-2 selective inhibitors are recommended for arthritis, arthralgias, and myalgias.[12] SOR Ⓑ
- Antimalarial drugs (hydroxychloroquine (Plaquenil) maximum 6.5 mg/kg/d) most commonly for skin manifestations and for musculoskeletal complaints that do not adequately respond to nonsteroidal anti-inflammatory drugs. They may also prevent major damage to the kidneys and CNS and reduce the risk of disease flares.[13] SOR Ⓑ
- Systemic glucocorticoids (1–2 mg/kg/d of prednisone or equivalent) alone or with immunosuppressive agents for patients with significant renal and CNS disease or any other organ threatening manifestation.[14] SOR Ⓑ Lower doses of glucocorticoids for symptomatic relief of severe or unresponsive musculoskeletal symptoms. In severe, life-threatening situations, high-dose methylprednisolone can be given for three consecutive days.
- Immunosuppressive medications (e.g., methotrexate, cyclophosphamide, azathioprine, mycophenolate, or rituximab) are generally reserved for patients with significant organ involvement, or who have had an inadequate response to glucocorticoids.[15] SOR Ⓑ
- Belimumab, a monoclonal antibody against B cell activating factor, was recently approved for therapy of mild to moderate SLE in adults but is not yet approved in children.[16]
- Patients with thrombosis, usually associated to the presence of antiphospholipid antibodies, require anticoagulation with warfarin for a

target international normalized ratio of 3:3.5 for arterial thrombosis and 2:3 for venous thrombosis.[17]

- DLE therapy includes corticosteroids (topical or intralesional) and antimalarials. SOR Ⓒ Alternative therapies include auranofin, oral or topical retinoids, and immunosuppressive agents.

PREVENTION

- Avoiding precipitating factors may decrease exacerbations.

PROGNOSIS

- SLE can have a varied clinical course, ranging from a relatively benign illness to a rapidly progressive disease with organ failure and death. Children have a higher risk of renal and neurologic involvement and a higher mortality than adults.
- Poor prognostic factors for survival in SLE include:[18]
  - Renal disease (especially diffuse proliferative glomerulonephritis).
  - Hypertension.
  - Male sex.
  - Young age.
  - Older age at presentation.
  - Poor socioeconomic status.
  - African American and Hispanic race, which may primarily reflect low socioeconomic status.
  - Presence of antiphospholipid antibodies.
  - Antiphospholipid syndrome.
  - High overall disease activity.

FOLLOW-UP

- The patient should have regular follow-up appointments to monitor for and attempt to prevent end organ damage. Regular follow-up visits are needed to monitor medication benefits and side effects and to coordinate care of the whole person.

PATIENT EDUCATION

- Educate the patient on the necessity of protection from the sun, since UV exposure can cause lupus flares. They should use sunscreen, preferably those that block both UV-A and UV-B, with a minimum skin protection factor of 30.
- Since cigarette smoking may increase the risk of developing SLE and smokers generally have more active disease, children and adolescents with SLE should be counseled to avoid smoking. Have patients report any signs of secondary infection in their rash, since this requires antibiotic therapy (**Figure 173-13**).
- If possible, avoid sulfa drugs, which have been related to lupus flares.

174 JUVENILE DERMATOMYOSITIS

Margaret L. Burks, MD
Richard P. Usatine, MD

PATIENT STORY

A teenage girl presents with a new rash on her face and hands for the past few months. In addition to going to school she works as a waitress and has noted that it is harder to carry heavy trays. She also has gum inflammation and is wondering if this could be related to everything else. The physician notes the heliotrope rash around her eyes (**Figure 174-1**) and the Gottron papules on the dorsum of her knuckles (**Figure 174-2**). He considers that this may be dermatomyositis and tests for proximal muscle weakness. The proximal muscles are not found to be weak on physical exam although a subsequent blood test showed a mildly elevated CK and AST. The physician uses his dermatoscope to look at the nail folds and sees many dilated capillary loops (**Figure 174-3**). On the oral examination, there is a marginal gingivitis and the dermatoscope shows a similar dilated capillary pattern around the tooth. A diagnosis of dermatomyositis is made. The patient was treated with prednisone and hydroxychloroquine and improves greatly. The patient was then tapered off the prednisone fully with no relapse.

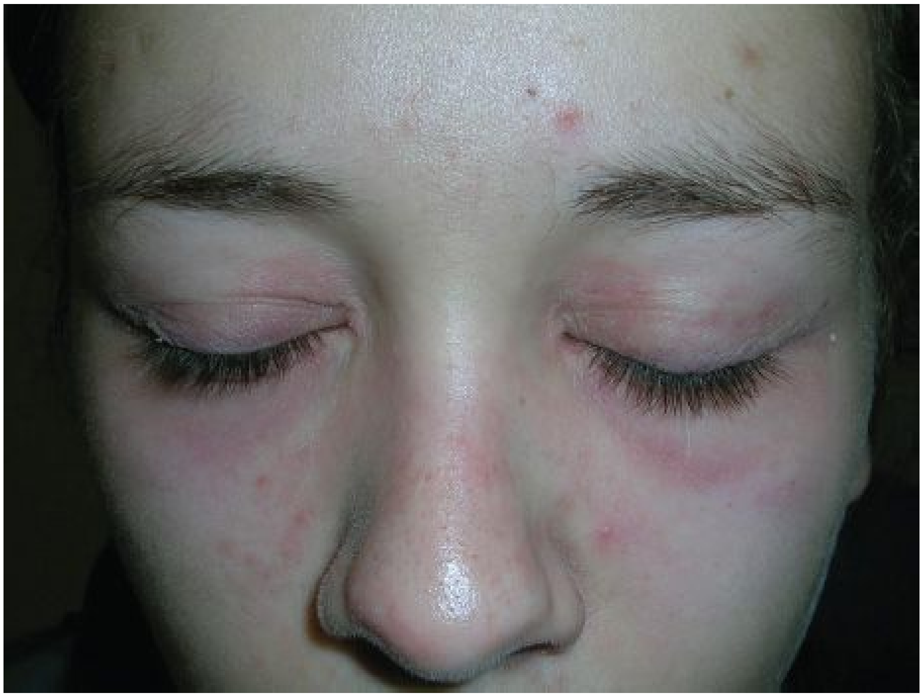

FIGURE 174-1 Classic heliotrope rash around the eyes of this teenager newly diagnosed with dermatomyositis. The color “heliotrope” is a pink-purple tint named after the color of the heliotrope flower. As expected, her heliotrope rash is bilaterally symmetrical. This rash resolved with prednisone and hydroxychloroquine. (*Used with permission from Richard P. Usatine, MD*.)

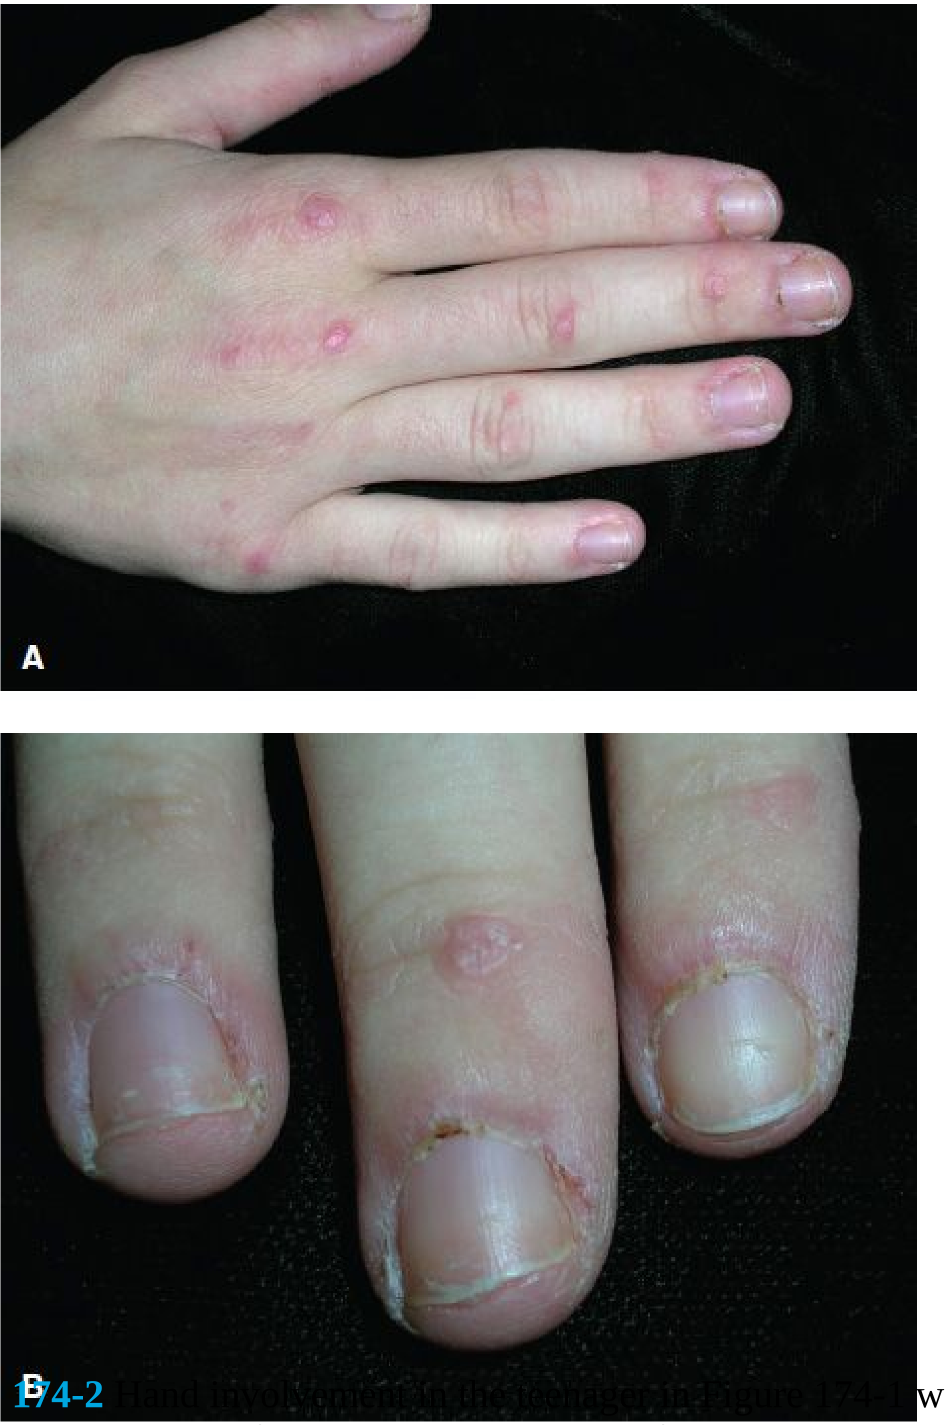

FIGURE 174-2 Hand involvement in the teenager in Figure 174-1 with Gottron papules over the finger joints. She has nailfold erythema and ragged cuticles (Samitz sign). (*Used with permission from Richard P. Usatine, MD.*)

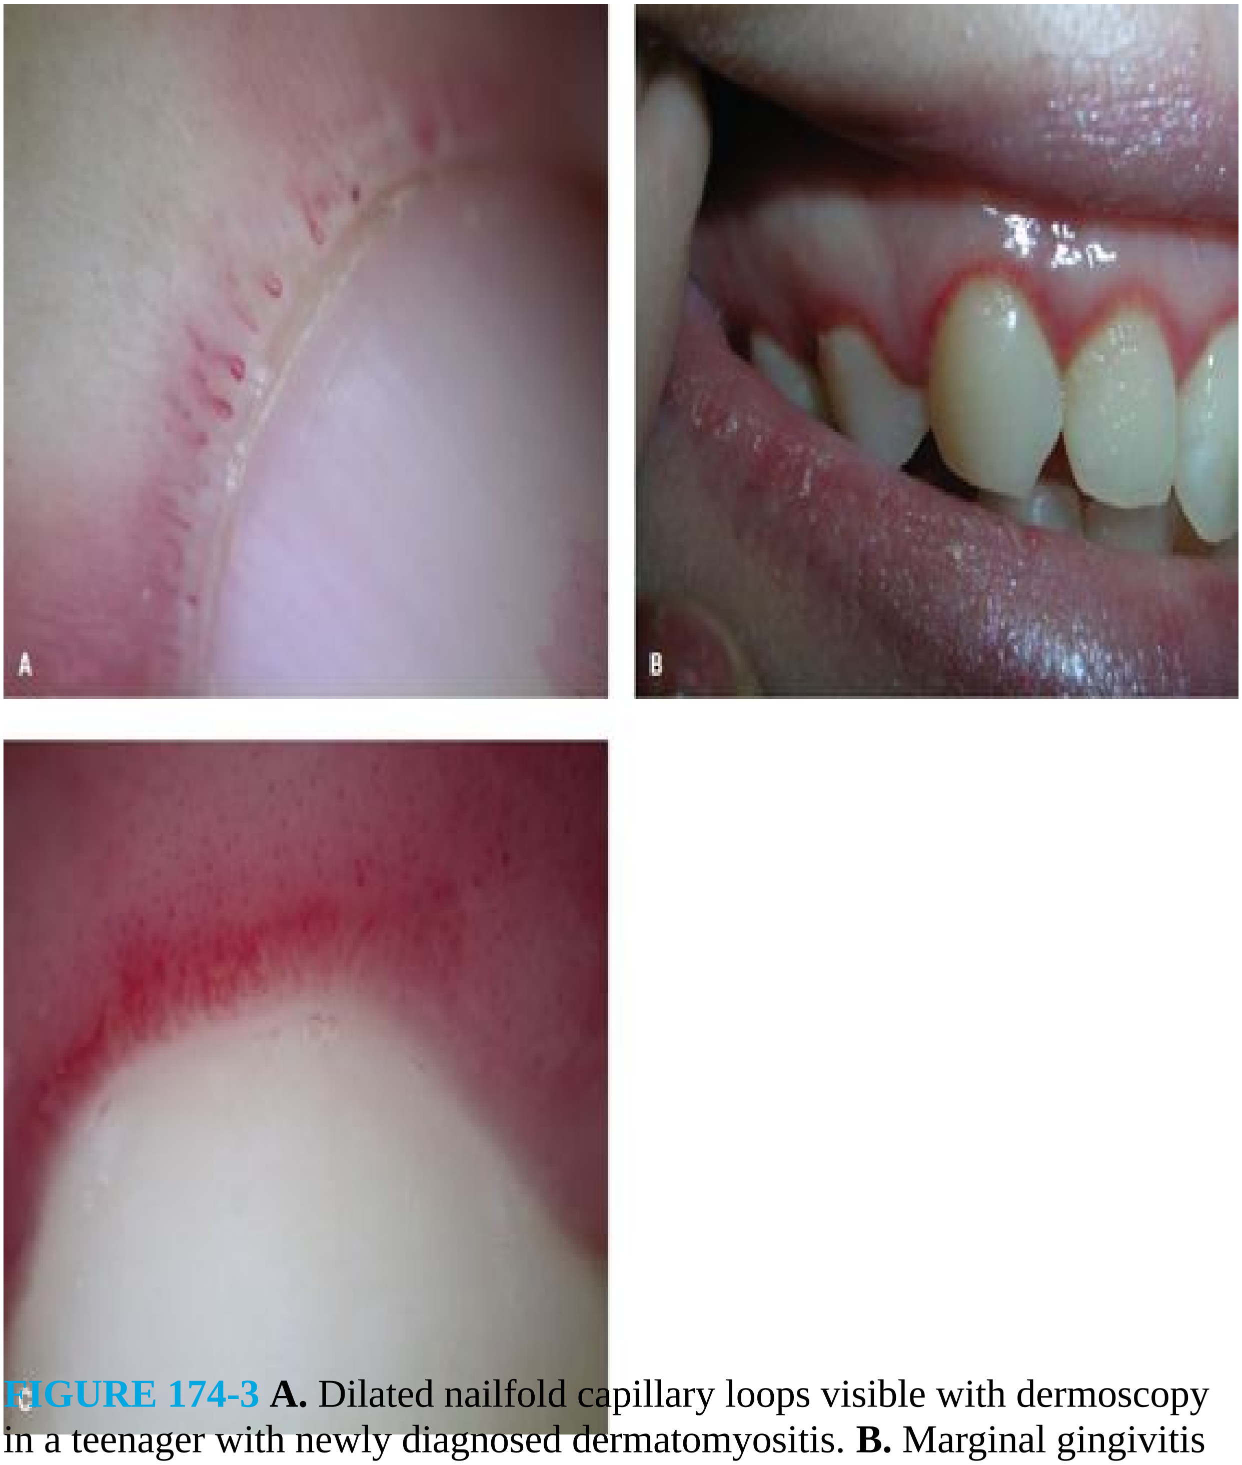

FIGURE 174-3 **A.** Dilated nailfold capillary loops visible with dermoscopy in a teenager with newly diagnosed dermatomyositis. **B.** Marginal gingivitis in the same teen with newly diagnosed dermatomyositis. **C.** She also had dilated capillary loops on the gingival borders of her teeth seen with dermoscopy. The nailfold findings and gingival findings both resolved with treatment. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Juvenile dermatomyositis is a rare, idiopathic inflammatory disease involving the striated muscles and the skin. Similar to adult cases of dermatomyositis, the disease is primarily characterized by progressive, symmetrical, proximal muscle weakness. Dermatologic manifestations may occur with or without muscular disease and include the heliotrope rash (**Figures 174-1**, **174-4**, and **174-5**), “shawl sign,” and Gottron papules over the finger joints (**Figures 174-4** to **174-7**). Although primarily a disease of muscle and skin, juvenile dermatomyositis has a clear association with myocarditis, vasculitis, calcinosis and interstitial lung disease.[1] Unlike adult dermatomyositis, juvenile cases are much less likely to be associated with an underlying malignancy.

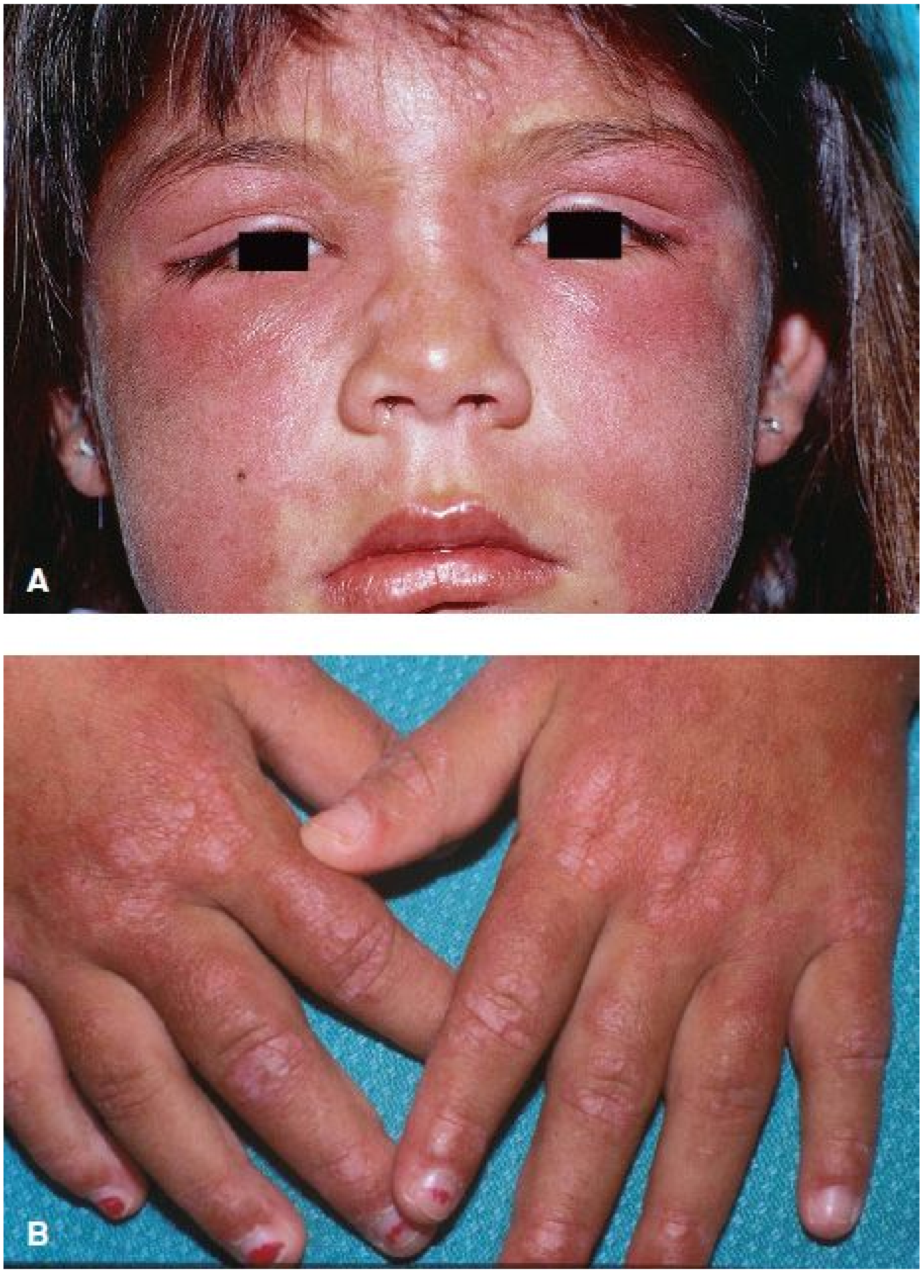

FIGURE 174-4 A. Juvenile dermatomyositis in a young girl with the characteristic heliotrope rash that is periorbital and violaceous. The periorbital edema and facial swelling are also commonly seen in juvenile dermatomyositis. B. Gottron papules on the dorsa of the knuckles. (*Used with permission from Eric Kraus, MD*.)

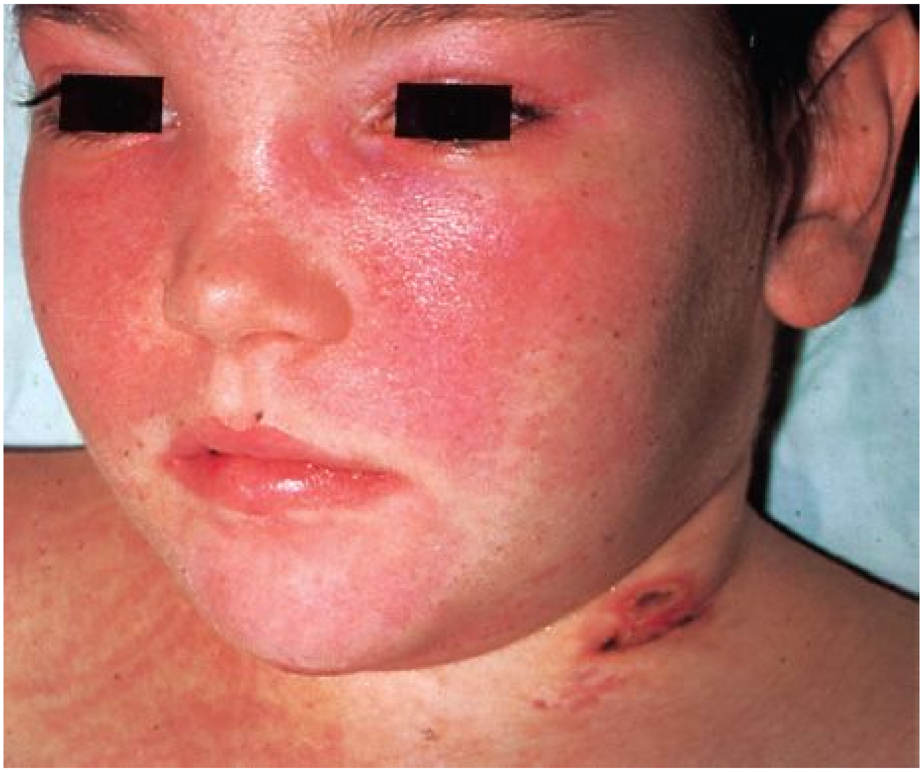

FIGURE 174-5 Heliotrope rash of juvenile dermatomyositis around the eyes of this young boy. Note the periorbital and facial edema. The erythema covers the cheeks, chin and shoulders. He also has a skin ulcer on the neck. Skin ulcerations are found in juvenile dermatomyositis. (*Used with permission from Weinberg S, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, New York: McGraw-Hill, 2008*.)

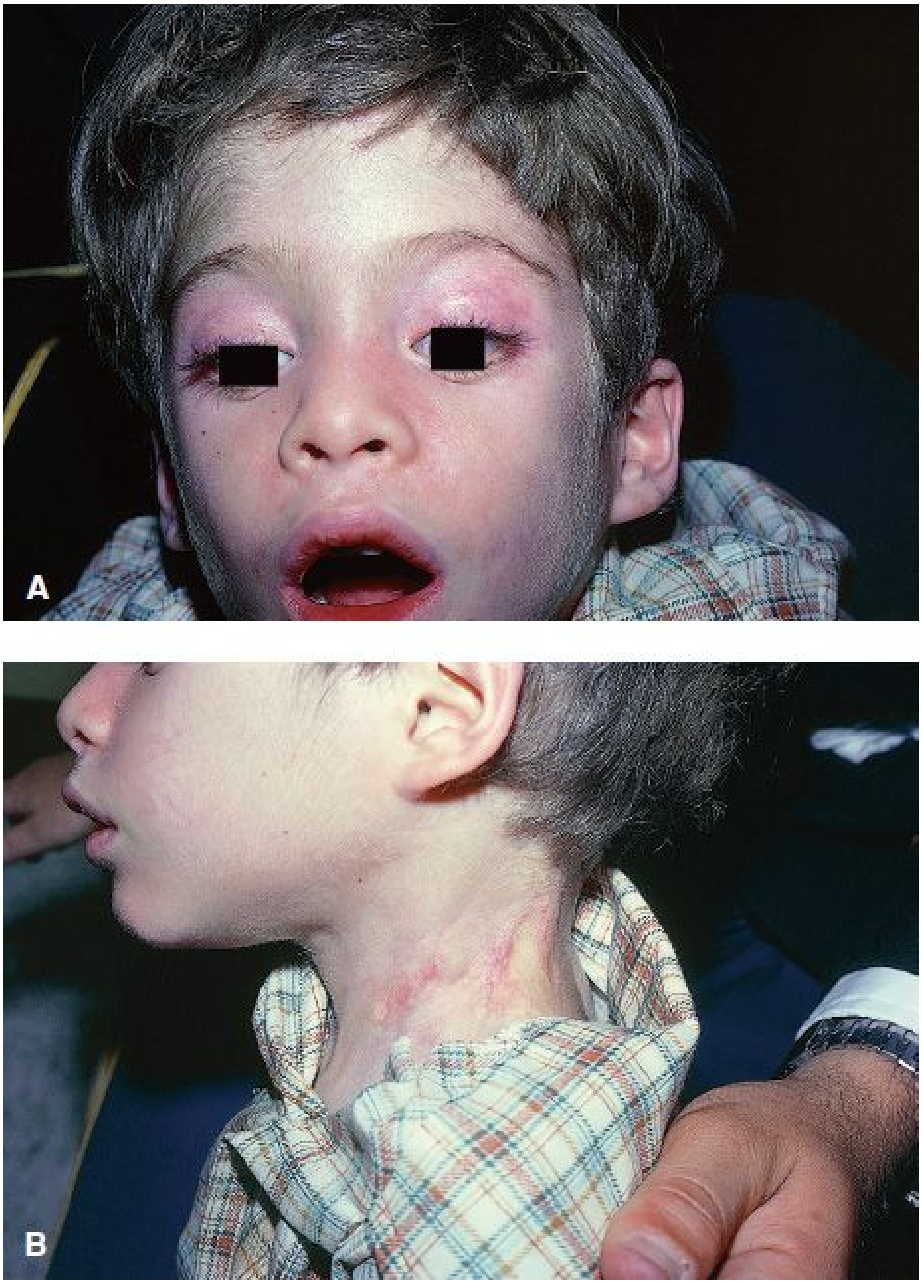

FIGURE 174-6 Juvenile dermatomyositis in a 5-year-old boy demonstrating **A.** heliotrope rash around the eyes. **B.** Calcinosis in the skin of the neck. (*Used with permission from Eric Kraus, MD.*)

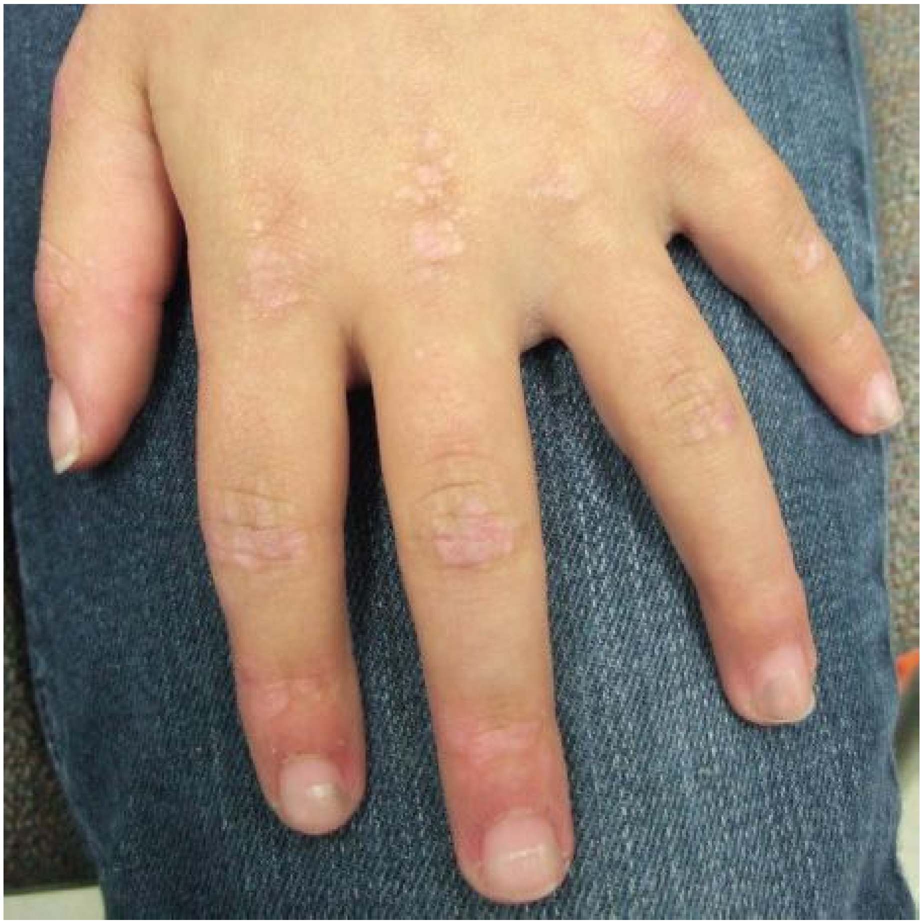

FIGURE 174-7 Child with juvenile dermatomyositis and Gottron plaques on the dorsum of the knuckles. (*Used with permission from John Browning, MD*.)

EPIDEMIOLOGY

- Annual incidence of 3.2 cases per 1 million population.[2]
- More common in females.[1,2]
- Children tend to have better long-term prognosis and survival compared to adults with dermatomyositis.[1]
- Mortality rate in children with dermatomyositis is lower than that of adults (less than 5.0% versus 20.8%).[1,3,4]

- Peak age of disease onset is 7 years old.[5–7]
- In contrast to adult patients with dermatomyositis, juvenile cases are much less likely to have concomitant interstitial lung disease (14% of juvenile cases versus 35% to 40% of adult cases).[8,9]
- Though linked to malignancy in 12 to 32 percent of adults, malignancy is not typically seen in children with dermatomyositis (approximately 1% of cases).[1,3,10,11,12]

ETIOLOGY AND PATHOPHYSIOLOGY

- Dermatomyositis is considered an autoimmune disease of unknown etiology. Environmental exposure and infectious agents may play a role in disease pathogenesis.[1]
- In children, some studies have shown a high incidence of infectious symptoms in the months prior to disease onset, although no specific pathogen has been linked to the disease.[6]
- Dermatomyositis is a microangiopathy that affects the skin and muscle. The muscle weakness and skin manifestations are likely a result of inflammatory cell infiltrate and activation and deposition of complement, causing lysis of endomysial capillaries and muscle ischemia.[13]
- Muscle biopsy reveals perivascular and perifascicular inflammation, focal muscle necrosis, vasculopathy, and inflammatory cell infiltrate (particularly CD4 cells, B cells, and macrophages).[1,13]

DIAGNOSIS

- Diagnosis includes five criteria: “definite” (typical skin findings plus any three of criteria 1 to 4 that indicate muscle inflammation), “probable” (skin findings plus two of any criteria 1 to 4), or “possible” (skin findings plus any one of criteria 1 to 4).[1,14,15]

    - Proximal symmetric muscle weakness that progresses over weeks to months.
    - Elevated serum levels of muscle enzymes (CK, AST, lactate dehydrogenase [LDH] and aldolase).
    - Abnormal electromyogram (EMG) demonstrating muscle irritability
    - Abnormal muscle biopsy with muscle necrosis or inflammatory infiltrate.
    - Skin findings—Presence of cutaneous disease characteristic of dermatomyositis. The heliotrope rash (**Figures 174-1**, **174-4**, and **174-5**) and Gottron papules (**Figures 174-4** to **174-7**) are considered pathognomonic. Nonpathognomonic manifestations include malar erythema, and periungual and cuticular changes (**Figures 174-2** and **174-3**).
- These criteria are still considered the “gold standard,” although they are old (1975) and currently under critical review because of several limitations. The criteria do not include specific autoantibodies or MRI findings.[5]
- Dilated nailfold capillary loops (**Figure 174-3**) have shown promise in juvenile dermatomyositis as a marker for both skin and muscle disease activity to guide treatment. Some authors propose adding this finding to criteria for diagnosis.[16,17]

CLINICAL FEATURES

- Bilateral periorbital heliotrope erythema (pathognomonic; **Figures 174-1**, **174-4**, and **174-5**) and scaling violaceous papular dermatitis in a patient complaining of proximal muscle weakness points to dermatomyositis.
- A psoriasiform scalp dermatitis may be seen in up to 25 percent and pruritus in up to 38 percent of new cases of juvenile dermatomyositis.[18]
- An older child may complain of difficulty climbing stairs, rising from a seat, or combing their hair. Notably the skin manifestations may precede, follow, or present simultaneously with muscle involvement.
- In younger children, proximal muscle weakness is often difficult for the clinician to evaluate. Signs to look for include a child not wanting to walk

or who insists on being carried, hesitancy to stand up off of the floor, difficulty keeping the head up after infancy, or the "Gower sign."[1] The "Gower sign" is typically associated with muscular dystrophy but can be seen in the proximal myopathy of dermatomyositis (see **Figure 208-1**).

- Severe muscular disease may include difficulty swallowing, choking on liquids, voice changes, or even acute respiratory failure if muscles of respiration are affected.[1,19]
- Hand involvement includes abnormal nailfolds and Gottron papules. "Moth-eaten" cuticles, also called the Samitz sign, are evidenced by periungual erythema and telangiectasias (**Figures 174-2** and **174-3**).
- Juvenile dermatomyositis is more often associated with vascular disease compared to adult cases. Telangiectasias (periungual and gingival) are more common in the pediatric population (**Figure 174-3**).[1]
- Severe vascular disease in juvenile dermatomyositis can lead to skin ulceration in up to 24 percent of pediatric cases (**Figure 174-5**).[20] Similarly, vascular disease may lead to abdominal pain, pneumatosis intestinalis, and GI hemorrhage with risk of perforation. Persistent or severe abdominal pain in a child with juvenile dermatomyositis should prompt immediate evaluation.[21]
- Gottron papules, smooth, purple-to-red papules and plaques, are classically located over the knuckles and on the sides of fingers (**Figures 174-2**, **174-4**, **174-7**, and **174-8**). Plaques may be present over the knuckles instead of or in addition to papules (**Figure 174-7**). The papules are much more evident upon presentation of juvenile-onset dermatomyositis.

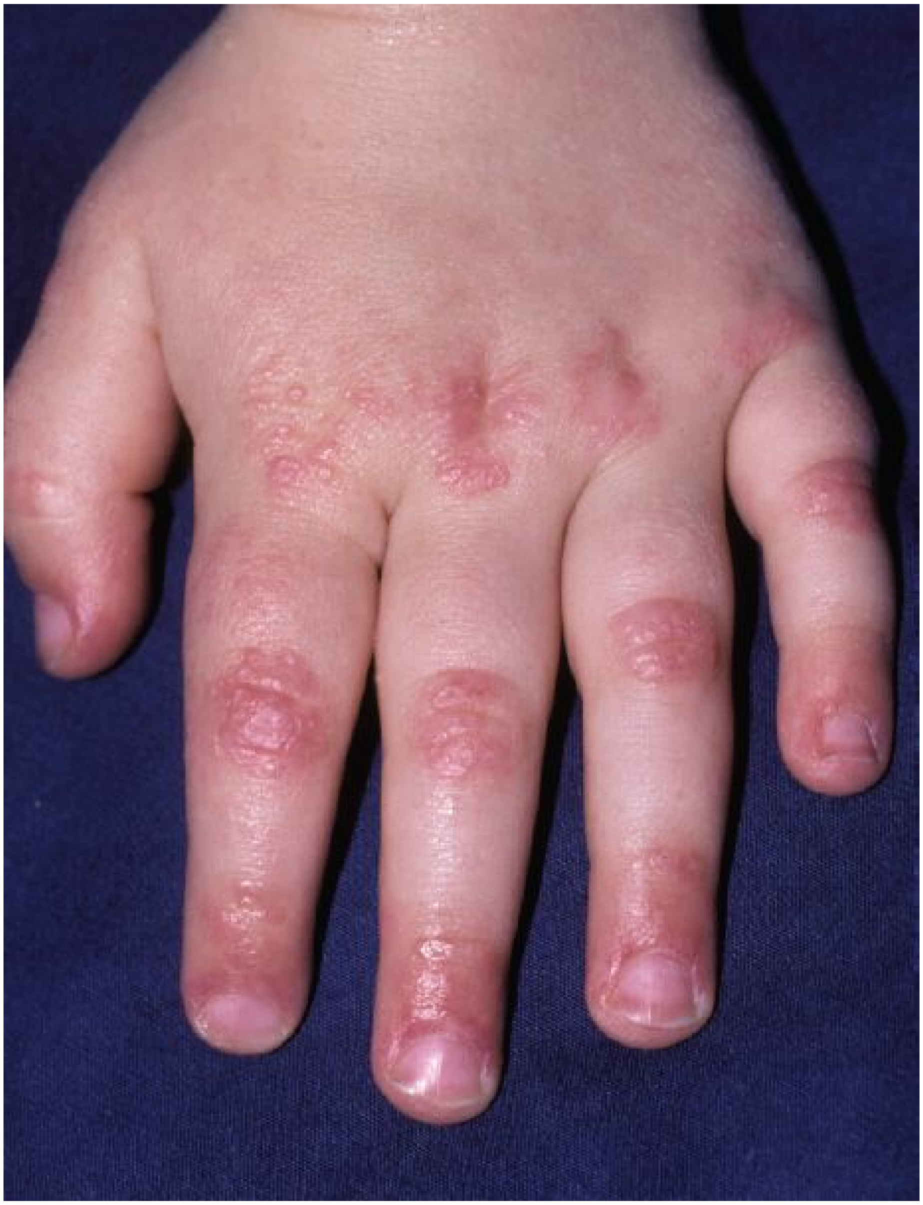

FIGURE 174-8 Prominent Gottron papules in this boy with juvenile dermatomyositis. in a young boy. Note how the erythematous papules and plaques are most prominent over the finger joints and spare the space between joints. (*Used with permission from Richard P. Usatine, MD, and from Goodall J, Usatine RP. Skin rash and muscle weakness. J Fam Pract. 2005;54(10):864-868. Reproduced with permission from Frontline Medical Communications*.)

- Calcinosis of tissues is present in up to 30 percent of cases (**Figure 174-6**). Calcinosis is due to precipitation of calcium and phosphate in inflamed tissues, which can lead to functional disability.[5,21–23] Typically, the deposits are on the extensor surfaces of joints and pressure points of the extremities, although they may be present anywhere.[22] The presence of calcinosis may be decreased if patients are treated early and aggressively.[21,24] Calcinosis can lead to ulceration, pain from nerve entrapment, and joint contractures.[21]
- Lipodystrophy has been associated with up to 10 to 40 percent of cases of juvenile dermatomyositis. This disease complication presents with loss of visceral and subcutaneous fat accompanied by increased insulin resistance and glucose intolerance.[1,21,25]

TYPICAL DISTRIBUTION

- Face—The characteristic heliotrope rash occurs around the eyes. The color “heliotrope” is a pink-purple tint named after the color of the heliotrope flower. This color is best seen in **Figure 174-1**. The heliotrope rash can also be a dusky-red color as seen in **Figures 174-4** and **174-6**. This heliotrope rash is bilaterally symmetrical.
- Hands—There is usually hand involvement with Gottron papules (and plaques) and abnormal nailfolds and cuticles (**Figures 174-2** and **174-4**, **174-7**, and **174-8**).
- Neck and upper trunk—A red or poikiloderma-type rash can be seen in a V-neck or in a shawl distribution. Poikiloderma refers to hyperpigmentation of the skin demonstrating a variety of shades and associated with telangiectasias. The rash here can be scaling and look psoriasiform.
- Extremities may have erythematous plaques and papules with scale.
- Scalp is often involved with erythema and scale and appears similar to seborrhea or psoriasis.
- Sun-exposed areas are often involved and worsen with sun exposure. This is why so many of the skin findings are on the face and upper chest. However, patients rarely complain of sun sensitivity.

LABORATORY STUDIES AND DIAGNOSTIC TESTS

- Elevated muscle enzymes, evidence of inflammation on electromyography (EMG), and inflammatory infiltrates on muscle biopsy confirm the diagnosis of dermatomyositis. The following serum muscle enzymes can be drawn during the acute active phase and may be found to be elevated: CK, LDH, alanine aminotransferase, aspartate aminotransferase, and aldolase. Of note, it is necessary to measure all of the aforementioned enzymes as only one of them may be elevated.
- The diagnosis may be made with confidence in a patient with characteristic skin findings and elevated muscle enzymes. If the presentation is not straightforward, then muscle biopsy should be performed.[5]
- T2-weighted MRI may be useful in unclear diagnoses and to assess disease activity. This imaging can show edema in the muscle and subcutaneous tissue.[5,26]
- The diagnosis can be supported with positive antibodies such as antinuclear antibody (ANA), anti-Mi-2, and anti-Jo-1. It is not necessary to order these antibodies to make the diagnosis of dermatomyositis. Antinuclear antibody can be present in >70 percent of juvenile dermatomyositis cases.[27] Anti-Jo and anti-Mi-2 are considered myositis-specific antibodies; however, they are positive in approximately 5 percent of Caucasian patients with juvenile dermatomyositis. This percentage is higher in African Americans.[13,28]
- Other papulosquamous diseases, such as lichen planus and psoriasis, may be differentiated from dermatomyositis with a punch biopsy.
- Seven to 19 percent of juvenile dermatomyositis cases have been associated with interstitial lung disease.[9,29–31] Though their use is not clearly defined, pulmonary function tests (PFTs), chest radiograph, and high-resolution CT have been used to identify patients with interstitial lung disease.[32] Many children with restrictive lung disease or ILD features seen on imaging may not report symptoms of dyspnea.[9,33] Some experts thus recommend the use of imaging and PFTs for evaluating all children

diagnosed with juvenile dermatomyositis for lung involvement, regardless of the presence or absence of symptoms.[33]

- PFTs demonstrate a restrictive pattern with interstitial lung disease. Abnormal results must be confirmed by CT scan as PFT results may also reflect coexisting respiratory muscle weakness. High resolution CT abnormalities may correlate with a child's reported health status and cumulative organ damage.[9]

BIOPSY

Muscle biopsy is typically recommended when the diagnosis is not clear or the patient presents with varying signs and symptoms. Muscle biopsy of dermatomyositis will show inflammatory cells around intramuscular blood vessels. Atrophic muscle fibers are seen around the periphery of muscle fascicles ("perifascicular atrophy"). Biopsy of juvenile dermatomyositis cases reveals increased destruction of capillaries compared to adult cases.[1] Muscle biopsy can also help determine disease severity and may help with predicting the long term impact of the disease.[34,35]

DIFFERENTIAL DIAGNOSIS

- Polymyositis is another form of inflammatory myopathy. It is distinguished from dermatomyositis by its lack of cutaneous involvement. Dermatomyositis can also occur without muscle involvement. This is called *dermatomyositis sine myositis* or *amyopathic dermatomyositis*. In children, it is unknown whether this represents a very mild muscle inflammation and whether or not these cases will eventually progress if left untreated.[1]
- Polymorphous light eruption or other photosensitivity reactions may be mistaken for the dermatologic findings of dermatomyositis as the cutaneous findings may be predominantly in light-exposed areas. Therefore, it is essential in the management and follow-up with patients with suspected photosensitivity reactions to inquire about muscle

weakness and to look for other signs of dermatomyositis. Examination of the hands and tests for muscle enzyme elevations might help to distinguish dermatomyositis from photosensitivity reactions.

- Juvenile idiopathic arthritis (JIA) is a cause of pain and rash in the pediatric population, although the pain in JIA is typically localized to joints. The rash in the systemic subtype of JIA is classically described as a salmon colored, macular rash that can accompany fever in children with JIA. This rash is characteristically distinct from those previously described in dermatomyositis (see Chapter 172, Juvenile Idiopathic Arthritis).
- Viral myositis can cause muscle aches and pains in pediatric patients, similar to dermatomyositis. However, viral myositis will not present with the classic cutaneous findings seen in juvenile dermatomyositis.
- Hypothyroidism can cause a proximal myopathy just like polymyositis and dermatomyositis. Although hypothyroidism can cause a dermopathy, it does not resemble the skin findings of dermatomyositis. All patients with proximal muscle weakness should have a screening thyroid-stimulating hormone (TSH) to rule out hypothyroidism regardless of their skin findings (see Chapter 191, Hypothyroidism).
- In children, eczema causes an erythematous rash on the face, as is often seen in dermatomyositis. Of course eczema does not cause muscle weakness and the erythema of eczema is classically confined to the flexor surfaces of the extremities (see Chapter 130, Atopic Dermatitis).
- Steroid myopathy may develop as a side effect of systemic steroid therapy. The symptoms develop 4 to 6 weeks after starting oral steroids for dermatomyositis and other autoimmune diseases. Therefore if muscle weakness recurs after improving, it could be from the steroids not the disease.
- Dermatomyositis-like reaction rarely may present with similar skin findings with initiation of the following medications and improvement with their discontinuation: penicillamine, NSAIDs, and carbamazepine.
- Overlap syndrome—The term *overlap* denotes that certain signs are seen in both dermatomyositis and other connective tissue diseases, such as scleroderma, rheumatoid arthritis, and lupus erythematosus. Scleroderma and dermatomyositis are the most commonly associated conditions and

have been termed sclerodermatomyositis or mixed connective disease. In mixed connective tissue disease, features of systemic lupus erythematosus (SLE), scleroderma, and polymyositis are evident, such as malar rash, alopecia, Raynaud phenomenon, waxy-appearing skin, and proximal muscle weakness.

MANAGEMENT

Given the autoimmune mechanism likely central to the disease process, treatment is geared toward the proximal muscle weakness and skin changes using immunosuppressive or immunomodulatory therapy. Treatment is nonspecific as the target antigen remains elusive.[1] Cutaneous manifestations do not always parallel muscle disease in response to therapy. Clinical improvement and physician judgment should guide treatment regimens.[36] Enzyme levels should not be used as a sole guide for gauging responsiveness to therapy because they frequently become normal during treatment even if active disease is present.[5] Effective therapies for the myopathy are oral corticosteroids, immunosuppressants, biologic agents, and/or intravenous immunoglobulin. Effective therapies for the skin disease are sun protection, topical corticosteroids, antimalarials, methotrexate, and/or immunoglobulin. Drug therapy for dermatomyositis continues to be based on empirical rather than evidence-based practice because of lack of controlled trials.[36]

NONPHARMACOLOGIC

- Physical and/or occupational therapy has been shown to preserve and increase muscle function and strength.[37]
- Photoprotective measures, which could consist of a broad-spectrum sunscreen, protective outerwear, and limitation of sun exposure.[13] SOR B

TOPICAL TREATMENT

- Topical corticosteroids may be used for refractory skin disease and may improve redness and itching; however resistant skin disease should clue the clinician to potentially increasing systemic disease activity.[1] SOR B
- Topical pimecrolimus also is also an adjunctive therapy used to decrease redness and itching in the treatment of refractory skin manifestations.[1]

ORAL TREATMENT

- Corticosteroids are the mainstay for treatment of juvenile dermatomyositis. First-line therapy for muscle disease is high-dose (2 mg/kg oral single daily dose with a maximum daily dose of 60 mg) systemic corticosteroids, usually prednisone, with or without an immunosuppressive (“steroid-sparing”) agent. Typically in children this agent is methotrexate (oral or subcutaneous).[13,36]
- Experts typically agree that steroid taper should be initiated based on: improved or normal muscle strength, enzymes improved or normal, rash stable or improved, and physician judgment after about 4 weeks on high-dose steroid treatment.[36]
- High dose oral steroid taper should be slow, typically over a minimum of 1 to 2 years.[24,36,38]
- If no response, based on clinician judgment, to initial four weeks of treatment with high-dose steroids, addition of an immune modulators (intravenous immunoglobulin, cyclosporine, mycophenolate mofetil, azathioprine, or biologic agent), or IV methylprednisolone should be considered.[36] SOR B
- Lack of response after 2 to 3 months of treatment should lead to a reexamination of the diagnosis and perhaps another muscle biopsy.[39]
- Methotrexate is effective in treating the muscular symptoms of juvenile dermatomyositis as a steroid-sparing agent. Methotrexate, when added to prednisone in initial therapy, has been shown to result in good disease control and limit the cumulative dose of steroid.[38] SOR B
- Oral or subcutaneous methotrexate dosing starts at 1mg/kg once weekly or 15 mg/m^2 weekly (maximum dose of 40 mg).[1,36]

- Using methotrexate safely requires a number of precautions. All patients should have a complete blood count with differential, liver and renal function panels, hepatitis, and VZV serology, a urinalysis, C-reactive protein, and erythrocyte sedimentation rate. A purified protein derivative (PPD) should be placed or a QuantiFERON-TB Gold assay performed to rule out latent tuberculosis. Patients with active liver disease, including hepatitis C and alcoholic cirrhosis, should receive alternative forms of therapy. Female patients should avoid becoming pregnant during therapy. Folic acid supplementation while on methotrexate of 1 mg of folic acid daily is important to prevent side effects.[40]
- While taking methotrexate, the patient should be followed with regular laboratory tests including: complete blood count with differential, liver and renal function panels, and a urinalysis. This should typically be performed after 4 weeks of treatment then every 8 to 12 weeks.[40] Methotrexate should only be prescribed by doctors familiar with its risks and benefits.
- Cyclosporine is a steroid sparing agent that is typically considered a second line agent in the treatment of juvenile dermatomyositis but has shown to be beneficial in the treatment of refractory disease.[1,39] SOR B Cyclosporine should be used cautiously with monitoring of blood pressure, renal function, liver function, and hematologic parameters. Side effects may include headache, tremor, and gastrointestinal symptoms.[39]
- Cyclosporine has also been shown to be efficacious in steroid-resistant interstitial lung disease associated with juvenile dermatomyositis. Initiation of cyclosporine has been recommended for rapidly progressive interstitial lung disease.[33,39]
- Azathioprine is also considered a second line agent in the treatment of juvenile dermatomyositis.[1] It is commonly used in chronic inflammatory diseases as a steroid-sparing agent. Like all of the other immunosuppressive agents, azathioprine must be used cautiously by physicians familiar with its risks.
- Tacrolimus, a calcineurin inhibitor, is second line therapy and has adverse effects similar to cyclosporine; however, tacrolimus has greater potency. It is effective in refractory juvenile dermatomyositis.[1,39]

- Mycophenolate mofetil, an inhibitor of T-cell and B-cell proliferation, is a corticosteroid-sparing agent that affects both refractory cutaneous and muscular disease. It is considered a second line therapy for juvenile dermatomyositis.[1]
- Hydroxychloroquine is used as a steroid-sparing agent in mild disease. It has been shown to be particularly beneficial for the rash of juvenile dermatomyositis.[41,42] One report, however, note worsening of the rash and another found a higher incidence of cutaneous drug reactions in patients taking hydroxychloroquine with dermatomyositis.[43,44] SOR Ⓒ
- Biologics, including tumor necrosis factor (TNF)-α inhibitors, are currently being tested for use in juvenile dermatomyositis. Conflicting and discouraging initial results prompt the need for further clinical trials. The TNF-α inhibitor, infliximab, has been used with good effect in the treatment of calcinosis in juvenile dermatomysositis.[1,45]
- Other agents used in the treatment of calcinosis include bisphosphonates and calcium channel blockers. Some patients may require surgical excision in areas causing chronic pain, recurrent infection, or debilitating functional status.[1]
- It is important to look at these medications’ side-effect profiles and monitor the patient accordingly during treatment. Patients must not get pregnant while on these medications and various labs need to be followed.

INTRAVENOUS TREATMENT

- Pulsed intravenous methylprednisolone has been advocated for severe disease in juvenile dermatomyositis.[41] SOR Ⓒ
- The safest and most efficacious route of steroid administration in juvenile dermatomyositis is unclear. IV methylprednisolone has not been shown to be superior to oral corticosteroids in the early treatment of moderate cases of juvenile dermatomyositis; however, it may improve cost effectiveness by decreasing the duration of disease.[46,47]
- Studies investigating the efficacy of intravenous immunoglobulin (IVIG) in children are lacking.[1] IVIG may be beneficial as a steroid-sparing

agent.[48] Risks associated with the use of IVIG include infusion reactions (nausea, vomiting, fever, or lethargy) and exposure to blood product. In children, this may be associated with the presence of IgA in the infusion.[49] SOR Ⓒ

- Rituximab is a monoclonal antibody directed primarily against proteins present on B-cells. Adult studies have shown potential efficacy in the treatment of myositis. Currently, placebo-controlled trials are underway to determine its potential benefit in the treatment of juvenile dermatomyositis.[1,39]

MALIGNANCY WORK-UP

- The association between adult cases of dermatomyositis and malignancy has been well documented. Adult patients with dermatomyositis, regardless of age, should undergo an age- and gender-relevant malignancy work-up beginning at the time of diagnosis. In contrast, malignancy is very rare in cases of juvenile dermatomyositis, often consisting of isolated case reports.[3,50]
- Extensive evaluation for an underlying malignancy at diagnosis is not recommended.[5,50]
- Cases of juvenile dermatomyositis that are associated with an underlying malignancy typically have additional features noted on physical exam, including extensive lymphadenopathy, splenomegaly, or an atypical rash. The finding of these additional features on exam indicates the need for further evaluation of malignancy in these patients before the initiation of immunosuppressive therapy.[50]
- The most common malignancies noted on review of patients with juvenile dermatomyositis were leukemias and lymphomas.[50]
- The link between malignancy and juvenile dermatomyositis remains unclear, though it is possible that dermatomyositis represents a paraneoplastic syndrome. Underlying changes in the immune system along with the effects of immunosuppressive agents used in treatment may play a role.[50]

- Patients with juvenile dermatomyositis should be continually monitored for malignancy during treatment with immunosuppressive therapy, even if malignancy is not suspected at diagnosis or on initiation of treatment.[50]

PROGNOSIS

The mortality rate of juvenile dermatomyositis is less than 5 percent, which is notably lower than that seen in adult cases.[1,3,4] Despite this, over half of patients have a chronic disease course, with continued disease activity and need for medications two to three years after diagnosis.[16,23] Eight percent of patients may have continued moderate to severe disability.[23] The median time to remission (absence of rash, no active myositis, and no need for immunosuppressive agents for 6 months) has been reported to be approximately 4.67 years.[16] Poor outcome has been linked to delay in treatment and the initiation of low-dose treatment.[24] The presence of lipodystrophy and calcinosis, both complications of dermatomyositis, is associated with a longer duration of active disease.[4] Similarly, the presence of Gottron papules 3 months after diagnosis and Gottron papules plus abnormal nailfold capillaries at 6 months after diagnosis may predict a longer time to remission.[16]

FOLLOW-UP

These patients need very close and frequent follow-up to manage their medications and overall care. High doses of steroids and steroid-sparing agents, such as methotrexate, have numerous potential side effects. These patients need to be closely followed with laboratory tests and careful titration of the toxic medicines used for treatment. Patients need physical therapy, periodic eye exams for cataracts, and weight monitoring. Specific supplements including calcium, vitamin D and folic acid may be added to prevent some of the side effects of the strong medications being prescribed.

Children on long-term corticosteroids should also be monitored for decelerated growth, one of the side effects of long-term corticosteroid use.

PATIENT EDUCATION

Discuss the importance of sun protection as sun exposure does make the cutaneous manifestations worse. Counseling about the serious nature of the disease and prognosis is important as many patients may develop substantial weakness and decline in physical functioning. Patients need to understand that the medications being used have many risks along with their benefits and need to report side effects to their physicians. Pregnancy prevention is needed for females of childbearing potential while on a number of the medications used to treat this disease.

175 HENOCH SCHONLEIN PURPURA

Margaret L. Burks, MD
Richard P. Usatine, MD

PATIENT STORY

A previously healthy 8-year-old boy presented with 2 days of knee and ankle pain with no known cause. His parents denied that he had any trauma or fever. On physical examination, he was afebrile in no apparent distress. His left knee was swollen and tender (**Figure 175-1**). He admitted to other joint pains but there was no swelling or tenderness in the other joints. The pediatrician noted a petechial and purpuric eruption from his buttocks down to his ankles (**Figure 175-1**). It was non-blanching but only barely palpable. There were prominent circumferential petechiae around the left sock area. Upon further questioning, the mother admitted that her son had a viral upper respiratory infection 2 weeks ago. A urinalysis showed mild hematuria but no proteinuria. He never developed abdominal pain. Therapy was supportive and systemic corticosteroids were not used.

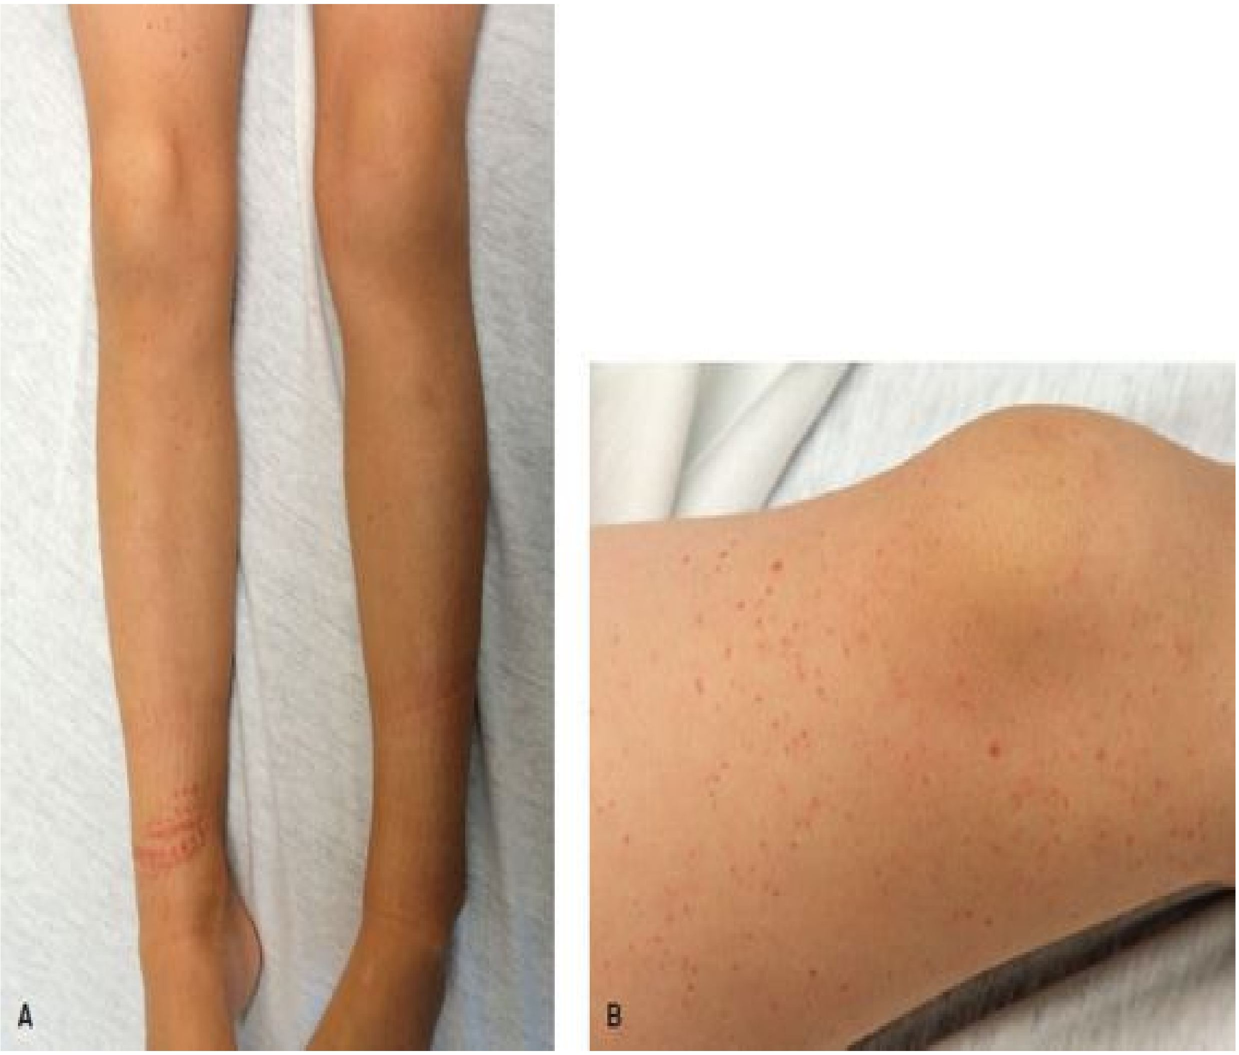

FIGURE 175-1 Henoch-Schönlein purpura (HSP) in an 8-year-old boy presenting with 2 days of knee and ankle pain 2 weeks after a viral upper respiratory infection. **A.** petechiae are visible on both legs with a prominent sock mark on the right ankle. Note the left knee is somewhat swollen. **B.** A close-up of the petechiae that are slightly palpable. There is no obvious purpura at this time. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

Henoch-Schonlein Purpura (HSP) is a small vessel vasculitis characterized in children by a classic, palpable, purpuric rash over the lower extremities.

In addition to the rash, children may also exhibit arthralgias, hematuria, and abdominal pain. The exact disease trigger is unknown; however, the symptoms of HSP are attributed to IgA deposition in the systemic vasculature. Though a minority of patients may develop long-term renal complications, the majority of cases are self-limited.

SYNONYMS

- In the early 20th century, HSP was thought to be due to anaphylaxis. Consequently, the disease was named "anaphylactoid purpura." Occasionally, this term may still be used in reference to HSP.[1]

EPIDEMIOLOGY

- HSP is the most common vasculitis in the pediatric population.[2]
- Although HSP may affect all age groups, it is most common between children ages 2 to 6 years old.[2–4]
- The disease affects an estimated 70.3 per 100,000 children per year.[2,3]
- A very slight male predominance exists with a 1.2:1 male to female ratio.[2,3]
- White children have a much higher incidence compared to black children.[2,3]
- Though the incidence has been reported to be about 100 times greater in children than adults, HSP is typically less severe in the pediatric population.[5]
- The peak disease occurrence is in the fall and winter months.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- HSP is an immune complex-mediated disease.[2]
- Clinical symptoms are due to widespread IgA deposits in the small vessels of the GI tract, renal glomeruli, and skin.[1,4] IgA activates a local inflammatory response which leads to necrosis of the blood vessels.[2]
- IgA may bind to endothelial cells of the vasculature and lead to the destruction of these cells by activation of complement or PMNs with the subsequent release of reactive oxygen species. The exact pathogenic mechanism, however, remains unknown.[6]

RISK FACTORS

- HSP is preceded by an upper respiratory tract infection in up to 90 percent of patients (**Figure 175-1**).[7] Many different respiratory pathogens have been linked to HSP, including group A β-hemolytic streptococcus.[1,5,7,8]
- Although many studies have speculated that a potential relationship exists between respiratory pathogens and the development of HSP, no single pathogen has shown to be the definitive causal agent.[1]
- Risk factors for renal disease in HSP remain unclear. Older age at onset, persistent purpura, and severe abdominal pain have been cited by some studies as risk factors for the development of renal disease.[9–11]
- Some experts hypothesize a genetic susceptibility towards the development of HSP as well as toward renal involvement; however, no definitive genetic polymorphism has been linked to the disease.[2,6,12]
- HSP is more common in children with a history of familial Mediterranean fever.[2,13]

DIAGNOSIS

- HSP is a clinical diagnosis.[5]
- Diagnostic criteria include—The presence of nonthrombocytopenic palpable purpura (considered a mandatory criteria) plus at least one of the following four clinical features:[5,14]
  - Diffuse abdominal pain.
  - Any biopsy showing predominantly IgA deposition.
  - Arthritis or arthralgia.
  - Renal involvement (proteinuria and/or hematuria).
- The majority of children do not require renal or skin biopsy to confirm diagnosis unless severe renal involvement is suspected or skin findings appear atypical.[15]
- Biopsy of the purpura, as well as of nonaffected areas, will reveal IgA deposition under immunofluorescence.[15]
- Renal biopsy will demonstrate mesangial proliferation and focal necrosis, classically described as a “focal and segmental proliferative glomerulonephritis.” Cresecent formation is evident in cases of rapidly progressive disease.[2,15]

CLINICAL FEATURES

- The classic palpable, purpuric rash is essential for diagnosis.[2] It is the presenting symptom in over half of the cases of HSP; however, it may not always be seen at initial presentation.[2,16,17]
- Both joint pain and abdominal pain may precede the classic rash in up to 43 percent of patients by up to two weeks.[1,2]
- The purpura are typically 2 to 10 mm in diameter and accompanied by scattered pinpoint petechiae and ecchymoses (**Figure 175-2**).[1]
- The rash may appear urticarial or macular-papular for the first 24 hours.[1]
- Bullous lesions may develop in some children.[1]
- Fatigue and low-grade fever are common.[18]

- Joint pain is present in up to 82 percent of patients. It most often involves the lower extremities, including the feet, ankles, and knees; however, up to 37 percent of patients may have additional pain in the hands, wrists and elbows.[1,2]
- Abdominal pain is present in 50 percent to 75 percent of cases of HSP (**Figure 175-3**). It is described as “colicky,” or a “bowel angina,” and may be accompanied by vomiting.[1,2,6]
- The abdominal pain is often considered mild, however severely debilitating pain may occur in some individuals.[2]
- Gastrointestinal bleeding, either gross or occult, is noted in approximately half of children with abdominal pain related to HSP.[1]
- Renal involvement is present in approximately 50 percent of cases.[5,19,20]
- While rarely severe, renal manifestations can range from mild and benign to a rapidly progressive glomerulonephritis with crescent formation and renal failure.[20,21]
- Nephritis is typically evidenced by microscopic hematuria with or without proteinuria; however, macroscopic hematuria may also be present.[2,21]
- Some children with renal involvement may also have hypertension.[2]
- A less common clinical feature includes testicular involvement in male children. This may present as epididymitis or orchitis with swelling and pain.[1,2,16] Testicular involvement may be the presenting symptom in some male children.[16]
- CNS involvement is rare, but may occur. Headache, seizures, intracranial hemorrhage and cerebral vasculitis may be present in about 2 percent of patients.[2,22]
- Most CNS manifestations are mild and resolve without permanent consequences. Severe or fatal neurologic complications are very rare.[22]

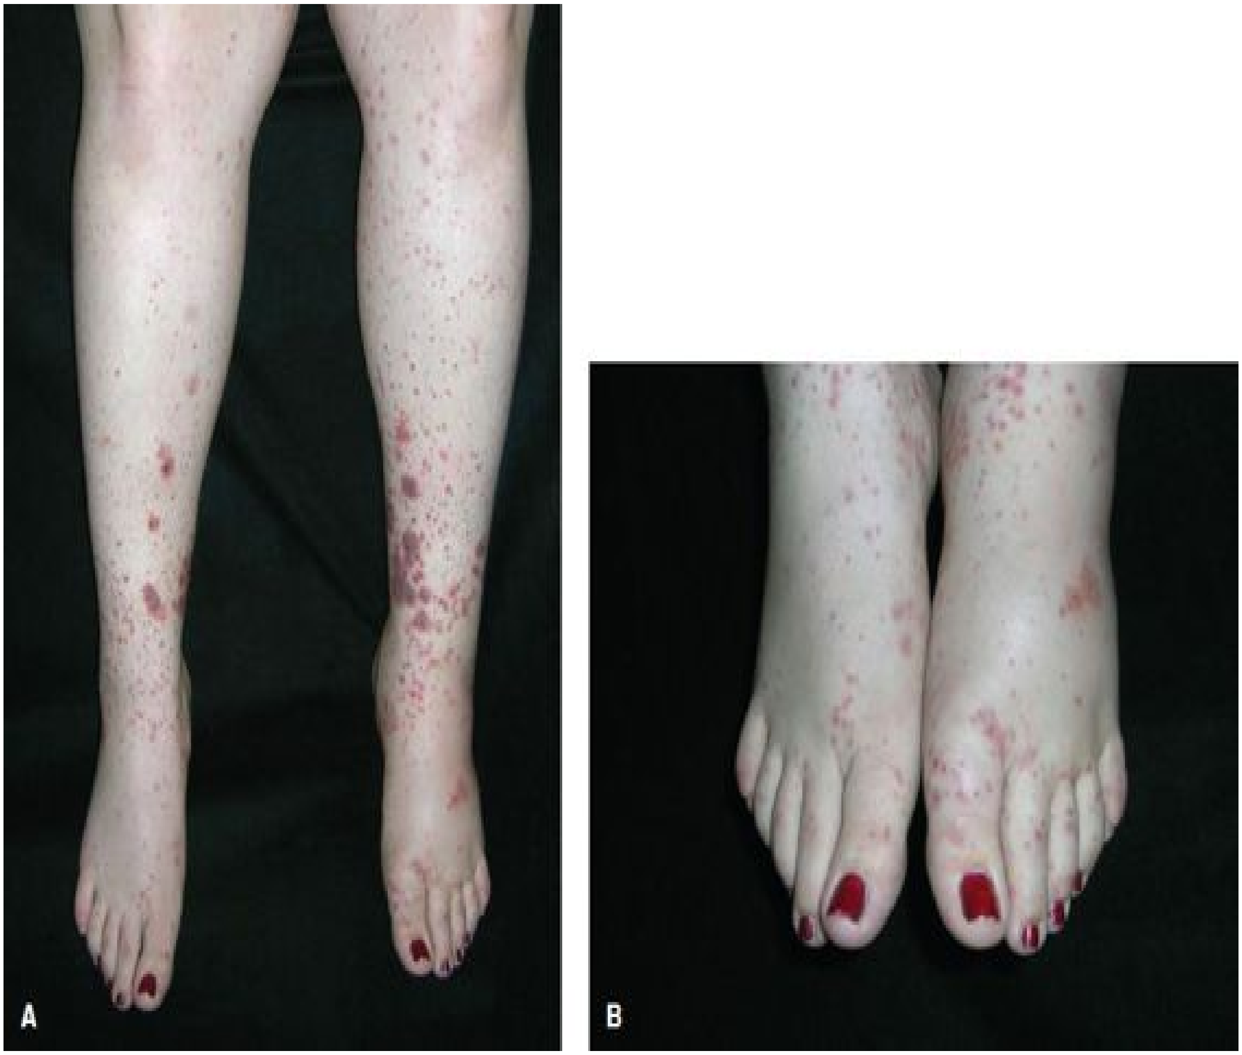

FIGURE 175-2 Henoch-Schönlein purpura (HSP) in an overweight teenage girl presenting with a rash, ankle pain and swelling. **A.** Note the palpable purpura on both legs and the ankle swelling. **B.** Note the soft tissue swelling of the feet along with the petechial eruption. (*Used with permission from Richard P. Usatine, MD*.)

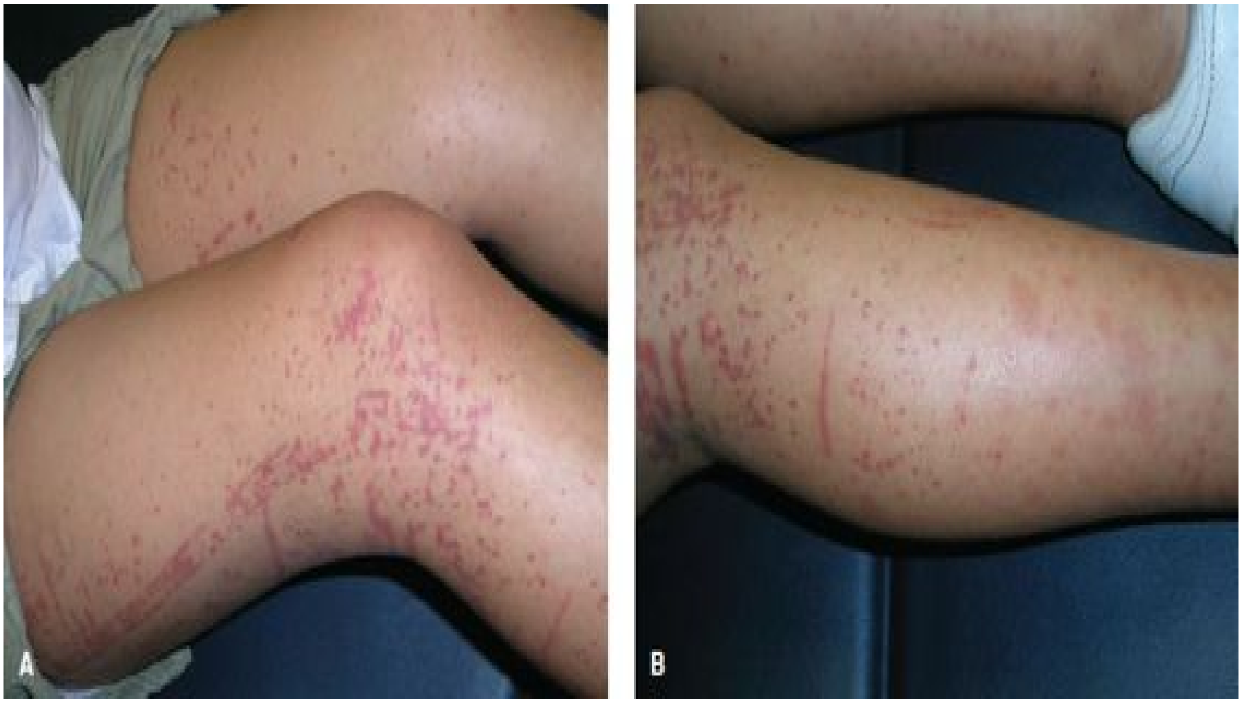

FIGURE 175-3 Henoch-Schönlein purpura (HSP) in an 11-year-old girl. She presented with a rash, knee pain and abdominal pain that was already resolving. **A.** Petechial eruption is particularly evident under the area where the seams of her jeans pressed on the leg. B. Petechiae and purpura on the lower leg. (*Used with permission from Richard P. Usatine, MD*.)

DISTRIBUTION

- The classic palpable, purpuric rash is symmetrical and distributed predominantly over the extensor surfaces of the lower extremities (**Figures 175-1** to **175-4**) and buttocks; however, it may be present in other areas as well.[1,2]

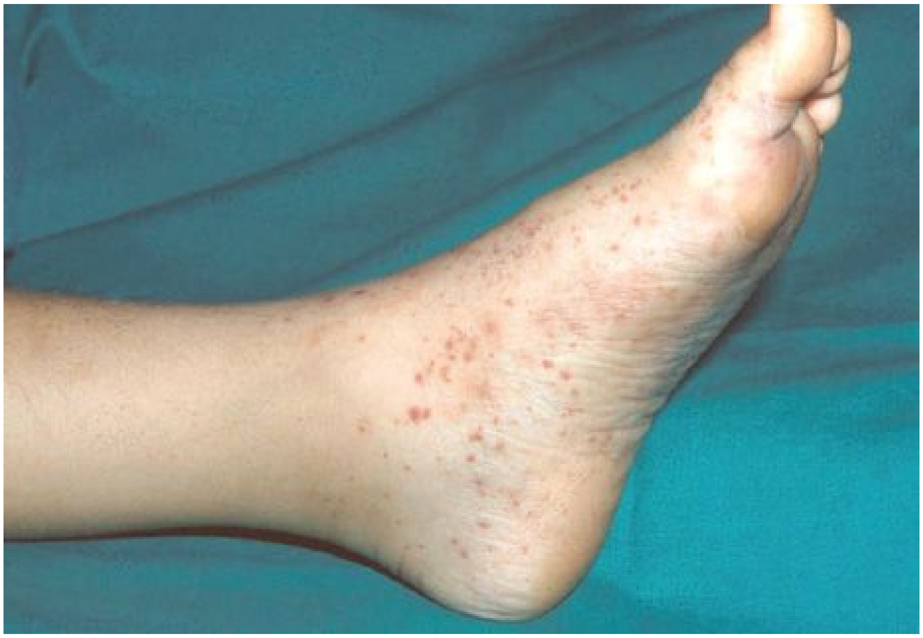

FIGURE 175-4 Henoch-Schönlein purpura (HSP) with prominent involvement of the foot of this child. (*Used with permission from Camille Sabella, MD.*)

- In some cases, the purpuric lesions may spread to the child's trunk and face.[2]

LABORATORY TESTING

- No single laboratory test is diagnostic for HSP.[2]
- Experts recommend the following for initial investigation of HSP:[2]
  - CBC (anemia due to GI bleeding and a leukocytosis may be present).
  - ESR (may be elevated).
  - Clotting profile (normal in HSP).
  - Serum chemistry (to monitor renal function).
  - Albumin (may be low due to GI or renal involvement).
  - ASO titer and anti-DNase B (for possible preceding streptococcal infection).
  - Urine dipstick (evaluate for proteinuria and hematuria).
  - If purpura are present and the diagnosis is unclear, a full sepsis work-up may be warranted.

- Increased levels of serum IgA are often present, especially during the acute phase of the disease.[6,7]
- Complement levels in HSP are typically normal.[23]

IMAGING

- Imaging is not routinely performed in the evaluation of HSP.[18]
- Intussusception is a rare complication of HSP in the pediatric population.[2,12] Ultrasound or CT may be used to look for a suspected intussusception in a child with abdominal pain.[24]
- MRI may be used for the diagnosis of suspected cerebral vasculitis.[22]

DIFFERENTIAL DIAGNOSIS

- IgA nephropathy (Berger's disease) has similar renal manifestations and histologic findings on renal biopsy, including hypercellularity and mesangial proliferation.[2] HSP and IgA nephropathy are both attributed to IgA deposition.[4] Some experts even suggest that HSP and IgA nephropathy actually represent different manifestations of the same disease process.[23,25]
- Septic meningococcal infection may present with purpura on the extremities, similar to HSP.[15] However, in meningococcal infection, the patient likely has additional symptoms of fever and meningitis (see **Figure 153-12**).
- Wegner's granulomatosis may mimic the renal effects of HSP with proteinuria and hematuria;[15] however, Wegner's will typically also affect the upper respiratory tract. In contrast to HSP, patients with Wegner's classically test positive for c-ANCA antibodies.[15,18]
- Rocky Mountain spotted fever may present with palpable purpura, similar in appearance to HSP.[18] The rash, however, has a characteristic spreading

pattern and will begin on the palms and soles and spread to the trunk and extremities (see **Figures 175-5** and **188-1**).

- Cutaneous leukocytoclastic vasculitis can present with palpable purpura and arthralgia; however, cutaneous leukocytoclastic vasculitis will not have renal involvement (see Chapter 153, Vasculitis).[15,18]
- Purpura due to thrombocytopenia of many causes (including leukemia in children) may mimic the characteristic rash of HSP with the appearance of purpura and petechiae; however, HSP will show a normal platelet count and coagulation profile.[15,18]

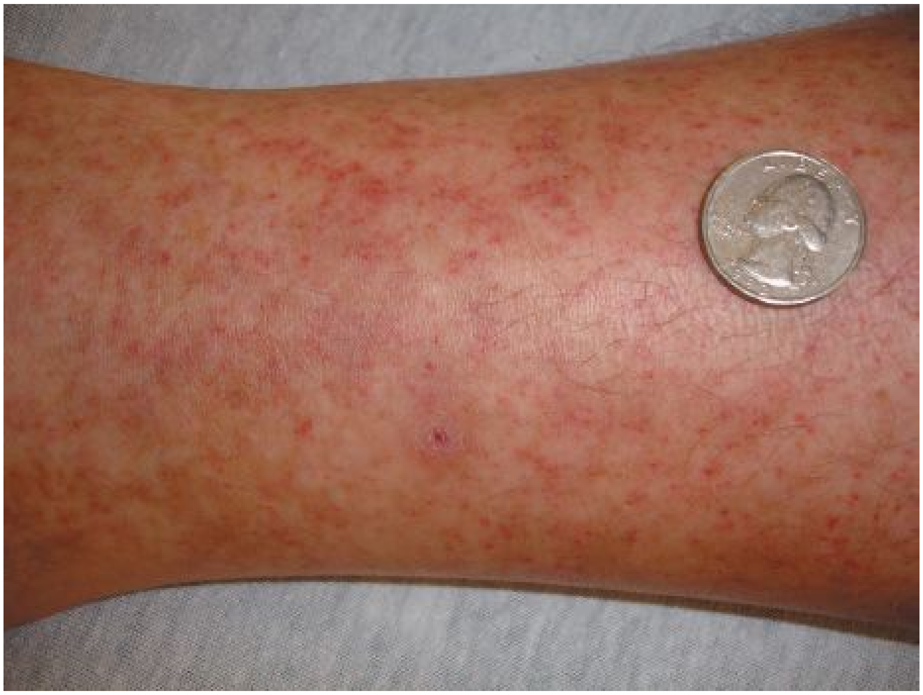

FIGURE 175-5 Rocky Mountain spotted fever with many petechiae visible around the original tick bite. This rickettsial disease looks similar to vasculitis. (*Used with permission from Tom Moore, MD*.)

MANAGEMENT

- There is not a consensus among experts about optimal treatment regimens for children diagnosed with HSP.[2]

- Not all patients with HSP require treatment with steroids. In general, patients with mild disease require only symptomatic treatment.[15,23]
- Some experts recommend that steroid treatment be specifically used in patients with a high risk of renal involvement or severe extrarenal symptoms.[9]

NONPHARMACOLOGIC

- Supportive therapy with hydration is adequate in mild cases.[18]
- Arthralgias may be lessened with rest and elevation.[15,18]

MEDICATIONS

- For skin lesions, most patients will not need treatment, as these lesions are typically self-resolving. However, bullous lesions may respond to corticosteroid treatment.[2]
- NSAIDS have been used with good effect in arthritis associated with HSP; however, caution must be exercised due to the detrimental effects of NSAIDS on renal function.[2]
- Prednisone has proven to be effective in the treatment of extrarenal symptoms such as joint pain and abdominal pain.[2,9,12,18] The early use of prednisone has been recommended for severe extrarenal symptoms, typically at 1mg/kg/day for 2 weeks with weaning over the following 2 weeks.[9,15] SOR Ⓒ
    - There is a lack of evidence and controlled trials to guide treatment of HSP nephritis.[12] It is controversial whether early treatment with corticosteroids is effective preventing the progression of renal disease.[9,26]
    - For children with >6 months of proteinuria, use of an ACE inhibitor may help reduce glomerular injury.[15,20]
    - Though very little data exists about the treatment of rapidly progressive glomerulonephritis due to HSP, uncontrolled data has shown that

  treatment options include aggressive therapy with corticosteroids, cyclophosphamide, and, potentially, plasma exchange.[15,20]
  - Cyclosporine A, azathioprine, and cyclophosphamide may also be effective in rapidly progressive disease.[15,20]
- Plasma exchange has been reported for use in rapidly progressive glomerulonephritis, though it is not recommended currently due to scarcity of data.[20]

SURGERY

- Contrast enema was shown in one recent study to be safe, though typically unsuccessful, in the reduction of intussusceptions due to HSP.[18,24]
- Intussusception in HSP is typically ileocolic or ileoileal and contrast enemas are often unable to reach these locations. The patient may subsequently require surgical reduction and resection.[24]

REFERRAL

- Immediate referral to a nephrologist should be made if the patient displays hypertension, abnormal renal function, acute nephritis, nephrotic syndrome, persistent proteinuria, or macroscopic hematuria for longer than 5 days.[2]

PREVENTION AND SCREENING

- Despite HSP being the most common vasculitis in children, definitive data on preventative measures is lacking in the literature.[5]
- Corticosteroid treatment at presentation has not been shown to prevent the development of nephritis in newly diagnosed cases of HSP.[9,12,20,27]
- Similarly, corticosteroids have not been shown to prevent recurrence of disease.[1]

PROGNOSIS

- In general, the prognosis of HSP is very good. The majority of children will not develop long term renal complications.[21]
- The mortality rate of HSP is <1 percent.[28]
- Most of the features of HSP are self-resolving, lasting an average of 4 weeks.[12]
- Chronic renal impairment is seen in only 1.1 to 5.0 percent of patients with HSP.[10,23,28]
- Long term prognosis is linked to the severity of renal disease.[2,12] Poor long-term outcome is associated with severe renal disease at diagnosis, while patents with hematuria and mild or absent proteinuria typically have a very benign course with full recovery.[23,29]
- No single prognostic factor (proteinuria, hematuria, renal function) can reliably predict outcomes of glomerulonephritis due to HSP in children; however, symptoms and severity of nephritis at onset of disease have been shown to be more predictive of long term morbidity than renal biopsy.[29–31]
- One study suggests that severity of renal symptoms at diagnosis should be regarded as equally important in making treatment decisions as biopsy results.[29]
- Patients with nephrotic syndrome have a worse prognosis, with 20 to 50 percent of these patients experiencing long-term renal impairment.[12,19,21]
- If no renal symptoms develop within one month of the onset of HSP, there is likely a very favorable prognosis for long term renal function.[9,29]
- Adult women with a history of HSP in childhood are at increased risk of hypertension and proteinuria during pregnancy and require frequent monitoring for these complications.[2] This risk exists even if the patient had only mild renal disease at diagnosis.[4,29]

FOLLOW-UP

- Up to 1/3 of patients will have a recurrence of their disease 6 months after the initial diagnosis.[18] Recurrence is more common in patients with renal disease and is usually is less severe and of shorter duration than the initial episode.[1,2,18]
- It is recommended by some experts that children diagnosed with HSP should be evaluated monthly for at least 6 months following their diagnosis, even if urinalysis is normal at diagnosis.[2,21]
- Follow-up should include monitoring of blood pressure as well as a urinalysis to evaluate for proteinuria and hematuria.[2,18] If proteinuria or hematuria is present, BUN and creatinine should be evaluated.[18,21]
- It is suggested that no follow up is needed after 6 months if the patient's urinalysis remains normal; however, patients diagnosed with nephritis due to HSP should be followed for longer than 6 months.[19,21]

PATIENT EDUCATION

- Reassure parents that most children with HSP have no long lasting effects.
- Renal disease is the most common long term complication so urine testing will be needed for some time.

176 PERIODIC FEVER SYNDROMES

Shoghik Akoghlanian, MD
Andrew Zeft, MD MPH

PATIENT STORY

A 6-year-old Caucasian boy is seen by his pediatrician for a 14-month history of fever episodes lasting up to 10 days. During these episodes, he develops a red rash, nonspecific joint pains, and abdominal pain variably accompanied by diarrhea. Between episodes he is asymptomatic. He has had serial evaluations in the primary care clinic and has been admitted to a children’s hospital for work up to rule out potential infectious, gastrointestinal, and oncologic etiologies. The work-up is only positive for nonspecific elevations in inflammatory markers and a mild leukocytosis. The pediatrician suspects a periodic fever syndrome and refers the child to a pediatric rheumatologist. During an episode of fever, the child is evaluated by the pediatric rheumatologist. The only clinical finding is a rash on the back and trunk (**Figure 176-1**). Work-up for a periodic fever syndrome reveals a heterozygous missense mutation in the gene encoding the cell surface receptor for tumor necrosis factor (TNF) TNFRSF1A, and the diagnosis of tumor necrosis factor receptor-associated periodic syndrome (TRAPS) is made. The boy is treated with etanercept, a soluble TNF-α receptor fusion protein, after which the frequency and severity of his episodes lessen.

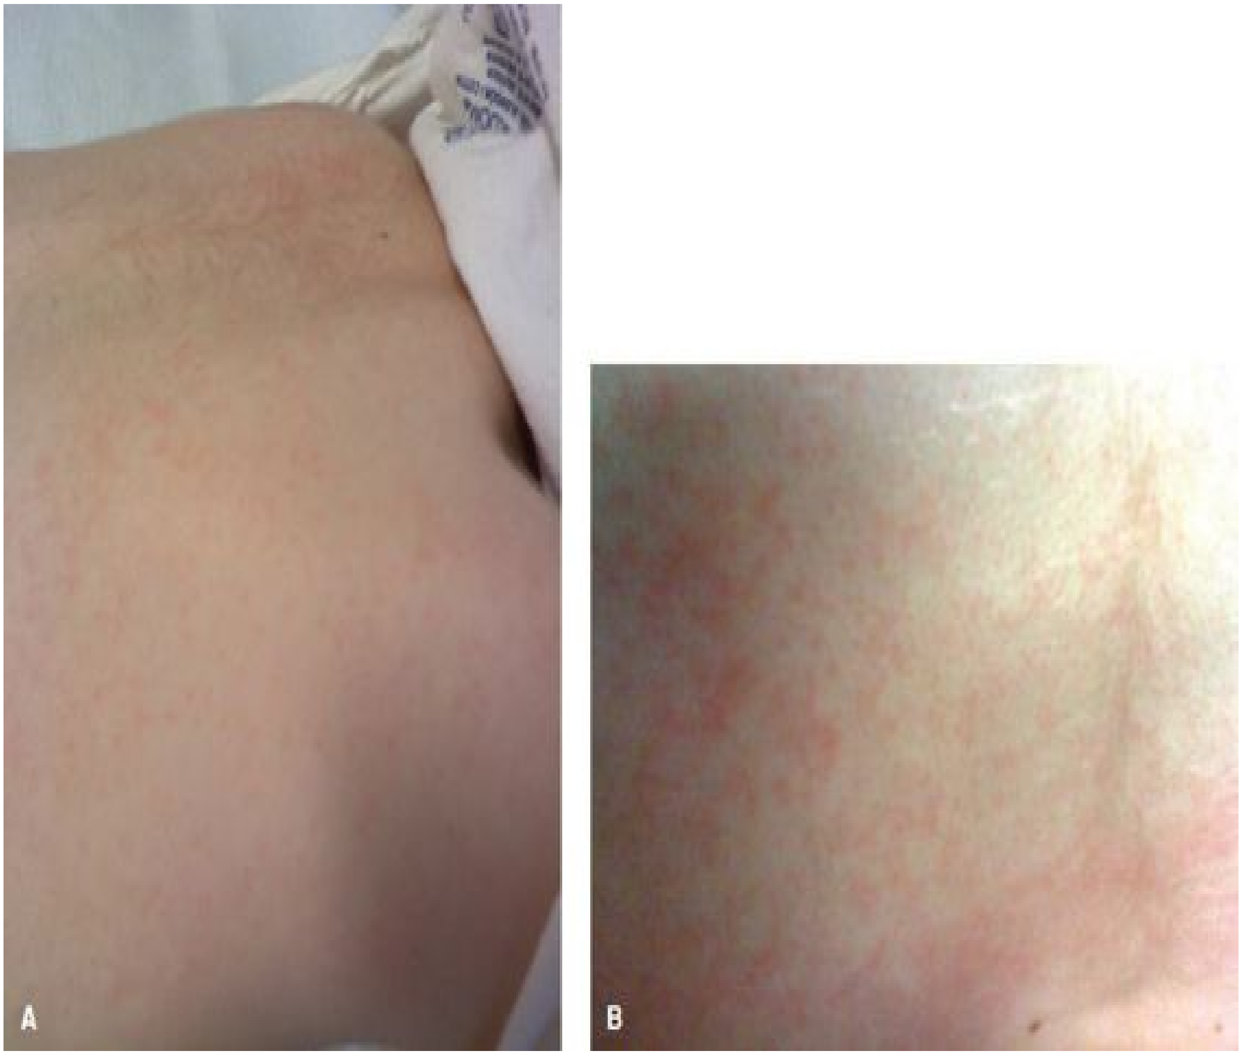

FIGURE 176-1 **A.** Erythematous eruption on the back of a child (a) with periodic fever who was confirmed to have tumor necrosis factor receptor associated periodic syndrome (TRAPS). **B.** A close-up view reveals speckled patches with some areas of confluence, which is characteristic of this syndrome. This resembles a viral exanthem. (*Used with permission from Andrew Zeft, MD*.)

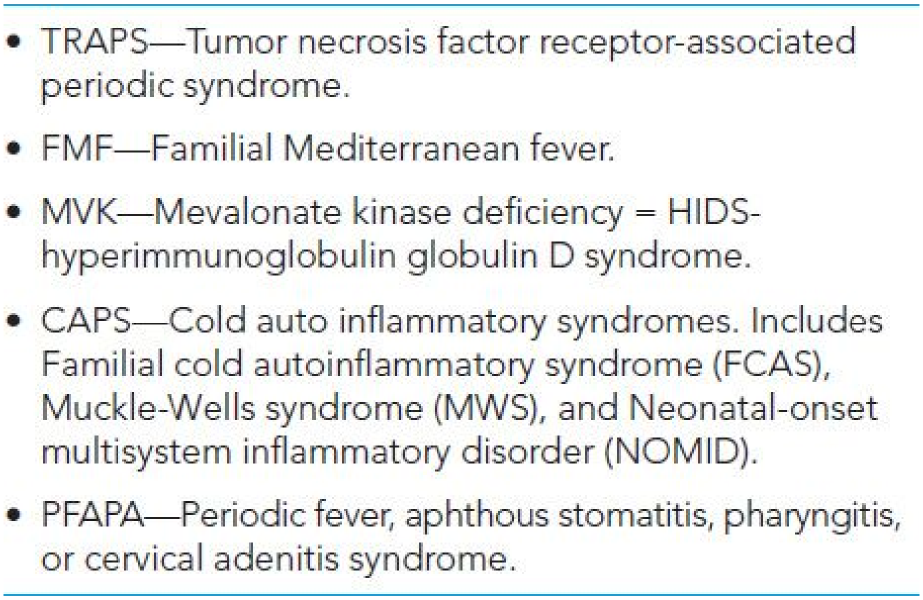
INTRODUCTION

Periodic fever syndromes refer to a class of auto-inflammatory (AI) disorders characterized by spells of fever with other associated symptoms, typically occurring with three or more episodes of unexplained fever in a six-month period at least seven days apart. As in the case presented, a recurrent fever syndrome diagnosis may have a monogenetic etiology; however, many cases are characterized phenotypically,[1] There is an expanding spectrum of genetic AI diseases including but not limited to: TRAPS, familial Mediterranean fever (FMF), mevalonate kinase deficiency (MVK), otherwise known as hyperimmunoglobulin D syndrome (HIDS), and cryopyrin associated periodic syndromes (CAPS), which includes three overlapping phenotypes (familial cold auto-inflammatory syndrome, Muckle-Wells syndrome, or neonatal onset multisystem inflammatory disease). The disorder termed periodic fever, aphthous stomatitis, pharyngitis, or cervical adenitis syndrome (PFAPA or Marshall Syndrome), is a benign condition with regular intervals of high fever which last approximately 5 days (**Table 176-1**).[2]

TABLE 176-1 Summary of Autoinflammatory Syndromes and Their Acronyms



- TRAPS—Tumor necrosis factor receptor-associated periodic syndrome.
- FMF—Familial Mediterranean fever.
- MVK—Mevalonate kinase deficiency = HIDS-hyperimmunoglobulin globulin D syndrome.
- CAPS—Cold auto inflammatory syndromes. Includes Familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and Neonatal-onset multisystem inflammatory disorder (NOMID).
- PFAPA—Periodic fever, aphthous stomatitis, pharyngitis, or cervical adenitis syndrome.

SYNONYMS

Periodic fever syndrome, recurrent fever syndrome, or auto-inflammatory disorder.

EPIDEMIOLOGY

- Of the periodic fever syndromes, PFAPA is perceived to be the most prevalent.
- TRAPS may present from infancy into adulthood, but most commonly presents in toddlers. TRAPS patients characteristically have an Irish ancestral pattern.
- FMF is more common in those with Sephardic Jewish, Armenian, or Turkish ancestry. Clinical signs of FMF typically develop by 10 years of age.
- The first HIDS episode typically occurs prior to 12 months. HIDS was first described in patients from the Netherlands and is believed more common in those from Western Europe.
- In France, the prevalence of CAPS with NLRP-3 (pyrin domain) mutations has been estimated 1/360,000.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Unlike classic rheumatic diseases with autoimmune pathogenesis, autoinflammatory diseases do not rely on autoreactive T lymphocytes or pathogenic autoantibodies.
- To date, nearly all mutations linked to AI syndromes disrupt inflammatory signaling within the innate immune system. This disruption generates a pro-inflammatory state, often leading to a final common pathway ending with activation of the inflammasome, a complex of distinct proteins, which serve to convert inactive pro-IL-1β to active pro-IL-1β (**Figure 176-2**).

- Stress or infection may trigger episodes by stimulating an inflammatory process through the inflammasome.
- TRAPS is an autosomal dominantly inherited disease with incomplete penetrance.
- CAPS’ inheritance is autosomal dominant, while FMF and HIDS inheritance is autosomal recessive.

FIGURE 176-2 The inflammasome, is a complex of distinct proteins that when brought together, serve to convert inactive pro-IL 1beta to active IL-1 beta. In CAPS, FMF, and HIDS, mutations stimulate the inflammasome, resulting in activation of Interleukin-1b. In TRAPS, mutant tumor necrosis factor receptor is sequestered, leading to the transcription of pro-inflammatory markers, including Interleukin-1b.

Abbreviations key:

- TRAPS—Tumor necrosis factor receptor-associated periodic syndrome.
- FMF—Familial Mediterranean fever.
- MVK—Mevalonate kinase deficiency.
- HIDS—Hyperimmunoglobulin globulin D syndrome.
- CAPS—Cold auto inflammatory syndrome.
- PFAPA—Periodic fever, aphthous stomatitis, pharyngitis, cervical adenitis syndrome.
- NF—Nuclear factor.
- ASC—Apoptosis-associated speck-like protein containing a casepase activation and recruitment domain.
- TNF—Tumor necrosis factor.
- IL—Interleukin.

(*Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography © 2012-2013. All Rights Reserved*.)

RISK FACTORS

- Family history of unexplained recurrent fever symptoms, hearing loss (Muckle-Wells), renal failure, recurrent abdominal pain, amyloidosis with or without renal failure.[4]
- Although no associated genetic mutation has been identified in PFAPA, close to half of patients have a positive family history of a parent or sibling with symptoms suggestive of the disorder.[5]

DIAGNOSIS

- A symptom log documenting fever duration and associated triggers and symptoms is very important in the diagnostic evaluation.

CLINICAL FEATURES

- Fever, rash, serositis, lymphadenopathy, GI disturbance, and musculoskeletal involvement are the most common clinical signs and symptoms of AI syndromes.
  - Familial Mediterranean Fever is characterized by symptomatic episodes of short duration (12 to 72 hours), fever (~90%), and severe abdominal pain (peritonitis) which may mimic appendicitis. Acute monoarthritis (typically knee or ankle) occurs in over half although chronic arthritis may be present. Headaches may be due to aseptic meningitis.
  - Tumor necrosis factor receptor-associated periodic syndrome is characterized by longer episodes (often >7 days) of fever, abdominal pain, erythematous rash (typically travels proximal to distal), regions of myopathy (**Figure 172-1**), with or without periocular swelling. Deep tissue biopsy often demonstrates a neutrophilic fasciitis sparing the underlying musculature.
  - Hyper Immunoglobulin D syndrome is characterized by cervical lymphadenopathy (90%) and polymorphic erythematous rash (80%, typically palms and soles; **Figure 176-3**). Attacks may be triggered by vaccination or infection; they typically last 3 to 7 days and may reoccur every 3 to 6 weeks.

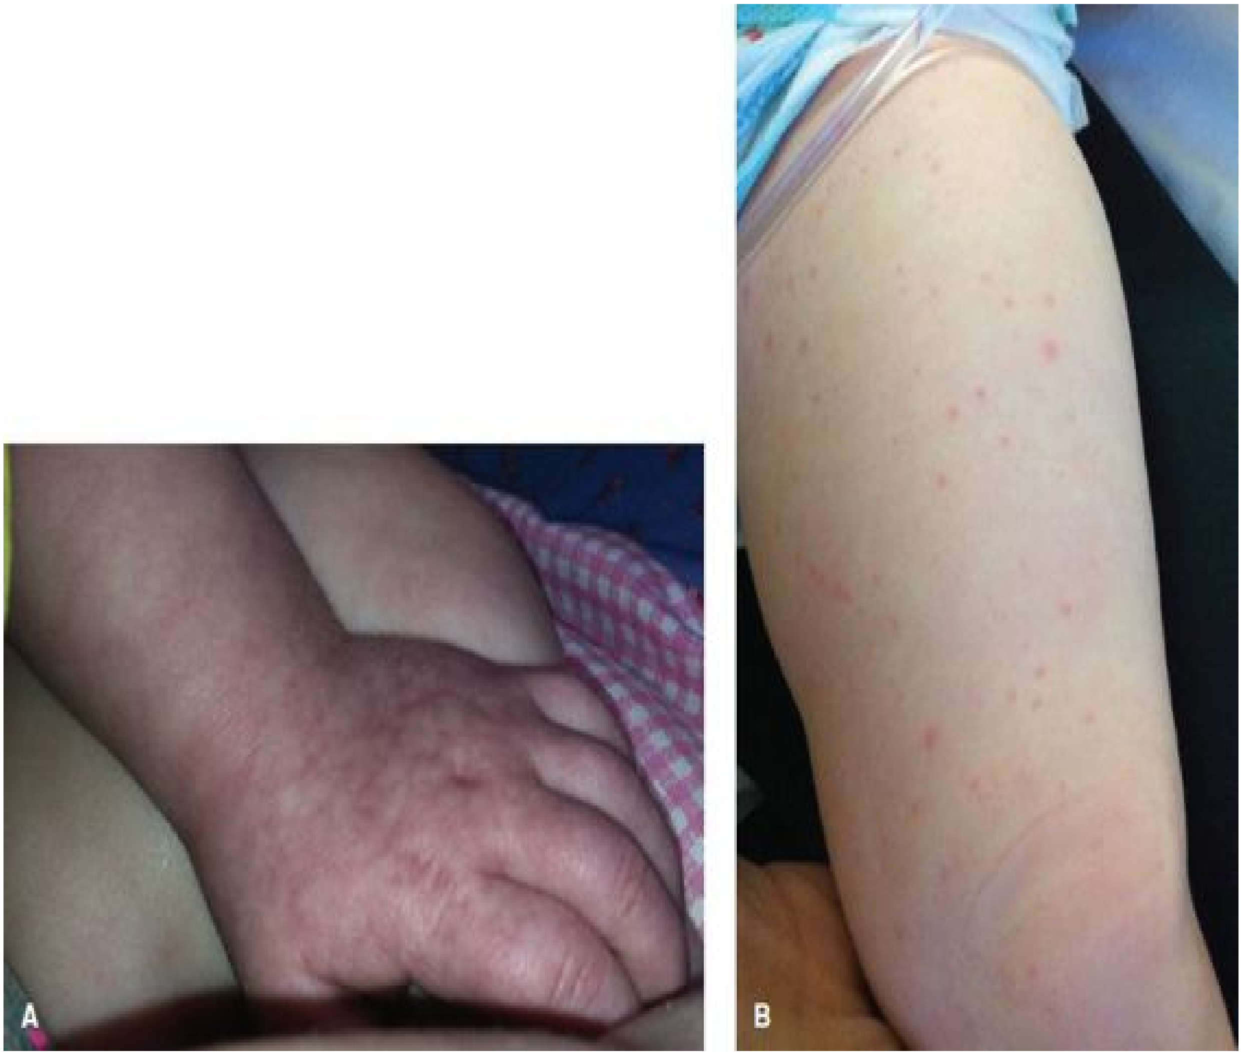

FIGURE 176-3 Polymorphic eruption in a child with hyperimmunoglobulin D syndrome (HIDS). **A.** Reticular pattern on hand and forearm. **B.** Diffuse petechial pattern on the leg. (*Used with permission from Sivia Lapidus, MD*.)

- Periodic fever, aphthous stomatitis, pharyngitis, cervical adenitis syndrome is classically characterized by periodic fevers, aphthous stomatitis, pharyngitis, and cervical lymphadenopathy. However, all the features are rarely present at once during the fever episodes, making the diagnosis difficult.

LABORATORY TESTING

- Elevated acute phase reactants (ESR, CRP) are typical of AI disorders. These may normalize between the attacks.
- FMF is primarily a clinical diagnosis supported by a response to colchicine, but sequencing a mutation within the Mediterranean fever (MEFV) gene is confirmative.
- TRAPS is confirmed by a mutation in the TNFRSF1A gene. Unlike other AI disorders, acute inflammatory markers (ESR, CRP) may remain elevated during subclinical periods.
- Urine mevalonic acid is usually elevated during HIDS attacks. A mevalonic kinase gene mutation is diagnostic. Elevated immunoglobulin D (IgD) is not specific for the diagnosis, but is commonly elevated in HIDS patients.

DIFFERENTIAL DIAGNOSIS

- Recurrent viral or bacterial infections are the most common cause of fever in the pediatric population and should primarily be ruled out.
- *Mycobacteria tuberculosis* and tick-borne relapsing fever may present with prolonged fever and rash. History of recent travel to an endemic area is critical when considering these diagnoses.
- Hematologic disorders such as cyclic neutropenia, leukemia, lymphoma, and inflammatory myofibroblastic tumor (“inflammatory pseudotumor”) should be considered, and prompt referral to a hematologist/oncologist may be necessary.
- Systemic onset Juvenile Idiopathic Arthritis (sJIA) is characterized by prolonged quotidian fever (typically at symptom onset) for >2 weeks, differentiating this condition from true periodic fever syndromes. Arthritis in one or more joint, evanescent erythematosus rash, lymphadenopathy, and hepatosplenomegaly are features of sJIA (see Chapter 172, Juvenile Idiopathic Arthritis).
- Inflammatory bowel disease should be considered in patients with fever and associated abdominal pain, bloody stool, weight loss, joint or eye

manifestations (see Chapter 59, Inflammatory Bowel Disease).

MANAGEMENT

- Supportive care with antipyretics and antianalgesics during the acute episodes are often helpful.

MEDICATIONS

- Systemic corticosteroids may be effective in treating flares of AI syndromes.[6] SOR Ⓒ However, the adverse effects of recurrent steroid use is a significant concern.
- Etanercept, a fusion protein linked to the Tumor necrosis factor (TNF) receptor, has variable efficacy in treating TRAPS.[7] SOR Ⓑ
- In cases not responding adequately to etanercept, an interleukin 1 (IL-1) inhibitor (anakinra, rilonacept) may be efficacious. SOR Ⓒ
- Colchicine is profoundly effective in minimizing the frequency and severity of FMF attacks and in preventing long-term complications (amyloidosis).[6] SOR Ⓐ IL-1 inhibitors may be efficacious in those not tolerating colchicine due to gastrointestinal-related side effects.[7] SOR Ⓑ
- In HIDS, a nonsteroidal anti-inflammatory agent may provide symptomatic relief; otherwise, systemic corticosteroids, colchicine, or biologic TNF or IL-1 inhibitors may be effective.[8] SOR Ⓑ Fortunately, the frequency of HIDS attacks typically decreases with age.[9]

SURGERY

Tonsillectomy leads to complete resolution of PFAPA related symptoms in approximately 2/3 of cases.[10]

REFERRAL

- A referral to a pediatric rheumatologist and/or a pediatric infectious diseases physician should be considered when the diagnosis of a periodic fever syndrome is suspected.
- A referral to an otolaryngologist should be considered for possible tonsillectomy for patients with PFAPA.

PROGNOSIS

- Prognosis depends on the specific periodic fever syndrome. The spectrum of complications is evolving for many of the more recently characterized disorders.
- PFAPA is a benign process that often resolves over time. The time to resolution however, is variable.
- The long-term complications of FMF (amyloidosis) can usually be prevented with appropriate therapy (colchicine).

FOLLOW-UP

- Close follow-up to assess the frequency of episodes and associated symptoms and the response to therapy is essential.
- Pediatric rheumatologists and/or pediatric infectious diseases specialists are often involved in the follow-up of these patients.

PATIENT EDUCATION

- A thorough log diary of the frequency of the episodes and associated features are very important.

- Parents should be told that a precise etiology for the periodic fevers is often not ascertained.

177 KAWASAKI DISEASE

Camille Sabella, MD
Athar M. Qureshi, MD

PATIENT STORY

A 13-month-old previously healthy boy was admitted to the hospital with a 7-day history of high fever and marked irritability. Over the past 3 days, his parents noted that he had developed a red rash over his face, trunk, and extremities, as well as redness and cracking of his lips. He was also noted to have swelling in his hands and feet. He was admitted because of concern of Kawasaki disease. On physical examination, he was irritable and ill-appearing, had a diffuse pleomorphic rash on his face, trunk, and extremities (**Figure 177-1**), nonpurulent conjunctivitis, cracked fissured lips (**Figure 177-2**), a tender 2 cm-diameter lymph node in his posterior cervical area, and swelling in his extremities (**Figure 177-3**). He was treated with intravenous immune globulin and high-dose aspirin and recovered completely. Baseline echocardiography did not reveal any coronary artery abnormalities. Follow-up echocardiograms 2 weeks and 8 weeks after his presentation were normal.

INTRODUCTION

Kawasaki disease is an acute vasculitis that has emerged as the most common cause of acquired heart disease in children in the developed world. Based on the epidemiology and clinical features of this disorder, an infectious etiology is considered likely, although the precise etiology remains elusive. It is important to recognize the clinical manifestations of KD because the diagnosis is based on clinical criteria, and because timely treatment significantly reduces the risk of coronary artery disease, the most feared consequence of this disease.

SYNONYMS

Mucocutaneous Lymph Node Syndrome or Kawasaki Syndrome.

EPIDEMIOLOGY

- Eighty percent of children are under 5 years of age; rare in infants less than 3 months of age and children older than 8 years of age.[1]
- Male: Female ratio is 3:2.
- Predominance of cases in winter-spring in temperate climates.
- Incidence highest among Asian children, even in those living in non-Asian countries.[2]
- Epidemics of disease can occur in all ethnic groups.
- Recurrence of disease occurs rarely.
- No person-to-person spread of disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Precise etiology is not known, but epidemiologic features (age group affected, seasonal predilection, occurrence of epidemics) point to an infectious etiology.
- Marked immunological activation in affected patients leads to inflammatory cell infiltration of blood vessels, particularly involving the coronary arteries.

RISK FACTORS

- Occurs in previously healthy infants and children.
- Infants and young children less than 5 years of age are most commonly affected.
- Annual incidence in Japanese children is 215 per 100,000 children younger than 5 year of age.[2]
- The attack rate in Caucasian children is 10-fold lower than in Asians; African- Americans have an intermediate incidence.
- Risk factors for the development of coronary artery disease on those affected include:
  - Age younger than 1 year.
  - Duration of fever longer than 16 days.
  - Recurrence of fever after an afebrile period of at least 48 hours.
  - Anemia.
  - Thrombocytopenia.
  - Hypoalbuminemia.

DIAGNOSIS

CLINICAL FEATURES

- Three phases of KD are classically described:
  - The acute phase, which lasts 7 to 14 days and is characterized by the classic clinical diagnostic criteria (see the following section).
  - The subacute phase occurs from about day 10 to day 25 of the illness, characterized by periungual desquamation, arthritis, and thrombocytosis.
  - The convalescent phase occurs from when all the clinical signs of illness have resolved until 6 to 8 weeks after the onset of the illness.

- The diagnosis of classic acute KD relies on clinical criteria, which include the presence of fever persisting for at least 5 days, along with four or the following five clinical findings:
    - Bilateral bulbar conjunctival injection without exudate (**Figure 177-4**).

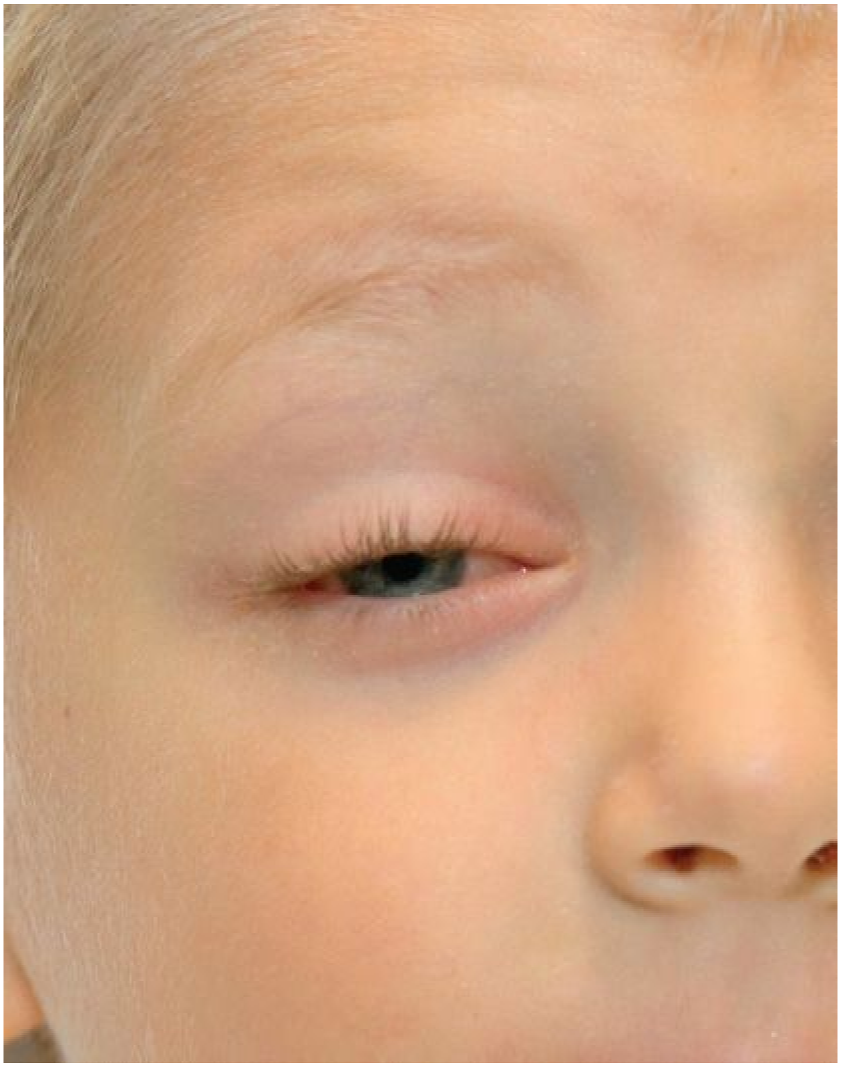

FIGURE 177-4 Nonpurulent conjunctivitis in a 5-year-old boy with Kawasaki disease (*Used with permission from Camille Sabella, MD*.)

-
    - Erythematous mouth and pharynx, red, cracked, fissured lips, and “strawberry tongue” (**Figure 177-5**).

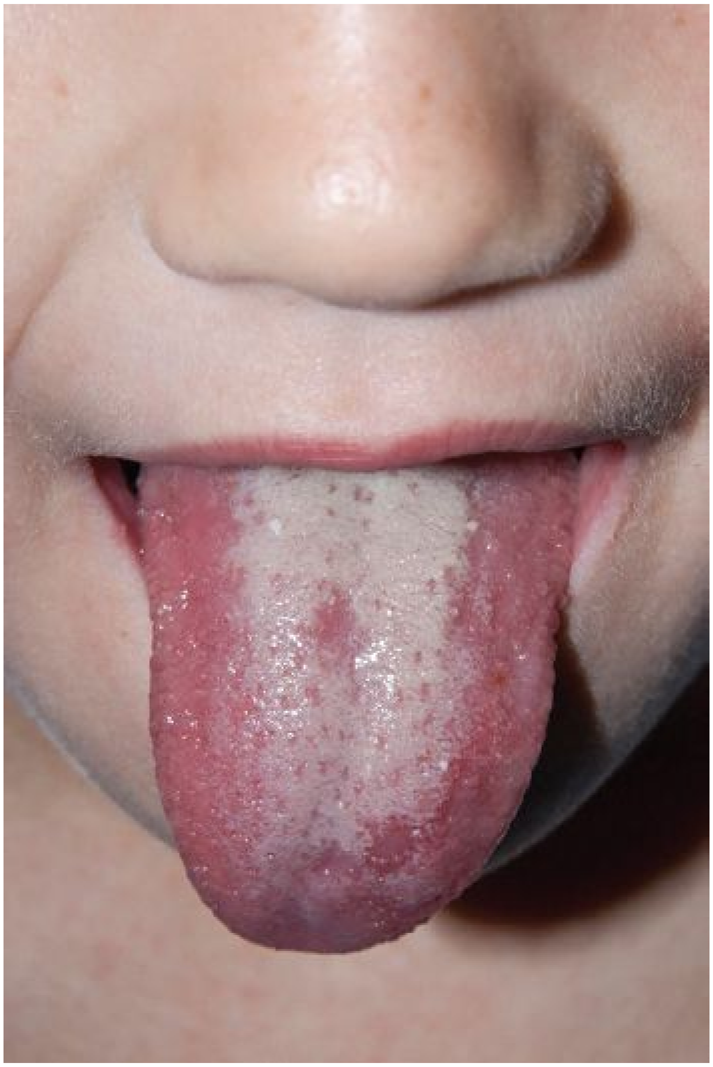

FIGURE 177-5 “Strawberry” tongue in a young boy with Kawasaki disease. (*Used with permission from Johanna Goldfarb, MD.*)

- Polymorphous, generalized, erythematous rash (may be maculopapular, morbilliform, scarlatiniform, or erythema multiforme-like; **Figure 177-6**).

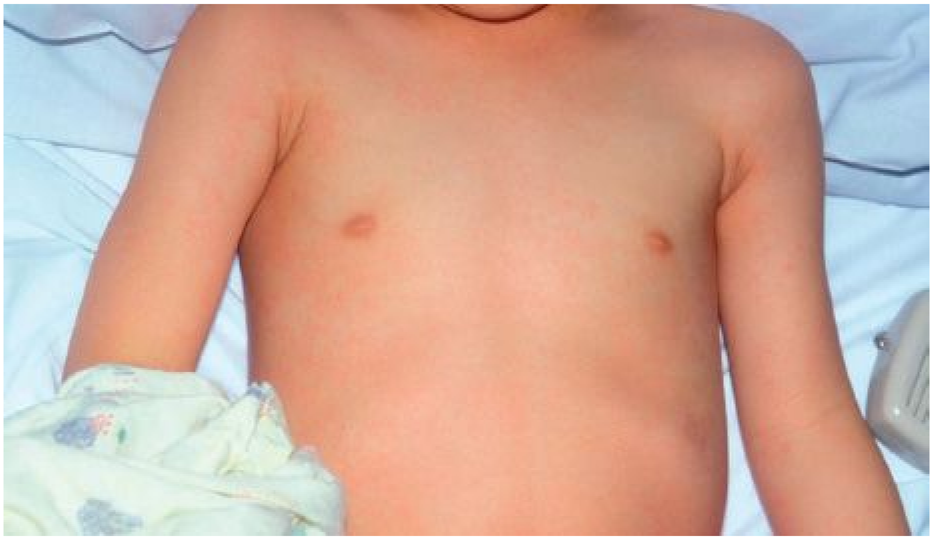

FIGURE 177-6 Diffuse maculopapular rash in a 5-year-old boy with Kawasaki disease. (*Used with permission from Johanna Goldfarb, MD.*)

- Erythema and swelling of the hands and feet, with subsequent periungual desquamation (**Figures 177-7** to **177-9**)

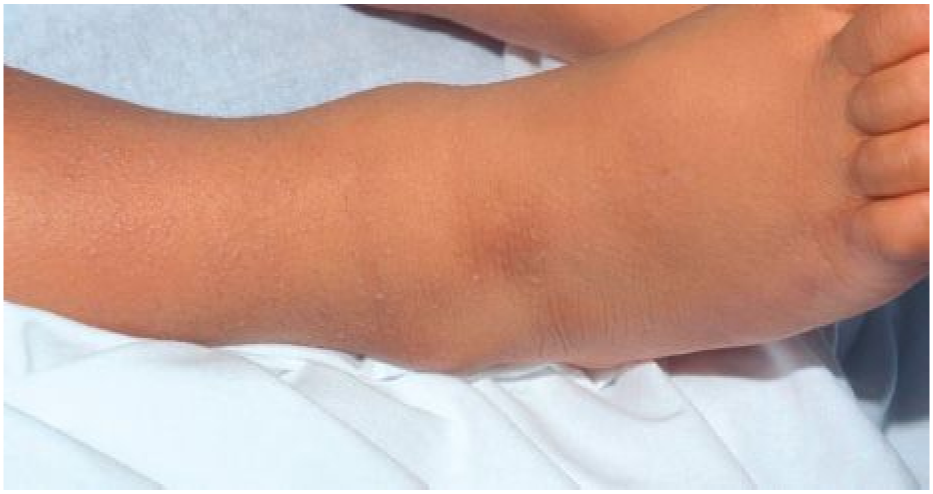

FIGURE 177-7 Extremity swelling, including the ankle joint, in a 2-year-old boy with Kawasaki disease. (*Used with permission from Camille Sabella, MD.*)

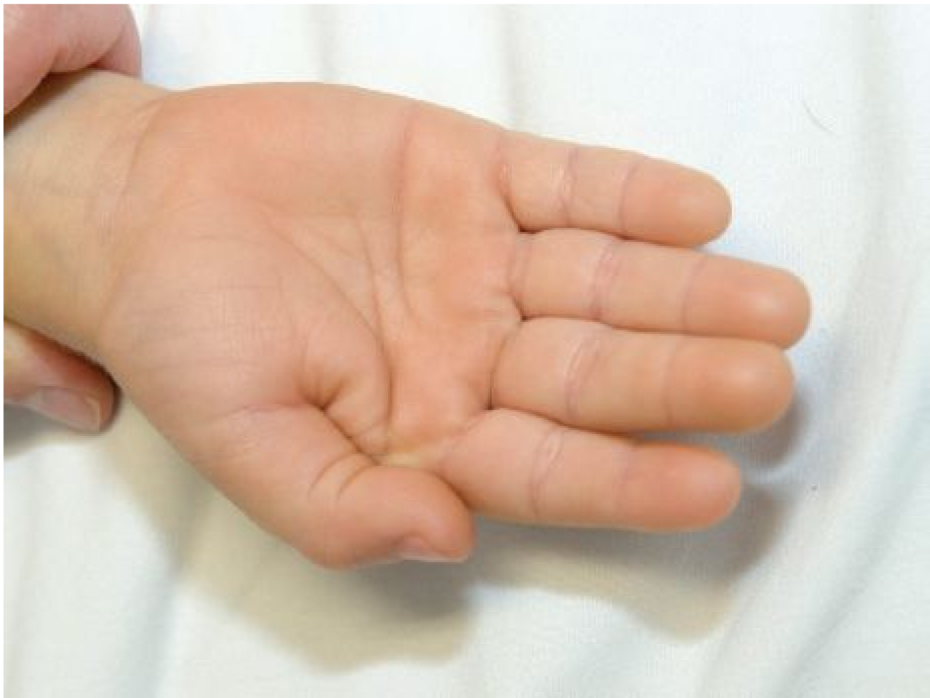

FIGURE 177-8 Palmar swelling and erythema in a 5-year-old boy with Kawasaki disease. (*Used with permission from Camille Sabella, MD.*)

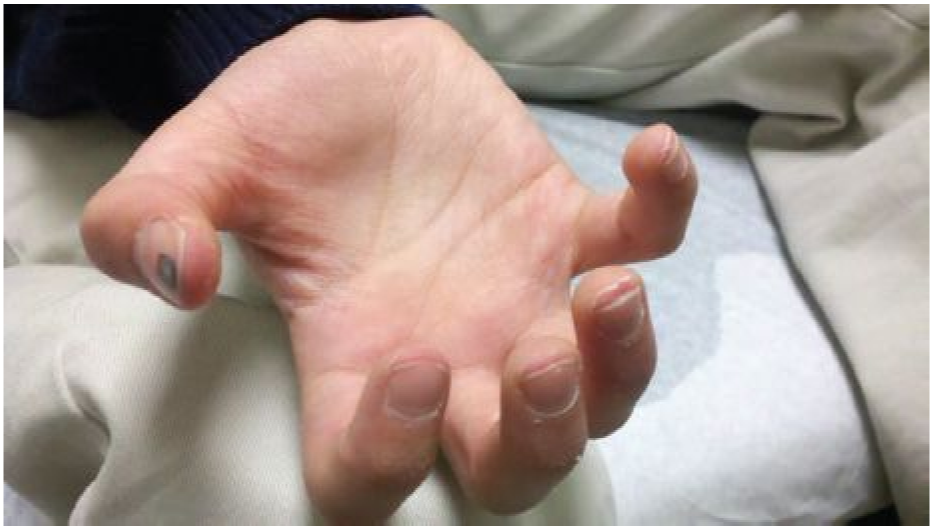

FIGURE 177-9 Periungual desquamation on day 10 of illness in this 9-year-old child with incomplete Kawasaki disease. (*Used with permission from Blanca Gonzalez, MD.*)

  - Cervical lymph node enlargement (usually unilateral) with at least one lymph node measuring 1.5 cm in diameter (**Figure 177-10**).

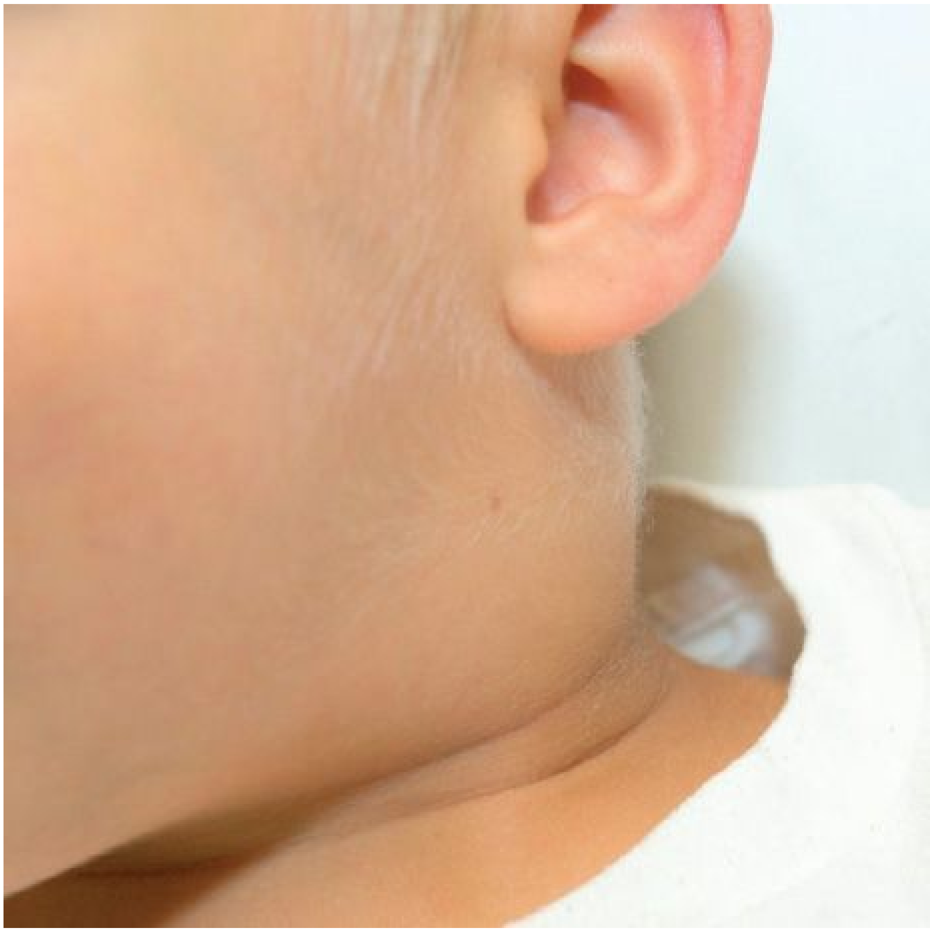

FIGURE 177-10 Posterior cervical adenopathy in a child with Kawasaki disease. (*Used with permission from Camille Sabella, MD*.)

- Other findings that may be present include:
  - Irritability, which is often marked.
  - Abdominal pain.
  - Diarrhea and vomiting.
  - Arthritis or arthralgia.
  - Meningismus.
- Coronary artery aneurysms, myocarditis, and pericarditis are well-known complications.
- Incomplete cases of KD can occur, particularly in young infants, usually heralded by the presence of fever and fewer than 4 of the 5 clinical features of the illness; these can be challenging to diagnose.[3,4]

- Periungual desquamation occurs during the subacute phase of the illness, usually occurring from day 10 to day 25 of the illness (**Figure 177-9**).

DISTRIBUTION

- Although the rash associated with KD is generalized, perineal involvement and accentuation is common.[5]
- Mild anterior uveitis may occur in 25 to 50 percent of patients.[6]

LABORATORY TESTING

- Common laboratory findings include:
    - Leukocytosis.
    - Anemia.
    - Markedly elevated acute phase reactants.
    - Sterile pyuria (secondary to urethritis).
    - Hepatitis (elevated serum transaminases with or without elevated serum bilirubin).
    - Hypoalbuminemia.
    - Cerebrospinal fluid pleocytosis.
    - Thrombocytosis (seen during the subacute phase of the illness).
- Although laboratory parameters are characteristic and helpful in making the diagnosis, none are diagnostic.
- Thrombocytosis is not present during the acute phase of the illness, the period during which the diagnosis should be made.

IMAGING

- A baseline 2D-echocardiographic study should be obtained at diagnosis and repeated during the subacute phase of the illness (1 to 2 weeks after diagnosis).[7]

- If the initial and second echocardiographic studies are normal, a follow-up echocardiogram should be obtained 6 to 8 weeks after diagnosis to assure that abnormalities have not developed during the subacute or convalescent phase of the illness.
- If abnormalities are detected at any time, such as saccular or fusiform aneurysms (**Figures 177-11** and **177-12**), additional studies are necessary.

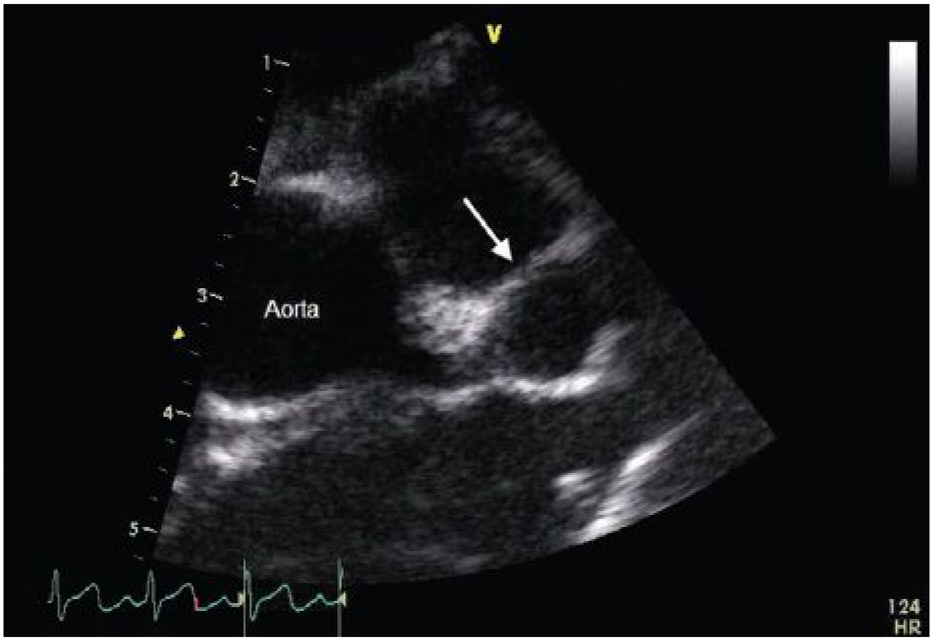

FIGURE 177-11 Transthoracic two-dimensional echocardiogram short axis view showing a saccular aneurysm (arrow) of the left anterior descending coronary artery. (*Used with permission from Athar M. Qureshi, MD*.)

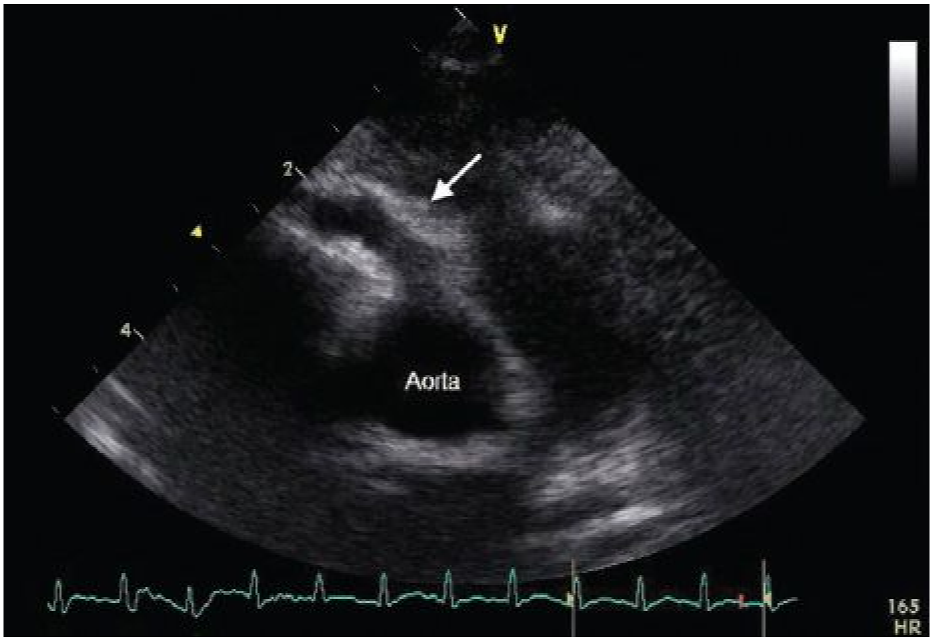

FIGURE 177-12 Transthoracic two-dimensional echocardiogram short axis view showing a fusiform aneurysm (arrow) of the right coronary artery. (*Used with permission from Athar M. Qureshi, MD.*)

- Angiography may be necessary in cases of unusual coronary artery abnormalities (**Figure 177-13**) or for long-term follow-up of large aneurysms (**Figure 177-14**). Cardiac Computed tomographs or magnetic resonance imaging may be performed as well; however, they have limitations particularly in small children

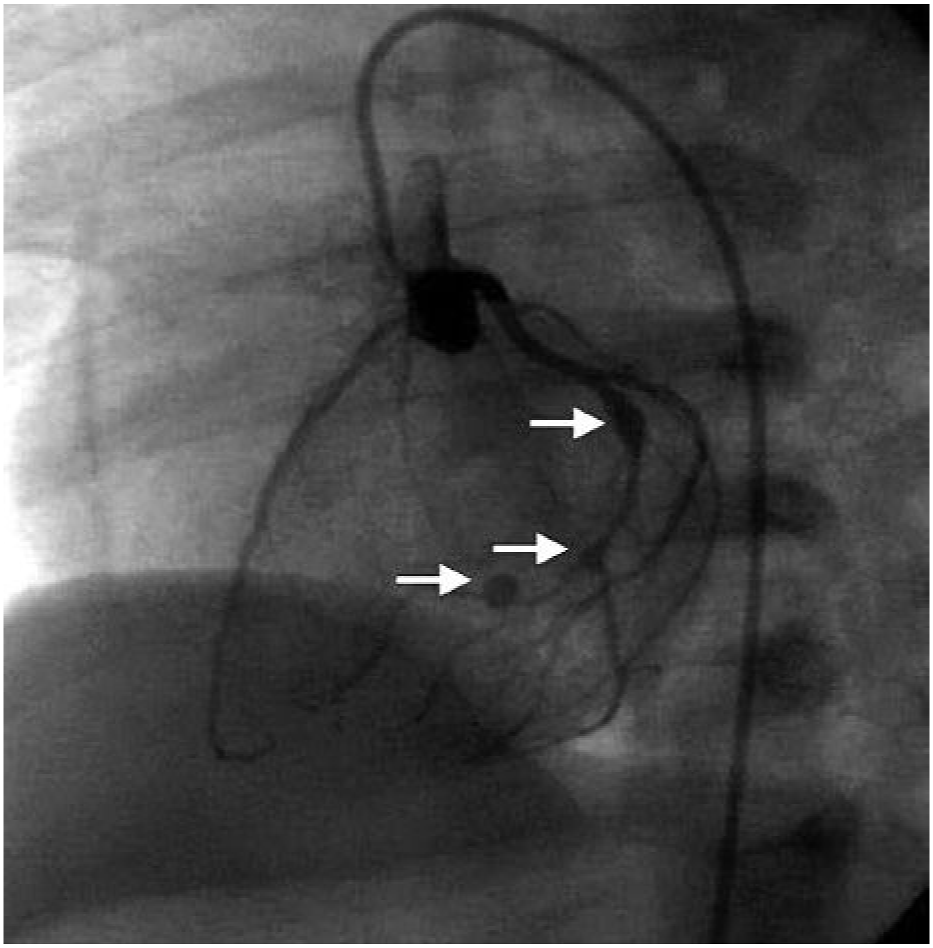

FIGURE 177-13 Left coronary artery angiogram (lateral projection) in an infant with an unusual presentation of Kawasaki disease. The circumflex coronary artery is seen with three aneurysms—one fusiform aneurysm (superior arrow) and two saccular aneurysms (inferior arrows). (*Used with permission from Athar M. Qureshi, MD*.)

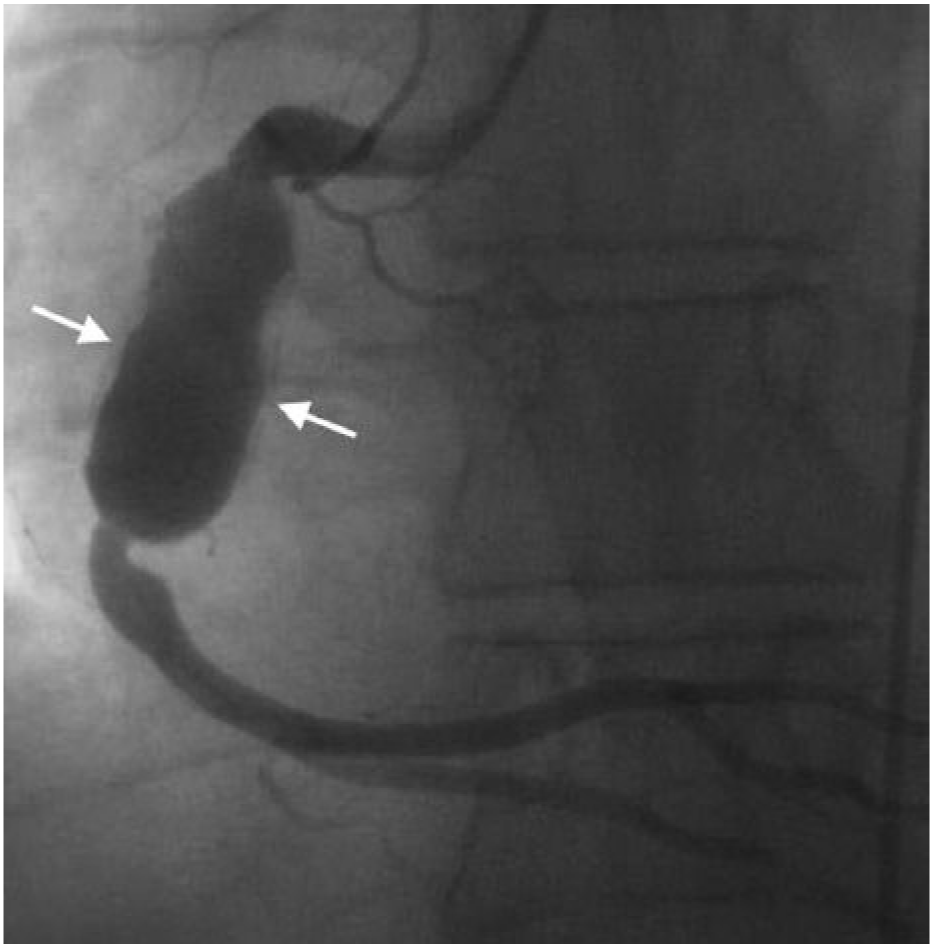

FIGURE 177-14 This right coronary artery angiogram was performed in an 18-year-old who had been followed for a giant right coronary artery aneurysm (arrow) since he was 3 years old. Note the rim of calcification surrounding the aneurysm and stenosis proximal and distal to the aneurysm. (*Used with permission from Athar M. Qureshi, MD*.)

- Hydrops of the gallbladder can be detected in about 10 percent of children with KD (**Figure 177-15**).[8]

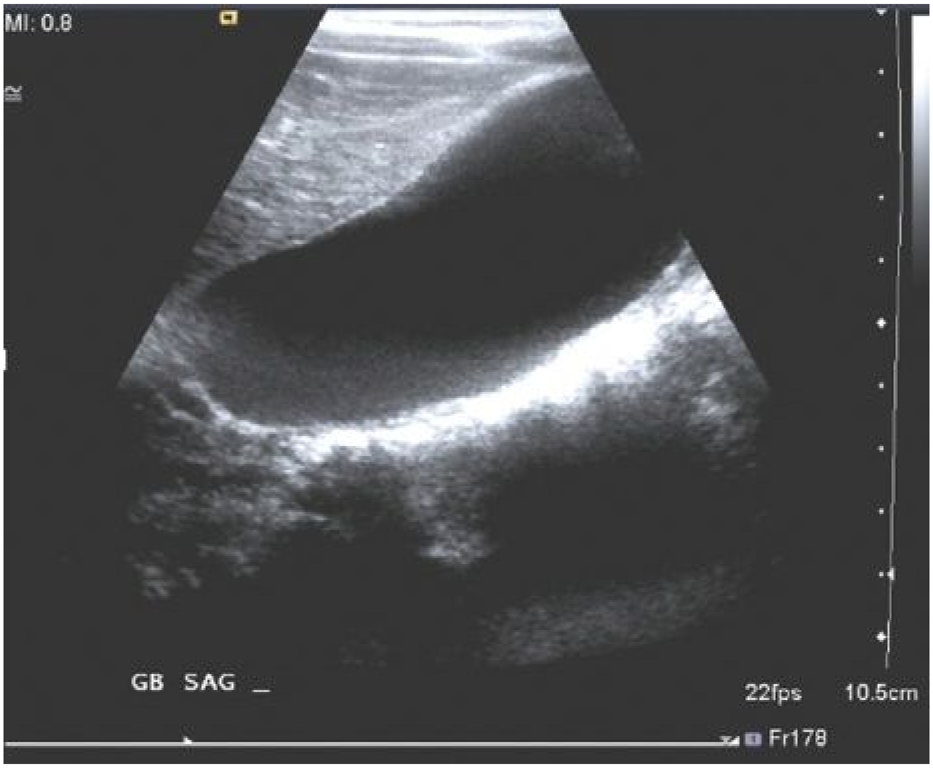

FIGURE 177-15 Hydrops of the gallbladder visualized on ultrasound of the liver and gallbladder. This occurs in about 10 percent of patients with Kawasaki disease. (*Used with permission from Camille Sabella, MD*.)

DIFFERENTIAL DIAGNOSIS

- KD is difficult to differentiate from many other febrile illnesses of childhood.
- Perineal accentuation of the rash without accentuation in other skin folds (as in scarlet fever) is characteristic of KD (see Chapter 28, Strawberry Tongue and Scarlet Fever).
- The presence of a bulbar conjunctivitis without exudate is more suggestive of KD than other entities that cause conjunctival injection (see Chapter 12, Conjunctivitis).
- In general, children with KD are ill-appearing throughout the illness; this can help to distinguish KD from viral illnesses and scarlet fever.

- Although the rash of KD is polymorphous, vesicular and bullous lesions are not characteristic.
- Measles and Streptococcus pyogenes (Group A) are the illnesses that most commonly resemble KD (see Chapter 111, Measles).
- Measles should be considered in the ill-appearing child whose immunization history suggests susceptibility to measles; serum IgM testing can confirm the diagnosis of measles.
- The clinical features and positive throat culture or rapid antigen test for GAS can help distinguish KD from GAS infection.
- Other entities in the differential diagnosis of KD include a viral illness/exanthem (especially adenovirus), toxic shock syndrome, erythema multiforme/Erythema multiforme, and juvenile rheumatoid arthritis (see Chapter 185, Toxic Shock Syndromes, Chapter 151, Erythema Multiforme/Stevens Johnson Syndrome, and Toxic Epidermal Necrolysis, and Chapter 172, Juvenile Rheumatoid Arthritis).

MANAGEMENT

- KD is a self-limited vasculitis. However, 20 to 25 percent of untreated children will develop coronary artery abnormalities.[9] The goal of therapy is to reduce the clinical symptoms and prevent the development of coronary artery abnormalities by reducing inflammation.

MEDICATIONS

- The combination of intravenous immune globulin (IVIG) and high dose aspirin given within the first 10 days of illness has been demonstrated to reduce the prevalence of coronary artery abnormalities from about 20 to 25 percent (in aspirin-treated patients) to about 5 percent.[9,10] SOR Ⓐ
    - IVIG is given as a single infusion of 2g/kg over 12 hours, which results in a dramatic response in 90 percent of patients.

    - Aspirin should be given in anti-inflammatory doses (80 to 100 mg/kg/day divided every 6 hours) until the acute phase of the illness has subsided; the dose can then be reduced to antithrombotic effects (3 to 5 mg/kg/day); aspirin is discontinued 6 to 8 weeks after the onset of therapy provided coronary artery abnormalities have not developed during the course of the illness and if the echocardiogram at that time does not show any abnormalities.

- About 10 percent of children with KD do not respond to IVIG and remain afebrile 48 hours after completing the IVIG infusion; most of these children respond to a second dose of IVIG.[11–13] SOR Ⓐ
- Optimal treatment of children who are refractory to 2 doses of IVIG is not clear; these children are often treated with corticosteroids or infliximab. SOR Ⓒ
- The addition of corticosteroids to high-dose aspirin and IVIG as primary therapy does not appear to be effective and is not indicated.[14] SOR Ⓐ
- If abnormalities of the coronary arteries are detected, low-dose aspirin therapy is continued; large aneurysm may require the use of additional anticoagulant therapy, such as warfarin, low-molecular weight heparin, or acute thrombolytic therapy, to prevent thrombosis.[7] SOR Ⓒ

INTERVENTIONAL CARDIOLOGY TREATMENT/SURGERY

- Rarely, patients with significant coronary artery abnormalities will require interventions such as transluminal coronary angioplasty, coronary atherectomy, stent implantation, coronary artery bypass surgery, or heart transplantation.

REFERRAL

- A pediatric cardiologist with expertise in the interpretation of echocardiographic studies of coronary arteries in children is mandatory.

- The care of patients with significant cardiac abnormalities should involve a pediatric cardiologist with experience in the management of children with KD.

PROGNOSIS

- Without treatment, 20 to 25 percent of children with KD will develop coronary artery abnormalities; the risk is reduced to less than 5 percent with appropriate treatment.
- Long-term prognosis depends on the severity of coronary artery disease; those with giant aneurysms are more likely to require surgical intervention and their prognosis is more guarded.

FOLLOW-UP

- Acute follow-up after the initial hospitalization is important in assuring a good clinical response to the initial therapy.
- Repeat echocardiographic studies during the subacute and convalescent phase is recommended as previously outlined.
- Long-term management of children with KD should be based on the extent of coronary artery abnormalities.
- Even in the absence of coronary artery disease, periodic cardiovascular risk assessment should be performed as some patients may develop premature atherosclerotic changes.

PATIENT EDUCATION

- Children with prolonged fever or fever associated with irritability or any of the other features of KD should receive medical attention.
- Once the diagnosis of KD is made, close follow-up will be required depending on the course and complications.

178 SCLERODERMA AND MORPHEA

E.J. Mayeaux, Jr., MD
Vidya Raman, MD

PATIENT STORY

A 4-year-old boy presented with a one-year history of skin redness and tightening over the right upper extremity. His mother had initially noticed the lesion after applying a temporary tattoo. He complained of occasional itching and pain over the area. His mother was concerned that his arm appeared to be "shrinking." He had no prior medical problems or preceding infections and his immunizations were up-to-date. He had difficulty grasping a crayon due to involvement of his fingers. On exam, he had a large area of skin tightening extending from the right scapular region and upper arm down to the forearm, index finger and thumb (**Figure 178-1**). He was referred to a dermatologist who performed a punch biopsy confirming a diagnosis of morphea (localized scleroderma). He was treated with topical fluticasone without benefit and referred to a pediatric rheumatologist for systemic therapy with methotrexate. Serologic testing showed a negative ANA and scleroderma antibody and he has had no features of systemic scleroderma.

INTRODUCTION

Scleroderma (from the Greek *scleros*, to harden) is a term that describes the presence of thickened, hardened skin. It may affect only limited areas of the skin (morphea), most or all of the skin (scleroderma), or also involve internal organs (systemic sclerosis).

EPIDEMIOLOGY

- Scleroderma is a spectrum of disorders that can be occur at any stage of life, but the clinical patterns seen in childhood differ somewhat from that seen in adults.
- The prevalence rates of diseases that share scleroderma as a clinical feature are reported ranging from 4 to 253 cases per 1 million individuals of all ages.[1]
- The most common form of childhood scleroderma is morphea (localized scleroderma or LSc) which principally involves the skin, subcutaneous fascia, muscle, and bone. It is 10 times more common than systemic sclerosis and may include circumscribed or generalized morphea, bullous morphea, deep morphea, and linear morphea (including the en coup de sabre subtype, characterized by a vertical scar on the forehead resembling a stroke from a sword).[2]
- In a retrospective multicenter review of 750 children with LSc, the most common subtype was linear morphea (65%), followed by circumscribed morphea (26%), mixed subtype (15%), generalized morphea (7%), and deep morphea (2%). Overall, the mean age of presentation was 7.3 years (range 0 to 16 years, median age 6.1 years).[3]
- In the US, the incidence of morphea has been estimated at 25 cases per 1 million individuals (of any age) per year.[1] Although data are scarce, it is estimated that childhood LSc occurs only in 1 per 1 million.[2] LSc infrequently progresses into a systemic form and can sometimes merge or overlap with eosinophilic fasciitis.[4]
- Juvenile systemic sclerosis (JSSc) is a chronic multisystem connective tissue disorder characterized by sclerodermic skin changes and abnormalities of the visceral organs. Systemic sclerosis has an annual incidence of 1 to 2 per 100,000 adults and children in the US.[1] Onset of JSSc in childhood is very uncommon and accounts for only 3 percent of all cases of systemic sclerosis.[6]

- The risk of JSSc is similar in both sexes in younger children, but it occurs three times more often in girls than in boys aged eight years or more.[7]
- The incidence of JSSc in the United Kingdom and Ireland was estimated to be 0.27 cases per million children/year in a 2005 to 2007 survey.[8] The incidence of JSSc in other populations is unknown.
- Worldwide, there are higher rates of scleroderma in the US and Australia than in Japan or Europe.[9]
- Pulmonary, cardiac, and renal disease are the leading causes of death as a consequence of these diseases.[10]

ETIOLOGY AND PATHOPHYSIOLOGY

- The etiology and pathogenesis of scleroderma remains uncertain. Two theorized contributing pathogenic processes include vasculopathy, abnormal fibroblast function, and autoimmune dysfunction.
- Scleroderma disorders can be subdivided into three groups: localized scleroderma (morphea; **Figures 178-1** to **178-3**), systemic sclerosis (**Figures 178-4** to **178-7**), and other scleroderma-like disorders that are marked by the presence of thickened, sclerotic skin lesions.

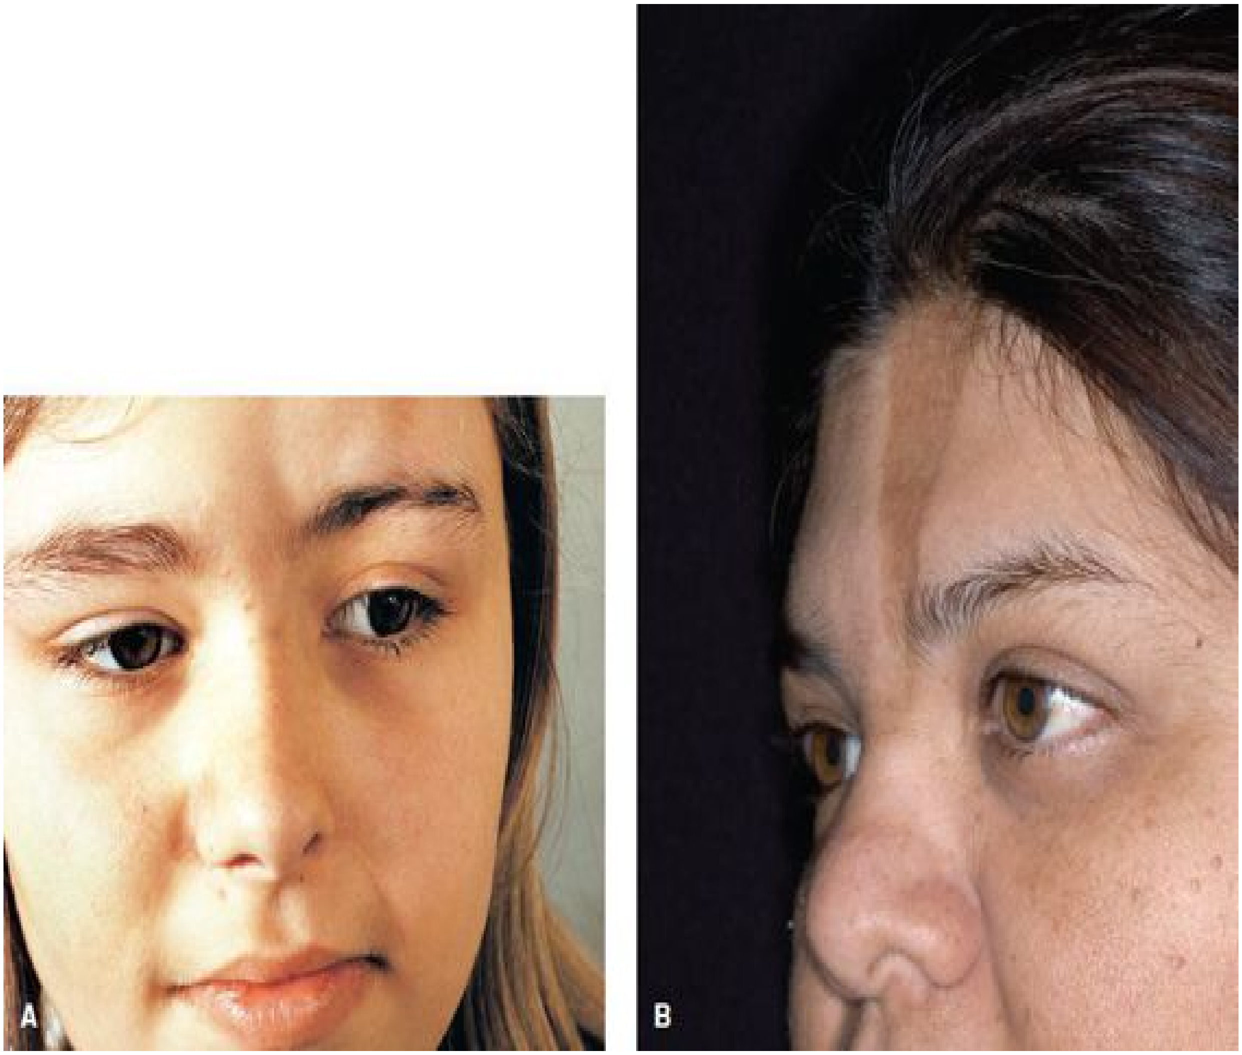

FIGURE 178-2 **A.** Linear morphea on one side of the brow on the forehead, commonly known as an “en coup de sabre” lesion, meaning the blow of a sword. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 17-4, New York, NY: McGraw-Hill, 2008*.) **B.** Another “en coup de sabre” lesion on the forehead with significant atrophy and hyperpigmentation. (*Used with permission from Richard P. Usatine, MD*.)

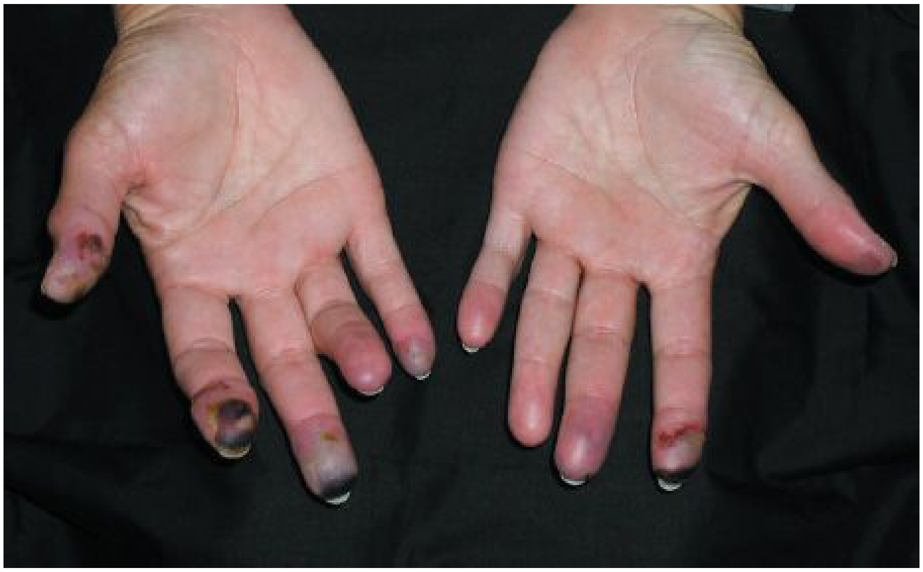

FIGURE 178-7 Raynaud phenomenon with severe ischemia leading to the necrosis of the fingertips. (*Used with permission from Ricardo Zuniga-Montes, MD*.)

- A multicenter European study of 750 children with LSc defined the prevalence and the clinical features of extracutaneous findings in patients with LSc.[11] There was one or more extracutaneous manifestations in 22 percent of children. In 92 percent of the cases, the skin lesion was the presenting sign of disease. The overall distribution of extracutaneous manifestations included:
  - Arthritis—19 percent.
  - Neurologic findings—4 percent.
  - Raynaud's phenomenon—3 percent.
  - Vascular findings (vasculitic rash and deep vein thrombosis)—2 percent.
  - Ocular findings—3 percent.
  - Gastrointestinal symptoms (GERD)—2 percent.
  - Restrictive lung disease—1 percent.
  - Two patients had cardiac findings (pericarditis and arrhythmia) and one patient had nephritis.
- Systemic sclerosis is used to describe a systemic disease characterized by skin induration and thickening accompanied by variable tissue fibrosis and inflammatory infiltration in numerous visceral organs. Systemic sclerosis

can be diffuse (DcSSc) or limited to the skin and adjacent tissues (limited cutaneous systemic sclerosis [LcSSc]).

- The majority of children with JSSc present with Raynaud phenomenon and/or skin changes (tightening, thinning, and atrophy) of the hands and face. In a multicenter retrospective study of 153 children with JSSc, the median age of onset was 8.1 years and the mean duration of symptoms prior to diagnosis was 1.9 years.[7] Eleven percent had a family history of autoimmune disease. Findings at diagnosis included:
    - Raynaud phenomenon—70 percent.
    - Skin induration proximal to the MCP and MTP joints—63 percent.
    - Musculoskeletal symptoms (arthralgia, muscle weakness, and arthritis)—33 percent.
    - Weight loss—18 percent.
    - Dyspnea—10 percent.
    - Dysphagia—10 percent.
- The most common vascular dysfunction associated with scleroderma is Raynaud phenomenon (**Figure 178-7**). Raynaud phenomenon is produced by arterial constriction in the digits. The characteristic color changes progress from white (pallor), to blue (acrocyanosis), to finally red (reperfusion hyperemia). Raynaud phenomenon generally precedes other disease manifestations, sometimes by years. Many patients develop progressive structural changes in their small blood vessels, which permanently impair blood flow, and can result in digital ulceration or infarction. Other forms of vascular injury include pulmonary artery hypertension, renal crisis, and gastric antral vascular ectasia.
- Patients with limited cutaneous scleroderma (LcSSc) usually have skin sclerosis restricted to the hands and, to a lesser extent, the face and neck. With time, some patients develop scleroderma of the distal forearm. They often eventually display the CREST syndrome, which presents with Raynaud phenomenon (**Figure 178-7**), esophageal dysmotility, sclerodactyly (**Figures 178-4** and **178-5**), telangiectasias (**Figure 178-6**), and calcinosis cutis (**Figure 178-8**). This variant is rare in children.

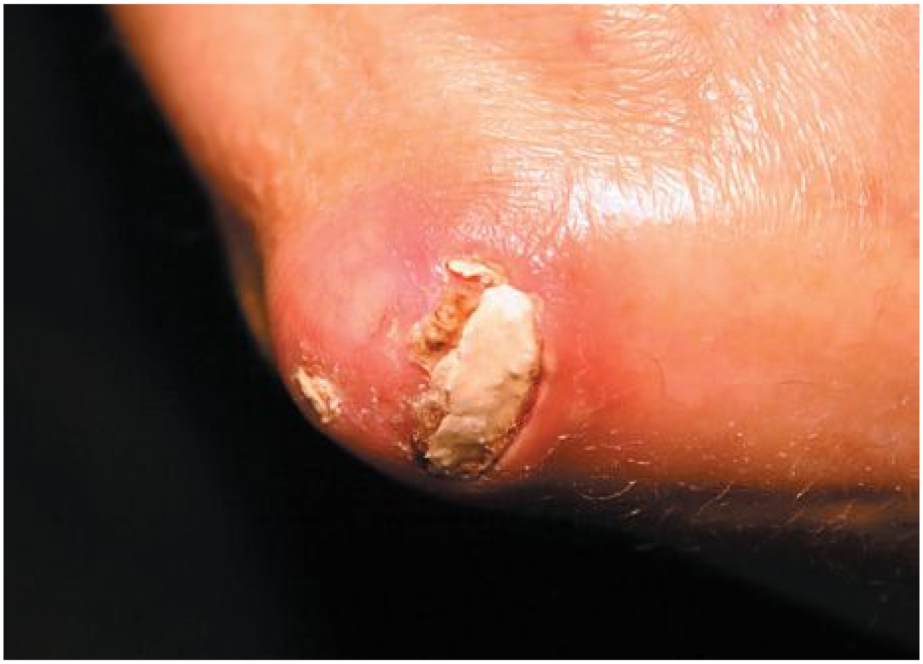

FIGURE 178-8 Calcinosis over the elbow in a patient with CREST syndrome. (*Used with permission from Everett Allen, MD*.)

- Patients with diffuse cutaneous scleroderma (DcSSc) often present with sclerotic skin on the chest, abdomen, or upper arms and shoulders. The skin may take on a “salt-and-pepper” look (**Figure 178-9**). They are more likely to develop internal organ damage caused by ischemic injury and fibrosis than those with LcSSc or morphea.

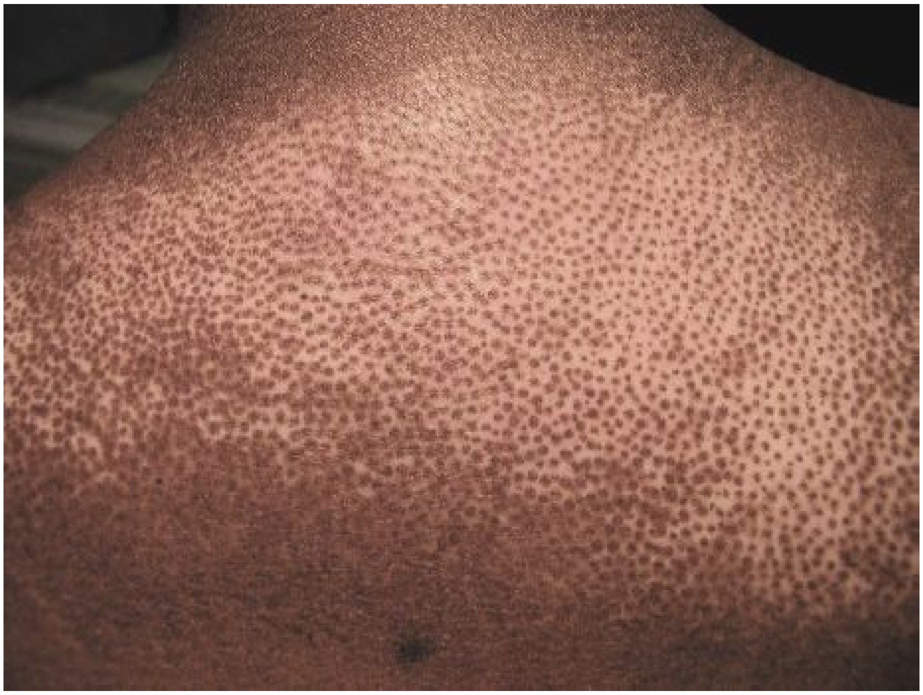

FIGURE 178-9 Scleroderma with mottled hypopigmentation. The skin may have a salt-and-pepper appearance as shown here. (*Used with permission from Ricardo Zuniga-Montes, MD*.)

- Arthralgias are the presenting symptom in about 15 percent of children and are usually mild and transient. Joint contractures are most common at the proximal intraphalangeal joints and elbows. Arthritis and myositis may occur in up to 30 percent of children, and may precede the diagnosis of JSSc.[7] Myositis leads to muscle weakness and myalgia, and is associated with elevated levels of creatinine kinase (CPK).
- GI involvement is seen in 30 to 74 percent of children with systemic sclerosis,[7,12] although half of these patients may be asymptomatic. Any part of the GI tract may be involved. Potential signs and symptoms include dysphagia, choking, heartburn, cough after swallowing, bloating, constipation, and/or diarrhea, pseudoobstruction, malabsorption, and fecal incontinency. Chronic gastroesophageal reflux is more common in children and recurrent episodes of aspiration may contribute to the development of interstitial lung disease. Vascular ectasia in the stomach (often referred to as “water-melon stomach” on endoscopy) is a common late finding, and may lead to GI bleeding and anemia.

- Pulmonary involvement is seen in more than 70 percent of patients, usually presenting as dyspnea on exertion and a nonproductive cough. Fine “Velcro” rales may be heard at the lung bases with lung auscultation. Pulmonary vascular disease occurs in 10 to 40 percent of patients with systemic sclerosis, and is more common in patients with limited cutaneous disease. The risk of lung cancer is increased approximately 5-fold in patients with scleroderma.
- Autopsy data suggest that 60 to 80 percent of patients with DcSSc have evidence of kidney damage.[13] Some degree of proteinuria, a mild elevation in the plasma creatinine concentration, and/or hypertension are observed in as many as 50 percent of patients.[14] Severe renal disease develops in 10 to 15 percent of patients, most commonly in patients with DcSSc.
- Symptomatic pericarditis occurs in 7 to 20 percent of patients, which has a 5-year mortality rate of 75 percent.[15] Primary cardiac involvement includes pericarditis, pericardial effusion, myocardial fibrosis, heart failure, myocarditis associated with myositis, conduction disturbances, and arrhythmias.[16] Patchy myocardial fibrosis is characteristic of systemic sclerosis, and is thought to result from recurrent vasospasm of small vessels. Arrhythmias are common and are most caused by fibrosis of the conduction system.
- Pulmonary vascular disease occurs in 10 to 40 percent of patients with scleroderma, and is more common in patients with limited cutaneous disease. It may occur in the absence of significant interstitial lung disease, generally a late complication in adults, and is usually progressive. Severe pulmonary arterial hypertension, sometimes with pulmonale and right-sided heart failure or thrombosis of the pulmonary vessels may develop.
- Contractures may develop, with contractures of the fingers being most common. Neuropathies and central nervous system involvement, including headache, seizures, stroke, vascular disease, radiculopathy, and myelopathy, occur.

DIAGNOSIS

CLINICAL FEATURES

- The diagnosis of systemic sclerosis and related disorders is based primarily upon the presence of characteristic clinical findings. Skin involvement is characterized by variable thickening and hardening of the skin with possible involvement of the underlying tissues. Skin pigmentary changes may occur, especially a salt-and-pepper appearance from patchy hypopigmentation (**Figure 178-9**). Other prominent skin manifestations include:
    - Pruritus and edema in the early stages.
    - Sclerodactyly (**Figures 178-3** and **178-4**).
    - Digital ulcers and pitting at the fingertips (**Figures 178-6** and **178-10**).

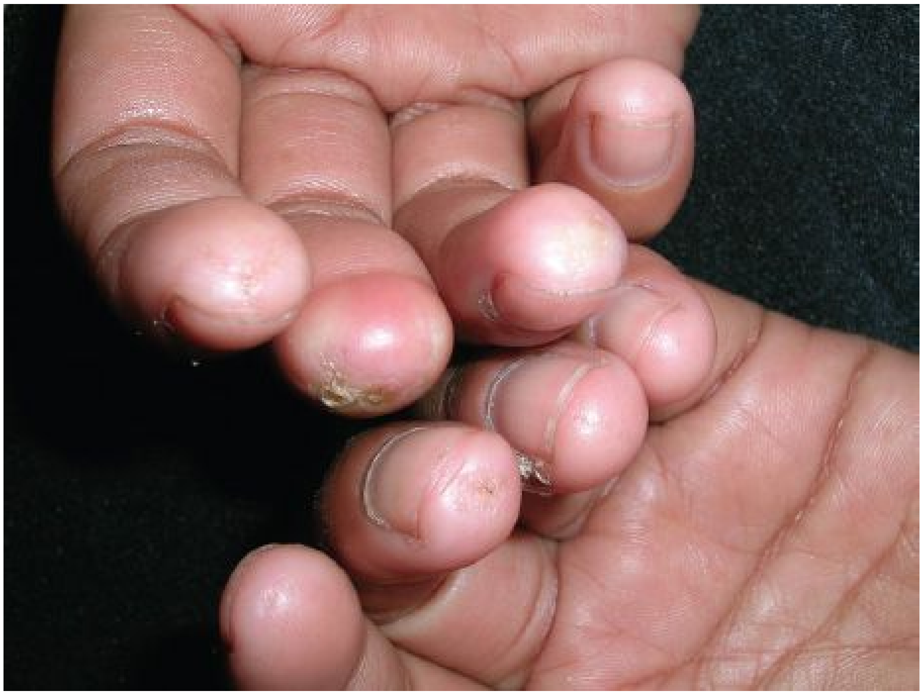

FIGURE 178-10 Digital pitting scars and loss of substance from finger pads in this patient with scleroderma and sclerodactyly. (*Used with permission from Richard P. Usatine, MD.*)

- Telangiectasia (**Figures 178-6** and **178-11**).

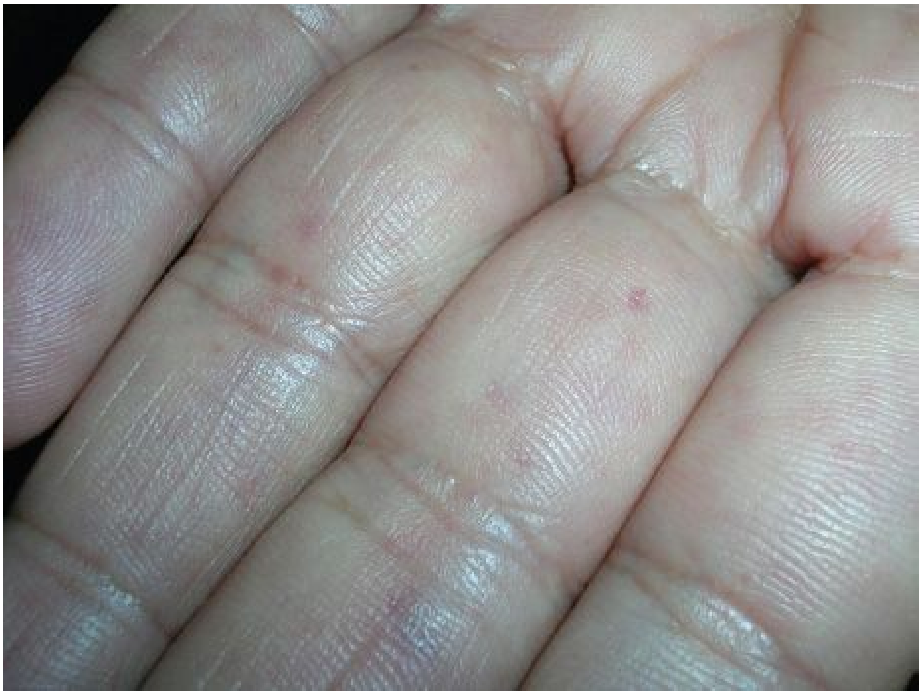

FIGURE 178-11 Telangiectasias on the hands of this patient with CREST syndrome. (*Used with permission from Richard P. Usatine, MD*.)

  - Calcinosis cutis (**Figure 178-8**).

- The diagnosis of localized scleroderma (morphea) is suggested by the presence of typical skin thickening and hardening confined to one area, with absence of internal organ involvement (**Figures 178-1** and **178-2**). The diagnosis of systemic sclerosis is suggested by the presence of typical skin thickening and hardening (sclerosis) that is not confined to one area (i.e., not localized scleroderma) and occuring proximal to the metacarpophalangeal (MCP) and metatarsophalangeal (MTP) joints. The combination of skin signs plus one or more of the typical systemic features supports the diagnosis of systemic sclerosis.
- Linear scleroderma is the most common type of LSc in children. The fibrotic lesion is elongated, and the direction is usually transverse when on the trunk and longitudinal on the limbs. When the lesion involves the face or scalp, it is referred to as “en coup de sabre.” Patients may develop contractures and defects of the limb with associated unequal growth and disabilities.

- The American College of Rheumatology, the Pediatric Rheumatology European Society, and European League Against Rheumatism defined criteria for the diagnosis and classification of JSSc.[17] In a patient less than 16 years of age, JSSc is diagnosed if the major criterion and at least 2 of the minor criteria are present:
  - Major criterion (required)—Sclerosis/induration of the skin proximal to the MCP and MTP joints.
- Minor criteria—Two of the following criteria are required:
  - Skin—Sclerodactyly.
  - Vascular—Raynaud phenomenon, nailfold capillary abnormalities, or digital tip ulcers.
  - Gastrointestinal—Dysphagia or gastroesophageal reflux.
  - Renal—Renal crisis or new onset arterial hypertension.
  - Cardiac—Arrhythmias or heart failure.
  - Respiratory—Evidence of pulmonary fibrosis, abnormality of diffusion capacity, or pulmonary hypertension.
  - Musculoskeletal—Tendon friction rubs, arthritis, or myositis.
  - Neurological—Neuropathy or carpal tunnel syndrome.
  - Serological testing—Presence of antinuclear antibodies or SSc selective autoantibodies.

LABORATORY TESTING

- A positive ANA with a speckled, homogenous, or nucleolar staining pattern is common in systemic scleroderma and is seen in 81 to 97 percent of children with JSSc.[7] A positive ANA was found in 42 percent of a large series of children with localized scleroderma, however, there was no correlation between the presence of ANA and disease course in this patient population.[3] Anticentromere antibodies are often associated with LcSSc. Anti-DNA topoisomerase I (Scl-70) antibodies are highly specific for both systemic sclerosis, and related interstitial lung and renal disease.[18] Although not very sensitive, anti-RNA polymerases I and III antibodies are specific for systemic sclerosis. Other testing for specific organ dysfunction is routinely done.

- The presence of characteristic autoantibodies, such as anticentromere, antitopoisomerase I (Scl-70), anti-RNA polymerase, or U3-RNP antibodies is supportive of the diagnosis of systemic sclerosis.
- Consider checking a CPK in children with myositis or any cardiac symptom. Children with significantly elevated CPK should be appropriately evaluated for cardiac disease.[7]

IMAGING

All patients with systemic sclerosis should have a chest x-ray (CXR) and pulmonary function tests (PFTs) screening for pulmonary involvement. The most common types of pulmonary involvement are interstitial lung disease and pulmonary hypertension. The diffusing capacity, DLCO, (as part of PFTs) is the most sensitive test for pulmonary disease in systemic sclerosis. High-resolution chest CT may be indicated for further evaluation of active pulmonary disease.

BIOPSY

- A punch biopsy can be used to diagnose morphea and scleroderma when the clinical diagnosis is not clear and to rule out other conditions such as eosinophilic fasciitis.

DIFFERENTIAL DIAGNOSIS

- Idiopathic occurrence of systemic sclerosis associated diseases such as Raynaud phenomenon, renal failure, and gastroesophageal reflux disease.
- Systemic lupus erythematosus (SLE) presents with systemic symptoms and a typical rash that may be scarring. ANA testing with lupus-specific antibodies usually helps establish the diagnosis (see Chapter 173, Lupus—Systemic and Cutaneous).

- Discoid lupus erythematosus (DLE) presents as localized plaque lesion that eventually scar. Biopsy usually makes the diagnosis (see Chapter 173, Lupus—Systemic and Cutaneous).
- Myxedema is associated with hypothyroidism and is characterized by thickening and coarseness of the skin. Thyroid testing usually makes the diagnosis (see Chapter 191, Hypothyroidism).
- Lichen sclerosus when it occurs away from the genital area can resemble morphea. Although it most commonly affects the genital (**Figure 178-12**) and perianal area, it can occur on the upper trunk, breasts, and upper arms. The plaques appear atrophic but a thin cigarette-paper crinkling appearance may help to differentiate it from morphea. A punch biopsy will lead to the correct diagnosis.

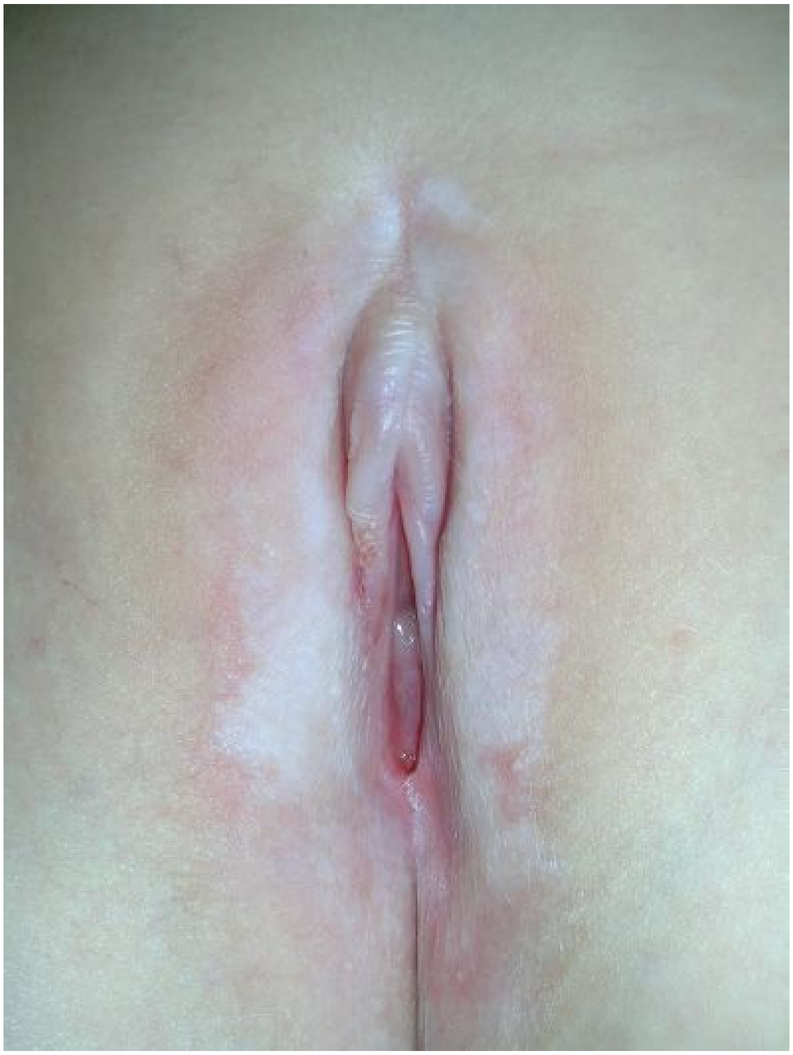

FIGURE 178-12 Lichen sclerosus of the vulva of a 4-year-old girl, which can be confused with morphea or a chronic candida infection. Affected girls may complain of vulvar itching, soreness, or painful urination. However, the degree of discomfort may not be proportional to the amount of disease present. (*Used with permission from Richard P. Usatine, MD.*)

- Amyloidosis of the skin may result in thickening and stiffness of the skin. Skin biopsy reveals amyloid infiltration. Biopsy usually makes the diagnosis.
- Juvenile idiopathic arthritis (juvenile rheumatoid arthritis) may produce joint symptoms and contractures similar to JSc (see Chapter 172, Juvenile Idiopathic Arthritis).

MANAGEMENT

NONPHARMACOLOGIC

- Localized scleroderma, including morphea, appears to soften with UVA light therapy.[19] SOR Ⓑ
- Physical therapy and massage is recommended in many children with LSc. SOR Ⓒ Regular physical therapy maintains functional ability, muscle strength, and joint movement while preventing flexion contractures. Deep connective tissue massage may be taught to parents to improve dermal elasticity. Attention to positive joint alignment and muscle development is important in linear scleroderma. SOR Ⓒ
- Telangiectasias may be covered with foundation make-up or treated with laser therapy.
- Small localized lesions of morphea can be removed surgically, but only after the active phase of the disease has abated and the child’s growth is complete.[20] SOR Ⓒ
- The use of corrective or functional splints may be necessary to treat or prevent contractures. Splints may be required for an extended period of

time.

MEDICATIONS

- For symptomatic therapy, skin lubrication, histamine 1 (H_1) and histamine 2 (H_2) blockers, oral doxepin, and low-dose oral glucocorticoids may be used to treat pruritus. SOR Ⓒ
- Treatment options for morphea include topical steroids such as clobetasol and topical calcipotriol.[21,22] SOR Ⓑ
- Methotrexate has been used successfully in children and adults with LSc (15 mg/m^2 as a single oral or subcutaneous dose per week for at least one year—maximum dose 25 mg per week).[23] SOR Ⓑ Addition of glucocorticoids (prednisone 1 mg/kg/day (maximum dose to 50 mg/day) orally or methylprednisolone 20 to 30 mg/kg/day (maximum dose to 1000 mg/kg/day) intravenously for three consecutive days monthly) during the first two to three months of therapy may be helpful for those with rapidly progressive disease.
- The combination of high-dose oral prednisone and low-dose oral methotrexate has been used successfully in adults and larger adolescents for localized scleroderma.[24] SOR Ⓑ Methotrexate can be started at 7.5 mg PO weekly and titrated up as needed. Of course the long-term goal is to taper the prednisone while using the oral methotrexate as a steroid-sparing agent.
- Calcium channel blockers (nifedipine at a dose of 0.2–0.3 mg/kg every eight hours—maximum 10 mg/dose), dipyridamole, aspirin, and topical nitrates may help symptoms of Raynaud phenomenon.[25,26] SOR Ⓑ Patients should be advised to avoid cold, stress, nicotine, caffeine, and sympathomimetic decongestant medications. Acid-reducing agents may be used empirically for gastroesophageal reflux disease. Prokinetic agents, such as erythromycin, may be useful for patients with esophageal hypomotility. SOR Ⓒ
- The mainstay of treatment of renal disease is control of blood pressure, with angiotensin-converting enzyme (ACE) inhibitors being the first-line agent. SOR Ⓒ Hemodialysis or peritoneal dialysis may be used as needed.

- Treatments of pulmonary hypertension associated with the systemic sclerosis being tested include the endothelin receptor antagonist bosentan (62.5 mg PO bid for 4 weeks, then increase to 125 mg PO bid), the phosphodiesterase-5 inhibitor sildenafil, and various prostacyclin analogs (e.g., epoprostenol, treprostinil, and iloprost). Pulmonary fibrosing alveolitis may be treated with cyclophosphamide.[27] SOR Ⓑ
- Myositis may be treated with oral prednisone 0.3 to 0.5 mg/kg per day. However, several studies have suggested that use of steroids in scleroderma is associated with a higher risk of scleroderma renal crisis and therefore, patients on steroids should have close monitoring of blood pressure and renal function. SOR Ⓑ Arthralgias can be treated with acetaminophen and NSAIDs. SOR Ⓒ

REFERRAL

Patients with systemic sclerosis should be referred to a rheumatologist as this is a complicated disease that requires the use of toxic medications. Depending upon the complications, patients with scleroderma may also need referral to pulmonology, cardiology, and nephrology.

PROGNOSIS

- In general, the prognosis of SSc in children is better than in adults. The commonest causes of death in children are related to the involvement of cardiac, renal, and pulmonary systems. Cardiomyopathy is a leading cause of early death, especially in children.[28]
- The prognosis for morphea is excellent as it only affects the skin. Although the appearance may be disturbing to the patient it is not life-threatening. If the morphea is extensive and over an extremity, it can affect function (**Figure 178-13**).

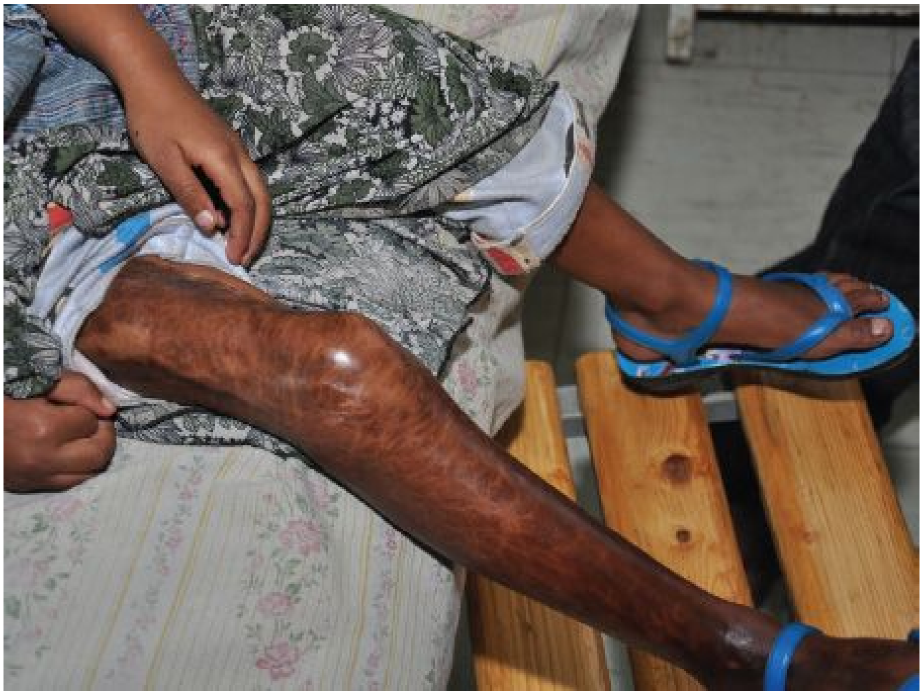

FIGURE 178-13 Localized morphea of the leg in this young girl. Although her disease is not systemic, the tightening of the skin around the knee does cause problems with knee movement and ambulation. (*Used with permission from Richard P. Usatine, MD.*)

FOLLOW-UP

- The patient with systemic sclerosis needs to be evaluated at least every 3 to 6 months to monitor disease activity and progression.

PATIENT EDUCATION

- Instruct the patient and parents to avoid skin trauma (especially the fingers), cold exposure, and smoking. Make patients aware of potential complications and have them watch for signs of systemic disease occurrence or progression.

- Encourage the child to be as physically active as possible. Physical therapy will help maintain functional ability, muscle strength, and joint movement while preventing flexion contractures. It should be performed consistently since irregular regimens will be less effective.
- Avoid exposures that irritate or dry the skin. Daily application of lanolin or water-soluble cream as an emollient may minimize this effect.
- Patients and parents should be told to avoid cold, trauma, heat, and sun exposure. Cold and trauma can exacerbate symptoms. These children are also susceptible to hyperpigmentation from sunlight and have difficulty in dissipating heat through sclerotic skin.

179 GASTROINTESTINAL INECTIONS (INCLUDING DIARRHEA)

Heidi Chumley, MD
Camille Sabella, MD

Gastrointestinal infections can be caused by a wide variety of infectious agents, including bacteria, viruses, and parasites. In this chapter, common viral and bacterial causes of diarrhea will be discussed, followed by a discussion of the most important parasitic infections.

BACTERIAL AND VIRAL GASTROENTERITIS

PATIENT STORY

A 3-year-old boy who attends a child care center presents to his pediatrician with a 2-day history of bloody diarrhea with mucus. On physical examination, he is well hydrated and has mild abdominal tenderness. The pediatrician orders a stool culture for enteric pathogens and recommends supportive care including appropriate hydration and close follow-up. Forty-eight hours later, the stool culture is reported as positive for *Shigella sonnei* (**Figure 179-1**). Because the boy continued to have bloody diarrhea, the pediatrician treated the boy with a 5-day course of azithromycin and he recovered completely. Two stool cultures obtained after the completion of therapy were negative and the boy was able to resume child care.

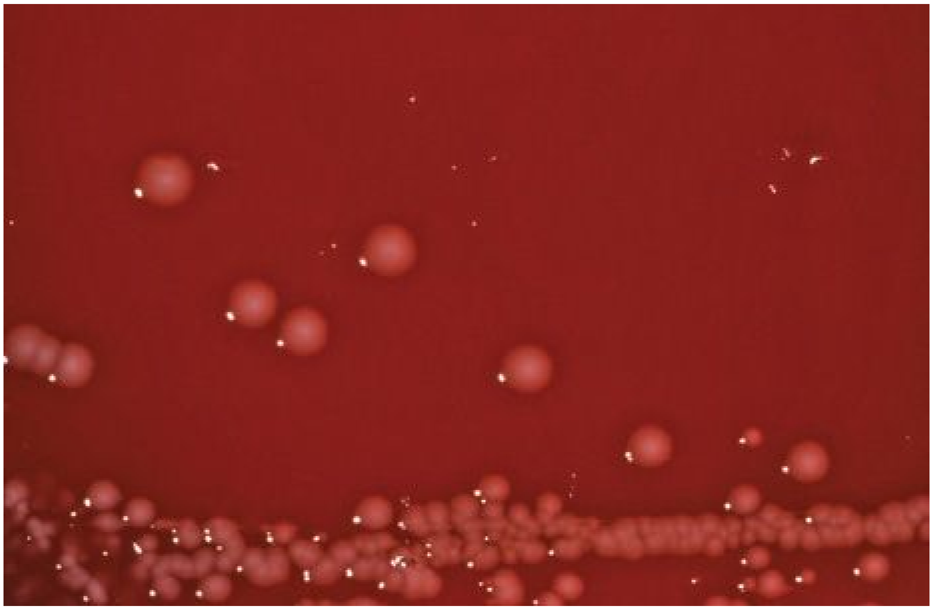

Figure 179-1 Shigella colonies on a blood agar plate. (*Used with permission from CDC Public Health Image Library.*)

INTRODUCTION

Gastrointestinal infections frequently manifest as diarrhea (loose, watery stools), frequently with fever, vomiting, and abdominal pain. Although many of these infections are self-limited, these infections can be associated with intestinal and extra-intestinal manifestations and can lead to significant morbidity.

EPIDEMIOLOGY

- Worldwide, diarrheal illness is a leading cause of morbidity and mortality.
- Diarrhea accounts for 2 to 4 million health care visits, 220,000 hospitalizations, and 300 to 400 deaths annually in the US.[1]

- Diarrhea is the most common illness encountered by international travelers to developing countries.[2]
- Acquisition of intestinal pathogens occurs through the fecal-oral route, from person-to-person contact or from contaminated food and water. Many pathogens can be spread by either person-to-person contact or from contaminated food and water.
- Pathogens that are spread through person-to-person contact include *Shigella spp, Escherichia coli* O157:H7, and most viral causes of diarrhea. These agents are commonly implicated in outbreaks in childcare centers.
- Pathogens that are spread through contaminated food and water include Salmonella *spp, Campylobacter spp*, enterotoxigenic *E coli*, and many viruses.
- Enterotoxigenic *E coli, Salmonella*, Campylobacter, and *Shigella* are the most common causes of traveler’s diarrhea.
- Pet reptiles are common sources of *Salmonella* infection. Transmission of this organism to household members, especially young infants, can occur in the absence of direct contact in household. Salmonella bacteremia and meningitis has occurred from transmission from pet lizards.

ETIOLOGY AND PATHOPHYSIOLOGY

- Common bacterial causes of gastroenteritis include *Campylobacter* spp, *Salmonella* spp, diarrheal-producing strains of *E coli, Shigella* spp, and *Yersinia* spp.
- Virulent traits of these agents include enterotoxins and cytotoxins that promote aggregation and invasiveness that result in clinical symptoms.
- Antibiotic-associated colitis is due to toxin-producing strains of *Clostridium difficile*.
- Common viral causes of diarrhea include rotavirus, enteric adenovirus, norovirus, and astrovirus.

- Universal immunization of infants in the US with rotavirus vaccine has resulted in a dramatic decline in rotavirus illness requiring hospitalization.[3]
- Viruses exert their diarrheal effect through selective destruction of absorptive cells in the mucosa, reduction of brush border enzymes, and alteration of the absorptive fluid balance in the gut.
- Host factors also influence susceptibility to infection and colonization. Children with underlying immunodeficiencies and premature infants are more at risk for severe episodes of diarrhea and complications of diarrhea, leading to increased morbidity and mortality.
- Extraintestinal manifestations of enteric pathogens result from direct local or remote spread of infection or are the result of immune-mediated mechanisms.

RISK FACTORS

- Child care attendance.
- Immunodeficiency.
- Prematurity.
- Ingestion of undercooked food.
- Exposure to animals and pets that may harbor infectious organisms like *Salmonella*.
- Travel to developing countries.

DIAGNOSIS

CLINICAL FEATURES

- Watery diarrhea is characteristic of infection with enteric viruses and enterotoxin-producing bacteria.
- Dysentery—Stools containing blood and mucus can result from bacterial causes that invade the large intestine, such as *Shigella* infection.
- Vomiting with minimal or no diarrhea—Can occur with viral causes as well as toxin-producing bacteria.
- Mesenteric adenitis is often a feature of bacterial gastroenteritis. This can simulate appendicitis if the pain is in the right lower quadrant.
- Disseminated infection and meningitis is a complication of *Salmonella* gastroenteritis and occurs mostly in young infants.
- Disseminated disease can occur with any bacterial cause of gastroenteritis in immunocompromised hosts.
- Extraintestinal immune mediated manifestations and the related pathogens include:
    - Erythema nodosum—Related to *Salmonella* spp, *Campylobacter* spp, and Yersinia spp.
    - Guillain Barre Syndrome—May follow *Campylobacter jejuni* infection.
    - Reactive arthritis—Related to *Shigella, Salmonella, Yersinia,* and *Campylobacter* infections.
    - Hemolytic uremic syndrome (HUS)—Most commonly related to Shiga-toxin producing *E coli*.
    - Seizures—Can be a feature of *Shigella* infection and may occur prior to the onset of diarrhea. These are benign and self-limited.

LABORATORY TESTING

- Most episodes of diarrhea are self-limited and testing is not warranted for most cases.
- Stool should be examined for the presence of blood and mucus, which may serve as a clue as to the pathogen. In general, pathogens causing invasion, such as shiga-toxin producing *E coli* and some serotypes of *Shigella*, produce bloody diarrhea.

- In general, stool cultures are indicated when stools contain blood or fecal leukocytes, when hemolytic uremic syndrome is suspected, during outbreaks, and in immunocompromised children.
- Routine stool cultures in most laboratories test for *Campylobacter, Salmonella, Shigella*, and *Yersinia* species. Identification of *E coli* O157:H7 requires special assays, which should be used for cases of suspected hemolytic uremic syndrome.
- Identification of toxin producing strains of *C. difficile* can be done using enzyme immunoassays or polymerase chain reaction techniques.
- Stool antigen tests can be used to detect rotavirus infection.
- When HUS is suspected, a renal panel and CBC are indicated. The finding of a microangiopathic hemolytic anemia, thrombocytopenia and renal dysfunction is consistent with HUS (see Chapter 69, Hemolytic Uremic Syndrome).

DIFFERENTIAL DIAGNOSIS

- Other causes of diarrhea such as irritable bowel disease, toddler’s diarrhea, and inflammatory bowel disease need to be considered in the differential diagnosis. A thorough history and associated findings such as fever are helpful clinically. Stool studies help to rule out infectious etiologies when the diagnosis is not clear.
- Toddler’s diarrhea (chronic nonspecific diarrhea of childhood) affects children from 6 months to 5 years of age. Children with toddler’s diarrhea will have 3 to 10 loose stools per day but continue to grow and gain weight normally. These children will grow out of this on their own without treatment.
- Bacterial causes of gastroenteritis can cause an intense mesenteric adenitis and can mimic appendicitis. This is classically attributed to *Yersinia* infection, but can occur with other bacteria that cause gastroenteritis.

MANAGEMENT

NONPHARMACOLOGIC

- Careful attention to fluid and electrolyte status is of the utmost importance in all cases of diarrhea.
- Oral rehydration therapy is preferred modality for the management of diarrhea in otherwise healthy children who have mild or moderate dehydration.[4]
- Current oral rehydration therapies in the US, such as Pedialyte, Rehydralyte, Enfalyte, and CeraLyte-50 are glucose-electrolyte solutions that can be used in infants and children with mild to moderate dehydration.
- Multiple studies, both in the US and in developing countries, have shown that early feeding of age-appropriate foods, including milk, to children with diarrhea after rehydration is associated with decreased stool output and reduction in duration of diarrhea.

MEDICATIONS

- Antimotility agents have not been shown to be effective in treating acute diarrhea in infants and children, and are associated with systemic toxic effects that may be exaggerated in infants and children; thus, their use is not recommended.
- Probiotics, especially *Lactobacillus rhamnosus* GG, used early in the course of acute viral gastroenteritis, may reduce the duration of diarrhea by 1 day.[5,6] SOR B
- Probiotics may also prevent antibiotic-associated diarrhea.
- There is no evidence to support probiotics in the prevention of infectious diarrhea or in the treatment of antibiotic-associated diarrhea.

- Definite recommendations regarding the use of specific probiotics are lacking and await further clinical trials in infants and children.
- Antimicrobial therapy for most cases of acute gastroenteritis is generally not of benefit. Antimicrobial therapy for acute gastroenteritis may be of benefit in specific cases:
    - *Shigella* infections—Therapy may be effective in shortening duration of diarrhea and hastening eradication of the organism and is recommended for patients with severe disease, dysentery, or underlying immunosuppressive conditions. Azithromycin, ciprofloxacin, or a parenteral third-generation cephalosporin may be used for treatment when required.[7] SOR Ⓑ
    - *Campylobacter* jejuni—Azithromycin and erythromycin shorten the duration of illness and excretion of organisms and prevent relapse when given early in gastrointestinal tract infection.[8] SOR Ⓑ
    - Non-typhi *Salmonella* infections in infants less than 3 months—Antimicrobial therapy is used in young infants to prevent dissemination of the organism, although the benefit of this practice is unproven. Treatment of Salmonella gastroenteritis in otherwise healthy children 3 months of age and older is not beneficial and not recommended.[9] SOR Ⓒ
    - Traveler's diarrhea—Azithromycin is preferred for children who develop a diarrheal illness in a developing country.
    - *C difficile* infections—Metronidazole administered orally or parenterally is the first line treatment. Oral vancomycin is reserved for refractory cases.
    - *Salmonella typhi*—See Chapter 7, Global Health.
    - Cholera—See Chapter 7, Global Health.

REFERRAL

- Children with severe dehydration, complications of gastroenteritis, or with extra-intestinal manifestations may require hospitalization and/or referral with a pediatric gastroenterologist or infectious disease specialist.

PREVENTION AND SCREENING

- Careful attention to public and personal hygienic practices is important in decreasing diarrheal illnesses.
- Assuring clean water, food, and sanitation is essential in preventing diarrheal illness.
- Careful hand hygienic practices are the most important personal measures that can be used to prevent transmission of diarrheal agents.
- Breastfeeding decreases morbidity and mortality associated with diarrheal illness.
- Proper food preparation is important in preventing contamination and transmission of infectious agents.
- Pet reptiles should not be avoided in households where young children and immunocompromised individuals reside.[9]
- A rotavirus vaccine should be given to all infants starting at 2 months of age; two vaccines are currently available for infants, and are safe and effective.[10]
- Two *S typhi* vaccines are licensed for children traveling to countries where *S typhi* is endemic; a polysaccharide vaccine parenteral vaccine is available for children 2 years and older, and a live oral typhoid vaccine is available for children 6 years of age and older.[9]

PROGNOSIS

- Morbidity and mortality associated with diarrheal illness is related to adequacy of treatment of dehydration.
- Meticulous supportive management of complications of diarrheal illness, such as HUS, is important in limiting morbidity and mortality.

FOLLOW-UP

- Close follow-up for patients with dehydration secondary to diarrheal illness is required.
- Documentation of negative stool cultures are required for *Shigella* and shiga-toxin producing *E coli* infections prior to the return to child care.

PATIENT EDUCATION

- The importance of adequate hydration should be stressed to parents of children with diarrhea.
- Travelers should be educated about appropriate food and water precautions.
- Parents of young infants and children should be educated as to the importance of proper food preparation.

PARASITIC INFECTIONS

PATIENT STORY

A parent brings in a 4-year-old boy suffering with anal itching. On examination the physician finds several excoriations around the anus and suspects pinworms. The physician then applies scotch tape to the perianal area and places the tape on a glass slide. Review of the slide demonstrates adult worms and ova of *Enterobius vermicularis* (pinworms; **Figure 179-2**). The boy is treated with a single dose of chewable mebendazole and his symptoms resolve. The parent is told to repeat the mebendazole dose in 2 weeks to increase the long-term cure rate. If the scotch tape test were negative, the physician could choose to treat empirically as mebendazole is a very safe medication. Another option is to test again having the parent apply the scotch tape to the boy’s perianal area first thing in the morning and bring that back to the office (the yield is higher in the morning).

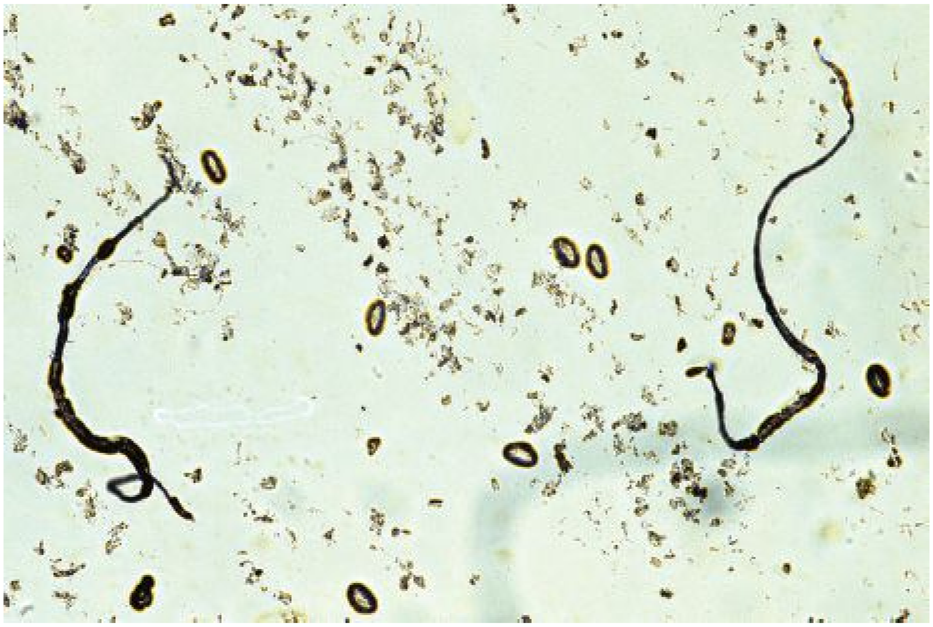

Figure 179-2 *Enterobius vermicularis* (pinworms and ova) seen under the microscope from a scotch tape specimen taken of the perianal region of a 4-

year-old boy with anal itching. (*Used with permission from James L. Fishback, MD.*)

INTRODUCTION

Intestinal parasites are most common in places with warmer temperatures and high humidity, poor sanitation and unclean water, and a large number of individuals (especially children) living in close proximity. In general, the parasites are either asymptomatic or cause symptoms related to their presence in the GI tract. Several migrate through the lungs and can also cause pulmonary symptoms during the migration. Diagnoses are made by history of worms being seen by the patient or parents or by laboratory examination for ova and parasites in the stool.

EPIDEMIOLOGY

- Nematoda is the phylum that contains pinworms, hookworms, *Ascaris*, *Strongyloides*, and whipworms.
  - *E. vermicularis* (pinworm) is the most prevalent nematode in the US. Populations at risk include preschool and school aged children, institutionalized persons, and household members of persons with pinworm infection (**Figure 179-3**).[11]

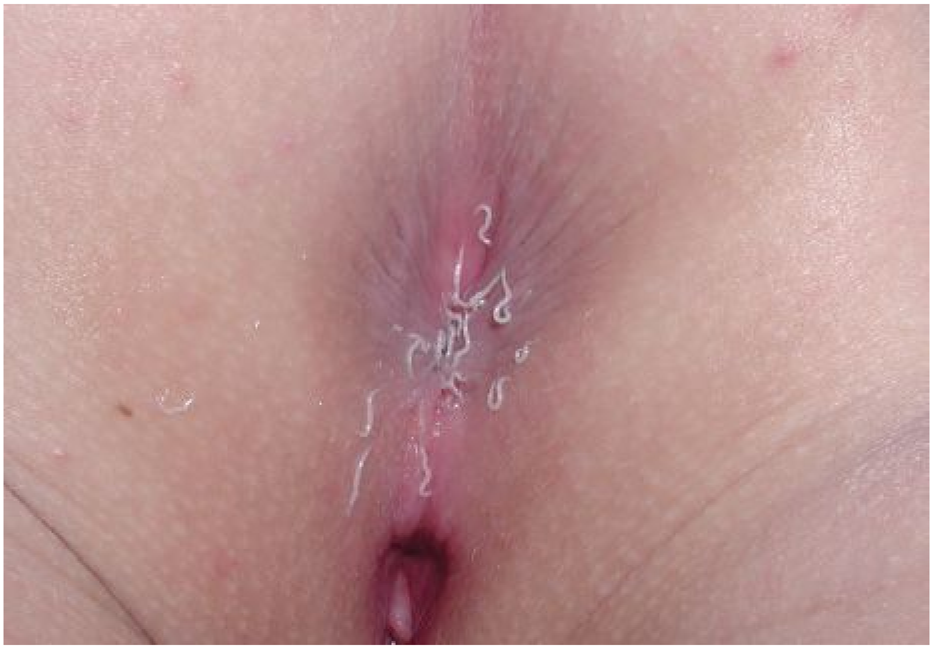

Figure 179-3 *Enterobius vermicularis* (pinworms) seen on the perianal and perineal regions of a young girl with anal itching. (*Used with permission from the Atlas of Emergency Medicine and Lawrence E. Heiskell, MD.*)

- *Necator americanus* (hookworm) is found predominately in the Americas and Australia, and is the second most common nematode identified in stool studies in the US (**Figures 179-4** and **179-5**).[11] *Ancylostoma duodenale* (hookworm) is found mostly in southern Europe, North Africa, the Middle East, and Asia.[11]

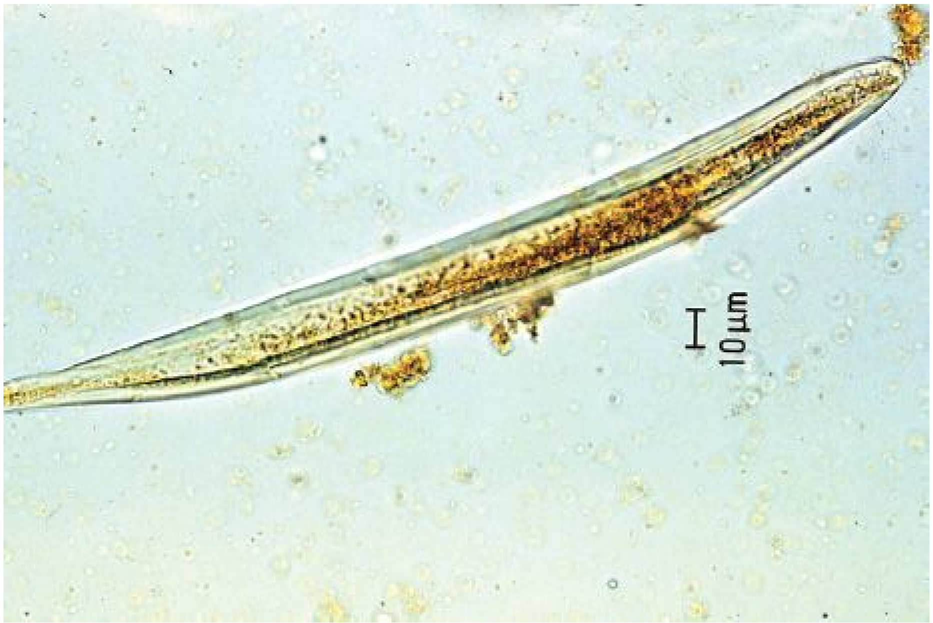

Figure 179-4 *Necator americanus* (hookworm) larvae can penetrate the skin, travel through veins to the heart then lungs, climb the bronchial tree to the pharynx, are swallowed, and attach to intestine walls. (*Used with permission from James L. Fishback, MD.*)

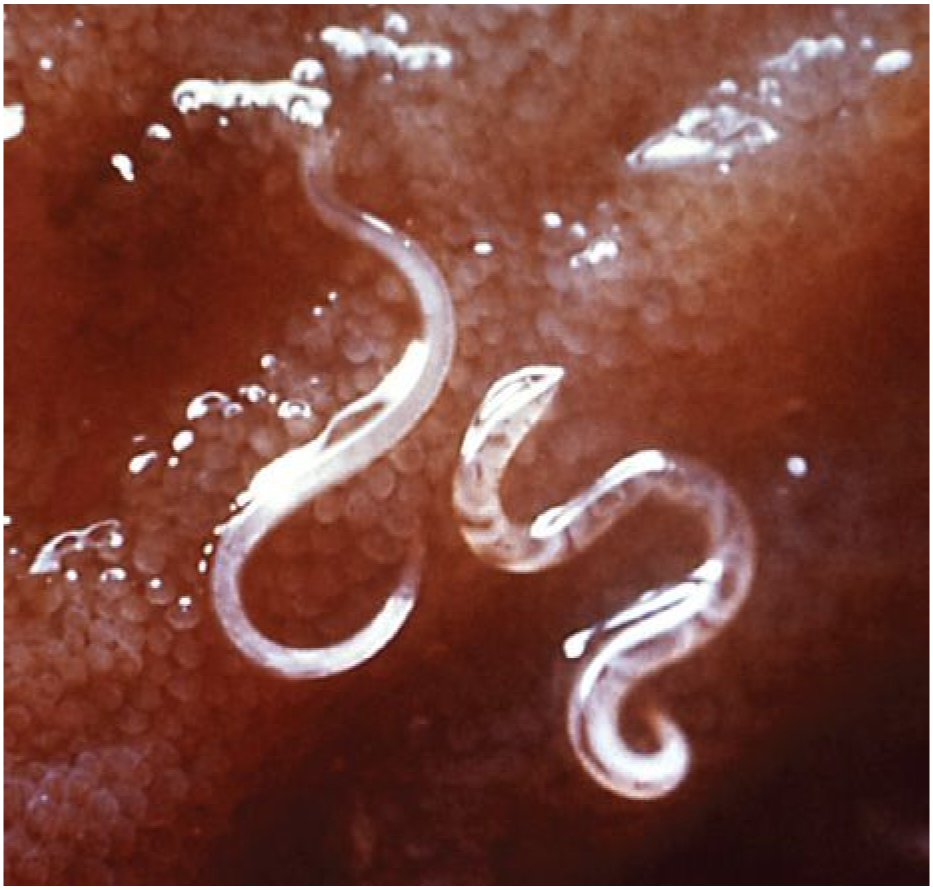

Figure 179-5 Adult hookworm attached to the intestinal wall. (*Used with permission from Centers for Disease Control and Prevention.*)

- *Ascaris lumbricoides* is the largest and most common roundworm found in humans in the world; although less common in the US, it is seen mostly in the rural southeast. It is found in tropical and subtropical areas, including the southeastern rural US (**Figures 179-6** and **179-7**).[11]

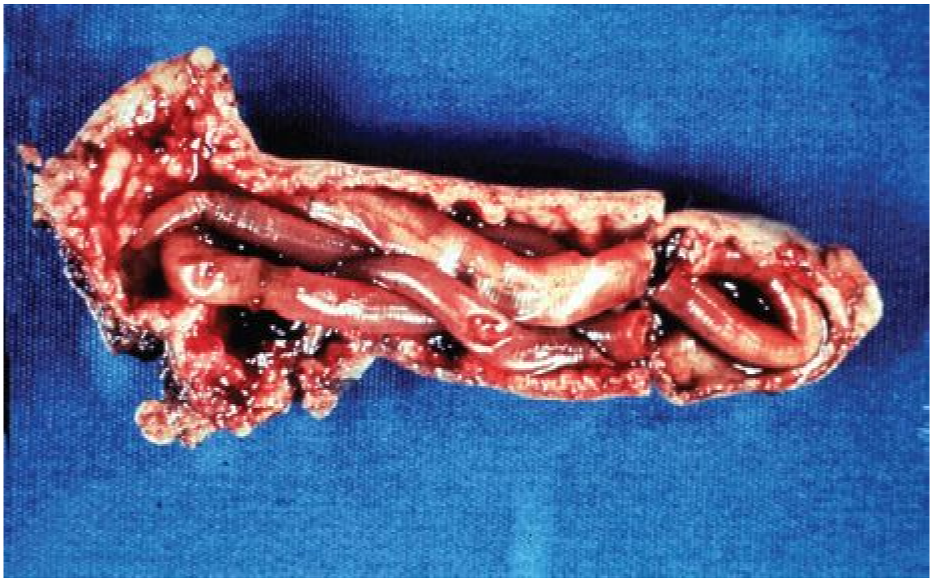

Figure 179-7 *Ascaris lumbricoides* in the appendix after being removed with an appendectomy for acute appendicitis. (*Used with permission from James L. Fishback, MD.*)

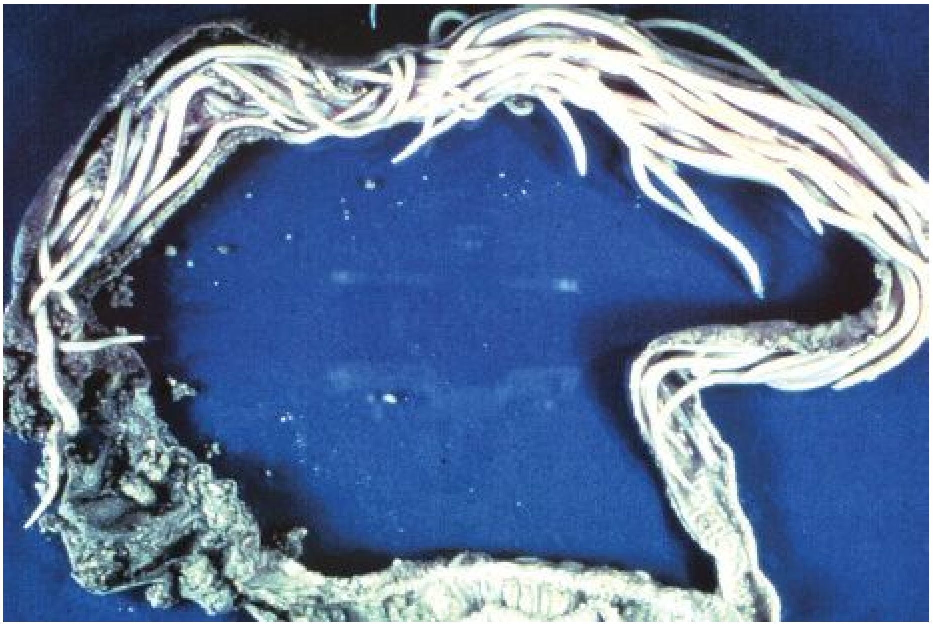

Figure 179-6 *Ascaris lumbricoides* in the resected bowel of a patient with bowel obstruction. (*Used with permission from James L. Fishback, MD.*)

- *Strongyloides stercoralis* is seen mostly in tropical and subtropical areas, but can be found in temperate areas, including the southern US

(**Figure 179-8**). It is more frequently found in rural areas, institutional settings, and lower socioeconomic groups.[11]

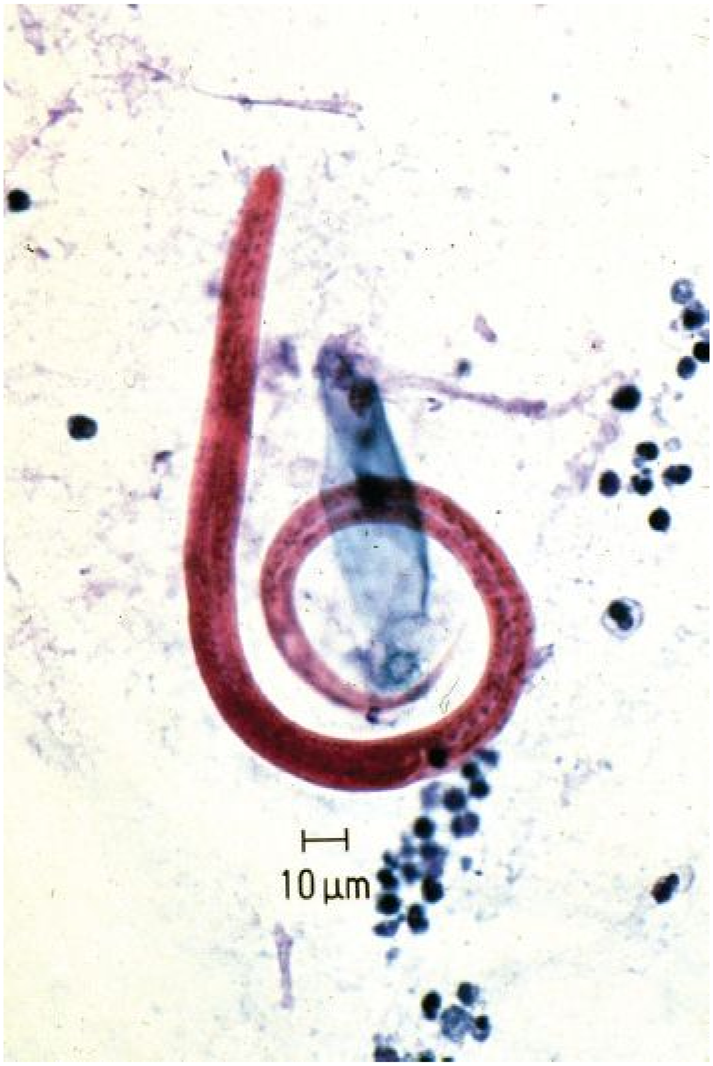

Figure 179-8 *Strongyloides stercoralis* ova and parasite in stool. (*Used with permission from James L. Fishback, MD.*)

- *Trichuris trichiura* (whipworm) is the third most common roundworm found in humans worldwide. Infections are more frequent in areas with tropical weather and poor sanitation practices, and among children (**Figure 179-9**). It is estimated that 800 million people are infected worldwide. Trichuriasis occurs in the southern US.[11]

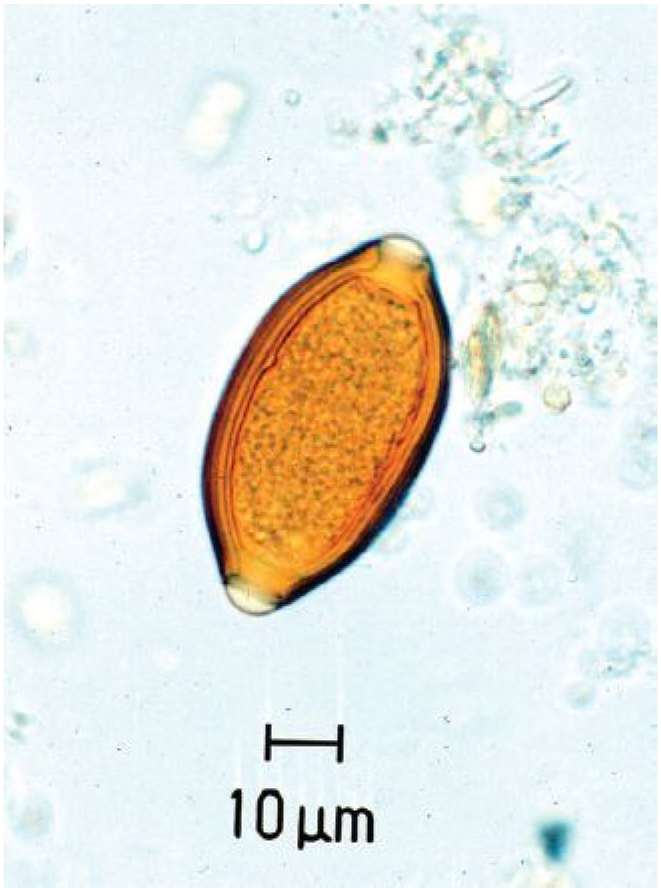

Figure 179-9 *Trichuris trichiura* (whipworm) egg in stool. (*Used with permission from James L. Fishback, MD.*)

- Cestodes (tapeworm) are a class in the phylum Platyhelminthes that contains *Taenia solium* (pork tapeworm).
    - *T. solium* is found worldwide where pigs and humans live in close proximity.
- Protozoa is the kingdom of one-celled organisms that includes *Giardia lamblia*, *Cryptosporidium species*, and *Entamoeba histolytica*.
    - *G. lamblia (Giardia intestinalis)* is the most common parasite infection worldwide and the second most common in the US (after pinworm), causing 2.5 million infections annually (**Figure 179-10**).[11]

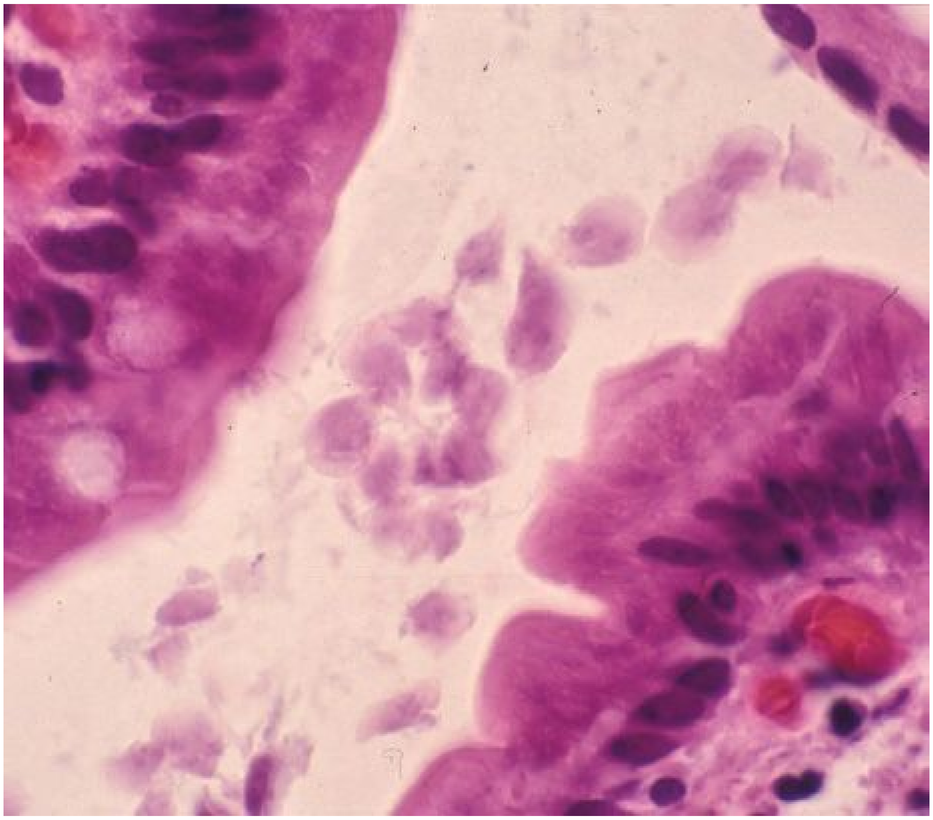

Figure 179-10 *Giardia lamblia* in a duodenal biopsy obtained by esophagogastroduodenoscopy in a patient with typical symptoms of chronic giardiasis (excessive flatulence and sulfurous belching) that failed to improve on metronidazole. (*Used with permission from Tom Moore, MD.*)

- *Cryptosporidium hominis* and *C parvum* causes diarrheal illness in normal and immunocompromised hosts. Large community outbreaks have occurred from contaminated municipal water supplies and swimming pools, and smaller outbreaks have occurred in child care centers.
- *E. histolytica* is seen worldwide, with higher incidence in developing countries. In the US, risk groups include men who have sex with men, travelers and recent immigrants, and institutionalized populations.[11]

ETIOLOGY AND PATHOPHYSIOLOGY

- Nematodes (roundworms).
    - *E. vermicularis* (pinworm; **Figures 179-2** and **179-3**) is acquired through an oral route when hands that have contacted contaminated objects are placed in the mouth. Larvae hatch in the small intestine. Adults live in the cecum. The pregnant female goes to the perianal region at night to lay eggs.
    - *N. americanus* (hookworm; **Figure 179-4**) larvae penetrate the skin, travel through veins to the heart and then to the lungs, climb the bronchial tree to the pharynx, and then are swallowed and attach to intestine walls (**Figure 179-5**).
    - When fertilized eggs of *A. lumbricoides* (**Figure 179-6**) are ingested, they hatch and the larvae enter the circulation through intestinal mucosa, travel to the lungs, climb to the pharynx, then are swallowed, and finally the adult *Ascaris* worms live in the small intestine.
    - *S. stercoralis* have both a free-living and parasitic cycle. In the parasitic cycle, larvae penetrate the skin, travel through the circulation to the lungs and are swallowed, and travel to the small intestine (**Figure 179-8**) to become adults. Adult females lay eggs, which become rhabditiform larvae, which can either become free living or can cause autoinfection by reentering the parasitic cycle or disseminating widely in the body.
    - *T. trichiura* (whipworm; **Figure 179-9**) eggs are ingested and hatch in the small intestine; worms live in the cecum or colon.
    - Cestodes (tapeworms)—*T. solium* is acquired by ingesting undercooked contaminated pork. Diphyllobothrium latum is the fish tapeworm that is acquired by ingesting uncooked contaminated fresh-water fish.
- Protozoa.
    - *G. lamblia* cysts are ingested from contaminated water, food, or fomites and travel to the small intestine (**Figure 179-10**).
    - Cryptosporidium species can be acquired and spread from person-to-person or from ingestion of contaminated water.
    - *E. histolytica* cysts or trophozoites are ingested from fecally contaminated food, water, or hands or from fecal contact during sexual practices; these then travel to the large intestine, where these either remain or travel through the bloodstream to the brain, liver, or lungs.

RISK FACTORS

- Endemic in developing countries with limited access to clean water.
- Living in an environment conducive to parasites (warm, humid climate) and parasitic transfer (crowded conditions, contaminated water supply, or poor hygiene) dramatically raises the risk of parasitic infection.
- Household contacts or caretakers of persons with intestinal parasites are at risk for contracting the parasites.
- Children or others with poor hygiene are also at high risk.
- Immunocompromised patients, once infected, may have a more serious course.

DIAGNOSIS

CLINICAL FEATURES

- Nematodes.
  - *E. vermicularis* (pinworm)—Perianal pruritus is the most common; female genital tract irritation also reported; rarely abdominal pain or appendicitis; infants show irritability, but can be asymptomatic.[11]
  - *N. americanus* (hookworm)—Most commonly presents with iron-deficiency anemia.[11]
  - *A. lumbricoides*—Frequently asymptomatic; high numbers of worms can cause abdominal pain or intestinal obstruction. Cough, dyspnea, hemoptysis, or eosinophilic pneumonitis when in the lungs. Patients may cough up visible worms.
  - S. stercoralis—Frequently asymptomatic; eosinophilia; may cause abdominal pain or diarrhea, cough, shortness of breath, or hemoptysis when in the lungs; can disseminate in immunocompromised patients causing abdominal pain, distention, septicemia, shock, or death.

  - T. trichiura (whipworm)—Frequently asymptomatic; high number of worms can cause abdominal pain or intestinal obstruction, especially in children.

- Cestodes.
  - *T. solium*—Frequently asymptomatic; risk of developing cysticercosis with symptoms based on location of cysts in brain (e.g., seizures, focal neurologic signs, and death), eyes, heart, or spine.

- Protozoa.
  - *G. lamblia*—Diarrhea, nausea, emesis, abdominal bloating occurs 1 to 14 days after ingestion for up to 3 weeks and can be asymptomatic.
  - Cryptosporidiosis in otherwise healthy children often results in asymptomatic infection. Some children may develop a self-limited watery diarrhea associated with vomiting, abdominal pain, and fever. Immunodeficient individuals, particularly those with human immunodeficiency virus infection and other T-cell deficiencies, may develop a severe protracted diarrheal illness with malabsorption and weight loss, or may develop disseminated infection and cholangitis.
  - *E. histolytica*—Asymptomatic, intestinal symptoms (e.g., colitis and appendicitis), or extraintestinal (e.g., abscess in the liver or lungs, peritonitis, and skin or genital lesions).

LABORATORY TESTING

- Nematodes.
  - *E. vermicularis* (pinworm)—Microscopic identification of eggs (**Figure 179-2**) collected from perianal area; apply transparent adhesive tape to the unwashed perianal area at the time of presentation or in the morning and then place tape on slide.
  - *N. americanus* (hookworm)—Microscopic identification of eggs in the stool.
  - *A. lumbricoides*—Microscopic identification of eggs in the stool.
  - S. stercoralis—Microscopic identification of larvae in stool (**Figure 179-8**) or duodenal fluid; often requires several samples. Immunologic tests are useful when infection is suspected, but larvae are not seen in

  several samples. Immunologic tests do not differentiate from past or present infections.
  - T. trichiura (whipworm)—Microscopic identification of eggs in stool (**Figure 179-9**).

- Cestodes.
  - T. solium—Microscopic identification of eggs or proglottids in stool indicates taeniasis; presumed neurocysticercus diagnosed from Centers for Disease Control and Prevention (CDC)'s immunoblot assay.[11]

- Protozoa.
  - G. lamblia—Microscopic identification of cysts or trophozoites in stool or trophozoites in duodenal fluid or biopsy (**Figure 179-10**). Antigen tests and immunofluorescence are available.
  - Cryptosporidium species—Microscopic identification of oocytes in stool using a modified acid-fast stain. Antigen assays are available and used commonly.
  - E. histolytica—Microscopic identification of cysts or trophozoites in stool (difficult to distinguish from nonpathogens); antibody detection for extraintestinal disease; antigen detection can distinguish pathogenic and nonpathogenic infections.[11]

IMAGING

- Cestodes.
  - T. solium—MRI is typically used to identify brain cysts.

DIFFERENTIAL DIAGNOSIS

- Abdominal symptoms seen with several intestinal parasites can also be caused by the following:
  - Viral or bacterial infections—May present with acute onset of emesis and diarrhea often with fever (see the preceding).

  - Irritable bowel disease—Chronic symptoms of abdominal cramping with diarrhea or loose stools and/or constipation; usually no bloody stools, weight loss, or anemia.
  - Inflammatory bowel disease—Intermittent abdominal pain and bloody stools; diagnosis confirmed by colonoscopy with biopsy.
  - Iron-deficiency anemia seen with hookworms can be seen with blood loss from any site from one of many causes. Of course, iron deficiency can be seen with a diet deficient in iron without having hookworms.
  - GI blood loss can be seen with other infections or inflammation, polyps, or masses.

MANAGEMENT

MEDICATIONS

All medication doses are from *The Medical Letter*.[12]

- Nematodes.
  - E. vermicularis (pinworm)—Pyrantel pamoate 11 mg/kg once (maximum 1 g), repeat in 2 weeks; or mebendazole 100 mg once, repeat in 2 weeks.
  - N. americanus (hookworm)—Albendazole 400 mg once; or mebendazole 100 mg twice a day for 3 days 500 mg once or pyrantel pamoate 11 mg/kg (maximum 1 g) for 3 days.
  - A. lumbricoides—Albendazole 400 mg once; alternate therapy mebendazole 500 mg once or ivermectin 150 to 200 mcg/kg po once.
  - S. stercoralis—Ivermectin 200 mcg/kg per day for 2 days; alternate therapy albendazole 400 mg bid for 7 days.
  - T. trichiura (whipworm)—Mebendazole 100 mg twice a day for 3 days or 500 mg once; alternate therapy albendazole 400 mg once a day for 3 days or ivermectin 0.2 mg/kg daily for 3 days.
- Cestodes.

  - T. solium—Praziquantel 5 to 10 mg/kg once for intestinal stage; cysticercosis require seizure prophylaxis and steroids in conjunction with albendazole 15 mg/kg per day up to 400 mg bid for 8 to 30 days; ophthalmologic examination for eye cysts is recommended.

- Protozoa.
  - G. lamblia—Metronidazole 15 mg/kg per day, up to 750 mg, divided tid for 5 to 7 days; or tinidazole 50 mg/kg (maximum 2 g) once; or nitazoxanide 500 mg bid for 3 days (age >12 years), 100 mg bid for 3 days (age 1 to 3 years), 200 mg po bid for 3 days (age 4 to 11 years).
  - Cryptosporidiosis—Nitazoxanide 500 mg bid for 3 days (age >12 years), 100 mg bid for 3 days (age 1 to 3 years), 200 mg bid for 3 days (age 4 to 11 years).
  - E. histolytica—Metronidazole 35 to 50 mg/kg per day, up to 1500 mg, divided in 3 doses for 7 to 10 days or 50 mg/kg per day in 3 doses up to 2 γ for 3 days. Then iodoquinol 30 to 40 mg/kg per day up to 2 γ in 3 doses for 20 days; or paromomycin 25 to 35 mg/kg per day in 3 doses for 7 days.

REFERRAL OR HOSPITALIZATION

Refer or hospitalize patients:

- Who do not respond to initial therapy or have recurrent infections.
- Suspected of having cysticercosis.
- Experiencing severe abdominal symptoms suggesting obstruction or an acute abdomen.

PREVENTION

- Clean uncontaminated water for drinking and cooking—Use bottled water, chemically treated water, or boiled water in endemic areas.
- Good hygiene, especially hand washing.

- When travelling to endemic areas, drink bottled water when possible. Water can also be treated with chlorine, iodine, or boiled if bottled water is not available. Clean water should be used for brushing teeth. Avoid eating fresh salads washed in local water.
- Children in developing countries who are drinking contaminated water (and lack access to clean water) should be considered for deworming with albendazole every 3 to 6 months (see Chapter 7, Global Health).

PROGNOSIS

Prognosis is excellent for most infections if adequate therapy and clean water is available.

FOLLOW-UP

Follow up at completion of therapy.

PATIENT EDUCATION

Most intestinal parasites are asymptomatic and easily treatable. Avoid infecting others by practicing good hygiene, including hand washing.

PATIENT RESOURCES

180 GONOCOCCAL INFECTIONS

Heidi Chumley, MD
Richard P. Usatine, MD

PATIENT STORY

A 17-year-old male presents to his pediatrician with 3 days of dysuria and penile discharge. A heavy purulent urethral discharge is seen (**Figure 180-1**). He has been sexually active with four female partners. He was diagnosed with gonococcal urethritis by clinical appearance and a urine specimen was sent for testing to confirm the gonorrhea and test for *Chlamydia*. He was treated with Ceftriaxone 250 mg IM for gonorrhea and 1 γ of oral azithromycin for possible coexisting *Chlamydia*. He was offered and agreed to testing for other sexually transmitted diseases. He was told to inform his partners of the diagnosis. He was counseled about safe sex. On his 1-week follow-up visit, his symptoms were gone and he had no further discharge. His gonorrhea nucleic acid amplification test was positive and his *Chlamydia*, rapid plasma reagin (RPR), and HIV tests were negative. His case was reported to the Health Department for contact tracing.

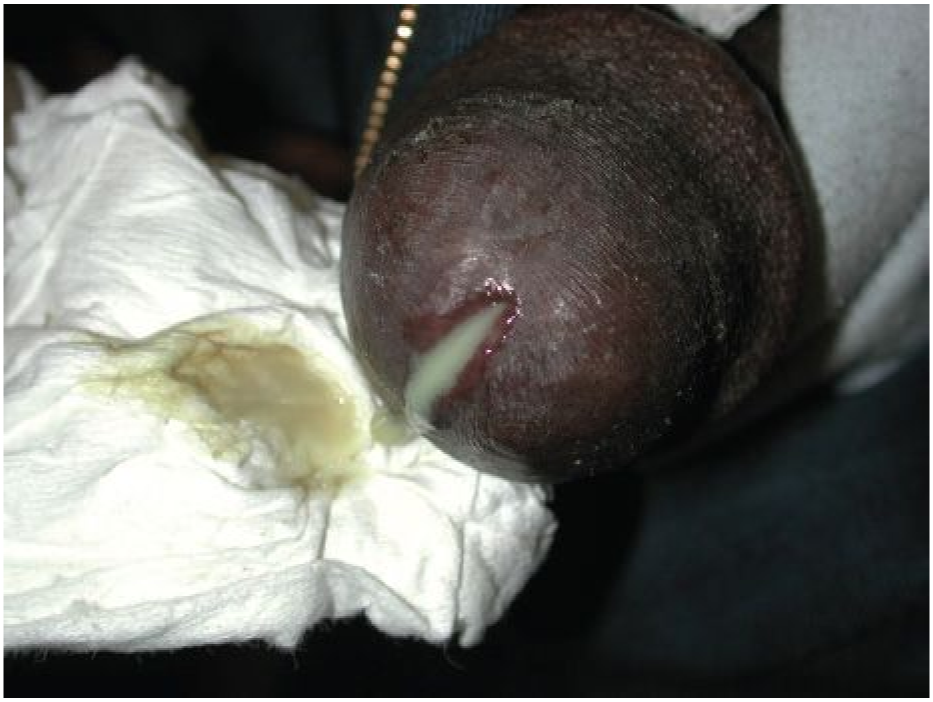

Figure 180-1 A 17-year-old with gonococcal urethritis and a heavy purulent urethral discharge. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Infections with *Neisseria gonorrhoeae* are the second most commonly reported sexually transmitted disease in the US. Gonorrhea can cause cervicitis, urethritis, proctitis, and conjunctivitis. Untreated infections can lead to pelvic inflammatory disease, increasing the risk for infertility, ectopic pregnancy and chronic pelvic pain. Exposed newborns can develop ophthalmia neonatorum. Diagnosis is suspected clinically and confirmed by a urine nucleic acid amplification test. Treat for both gonorrhea and *Chlamydia* until one or both are ruled out by laboratory testing.

EPIDEMIOLOGY

- The prevalence of gonorrhea in boys and girls ages 15 to 19 was 248.6 and 556.5 per 100,000 persons in the US in 2011. In 2011, gonorrhea rates remained highest among black men and women (427.3), which was 17 times the rate among whites (25.2 per 100,000 population). The rates among Hispanics (53.8) was 2.1 times those of whites.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- *Neisseria gonorrhoeae* is a gram-negative cocci.
- Urethritis is most common infection in males, with an incubation period of 2 to 7 days.
- Cervicitis is the most common infection in females, with symptoms typically developing within 10 days of exposure.
- Vaginitis is rare in adolescents but can be seen in prepubertal girls due to lack of estrogen effect on the vaginal mucosa.
- May also cause anorectal or pharyngeal infections.
- Ophthalmia neonatorum presents 2 to 5 days after birth (see Chapter 72, Neonatal Conjunctivitis).
- Gonococcal bacteremia can cause a polyarthritis often accompanied by skin lesions.

DIAGNOSIS

CLINICAL FEATURES

Male patients with urethritis can be asymptomatic or present with urethral discharge, dysuria, or urethral pruritus.

Urethritis is diagnosed when one of the following is present:[2]

- Mucopurulent or purulent urethral discharge (**Figures 180-1** and **180-2**).

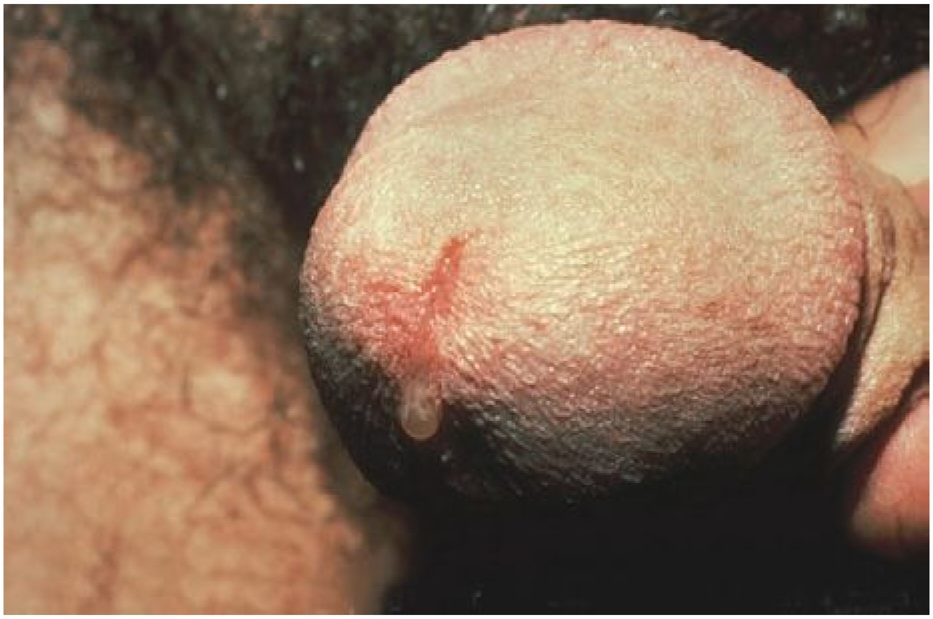

FIGURE 180-2 Nongonococcal urethritis caused by *Chlamydia*. Note the discharge is clearer and less purulent than seen with gonorrhea. (*Used with permission from Seattle STD/HIV Prevention Training Center, University of Washington*.)

- First-void urine positive leukocyte esterase test ≥10 white blood cells (WBCs) per high-power field. (This can also be seen with a urinary tract infection [UTI]; however, the incidence of UTI in men younger than 50 years of age is approximately 50 per 100,000 per year, much lower than the incidence of gonococcal or chlamydial urethritis in this age group.)
- Female patients can be asymptomatic, present with mild symptoms such as scant discharge or dysuria, or present with mucopurulent vaginal discharge (**Figures 180-3** and **180-4**).

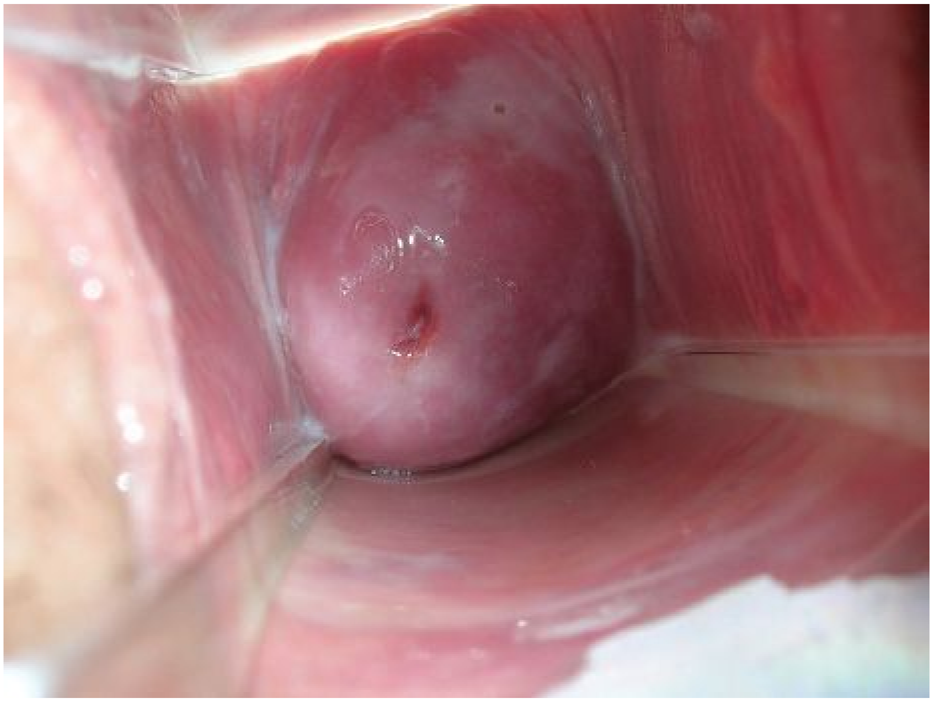

FIGURE 180-3 Normal appearing cervix in a patient with a mild white vaginal discharge and proven gonorrhea and Chlamydia. During this visit when the liquid-based Pap test was performed the specimen was also sent for gonorrhea and chlamydia and found to be positive. She was enrolled in a residential drug rehabilitation program and had a history of unprotected sex with multiple partners. (*Used with permission from Richard P. Usatine, MD*.)

FIGURE 180-4 Thick mucopurulent discharge from the cervix infected with gonorrhea. (*Used with permission from Seattle STD/HIV Prevention Training Center, University of Washington. http://depts.washington.edu/handbook/gallery/index.html image 7-6*.)

LABORATORY TESTING

- Nucleic acid amplification test (NAAT) is the recommended test for screening asymptomatic at-risk adolescent boys and testing symptomatic adolescent boys.[2] Urine is a better specimen than urethral swab and does not hurt.[2,3]

- Self collected vulvovaginal swabs, in women age 16 or older, are equivalent to clinician collected endocervical swabs.[4]
- Gram stain of urethral secretions with ≥5 WBC per oil immersion field. (If Gram-negative intracellular diplococci are seen, gonococcal urethritis is present.) Gram stain will identify most cases; ≥5 WBCs are seen in 82 percent of *Chlamydia* and 94 percent of gonococcal infections.[5] Government regulations concerning in-office laboratory testing have severely curtailed the use of Gram stains in the office.
- In males, leukocyte esterase test on urine has a good negative predictive value (NPV) but poor positive predictive value (PPV) in a low-prevalence population (NPV 96.4% and PPV 35.4%).[6] Urethral culture is less commonly necessary when NAAT is available.
- Consider culture when tests for gonorrhea and *Chlamydia* are negative, or symptoms persist despite adequate treatment in a patient who is unlikely to have been reinfected by an untreated partner.

DIFFERENTIAL DIAGNOSIS

Dysuria in males can be caused by the following:[7]

- Infections in other sites or the urogenital tract—Cystitis, prostatitis with perineal pain or prostate tenderness, or epididymitis with scrotal pain.
- Penile lesions—Vesicles of herpes simplex, ulcers of syphilis, chancroid, or lymphogranuloma venereum, and glans irritation from balanitis.
- Mechanical causes—Obstruction from benign prostatic hyperplasia (BPH) causing inflammation without infection, trauma including catheterization, urethral strictures, or genitourinary cancers.
- Inflammatory conditions—Spondyloarthropathies, drug reactions, or autoimmune diseases.

Vaginal discharge is also commonly caused by Chlamydia, Trichomonas, or candidiasis. Co-infection with gonorrhea should be ruled out with any sexually transmitted infection causing vaginal discharge.

MANAGEMENT

When clinical suspicion is high, treat male and female patients empirically for both *N. gonorrhoeae* and *C. trachomatis* until results are available. In males, treat patients who meet criteria for urethritis. Test patients with dysuria who do not meet criteria for urethritis, for *N. gonorrhoeae* and *C. trachomatis*, and treat if positive. Advise sex partners to be evaluated and treated.[1]

MEDICATIONS

- The 2010 CDC STD treatment guidelines recommend treating uncomplicated gonococcal urethritis or cervicitis with ceftriaxone 250 mg IM in a single dose plus treatment for *Chlamydia* with azithromycin or doxycycline. Most gonococci in the US are susceptible to doxycycline and azithromycin, so that routine co-treatment might also hinder the development of antimicrobial-resistant *N. gonorrhoeae*.[8] Avoid fluoroquinolones and oral cefixime as drug resistance is too high.[8,9] SOR Ⓐ
- The 2010 CDC STD treatment guidelines recommend treating *Chlamydia* urethritis or cervicitis with azithromycin 1 γ orally in a single dose or doxycycline 100 mg orally twice a day for 7 days.[10] SOR Ⓐ Acceptable alternate regimens include:
    - Erythromycin base 500 mg 4 times a day for 7 days or erythromycin ethylsuccinate 800 mg 4 times a day for 7 days or ofloxacin 300 mg orally twice a day for 7 days or levofloxacin 500 mg orally once daily for 7 days.[10]
- For persistent urethritis or cervicitis, consider *Trichomonas vaginalis* as a possible cause—Culture and treat with a single dose of metronidazole 2 g.

- Consider expedited partner therapy (EPT). EPT is the delivery of medications or prescriptions by persons infected with a sexually transmitted disease (STD) to their sex partners without clinical assessment of the partners. Legal status by state is available at www.cdc.gov/std/ept/legal/default.htm.

PREVENTION

- Encourage safe-sex practices.
- From the US Preventive Services Task Force:
    - Screen asymptomatic sexually active adolescent females for gonorrhea. SOR Ⓑ
    - There is insufficient evidence to recommend screening asymptomatic sexually active adolescent males for gonorrhea. SOR Ⓐ
- Offer STI testing, including testing for gonorrhea, in patients with an STI.
- Use prophylactic ocular topical medicine in all newborns. SOR Ⓐ

PROGNOSIS

Gonococcal and chlamydial urethritis and cervicitis respond well to appropriate antibiotic therapy. Partners must be treated to avoid reinfection.

FOLLOW-UP

- Reevaluate patients with persistent or recurrent symptoms after treatment. Reexamine for evidence of urethral or cervical inflammation and retest for gonorrhea and *Chlamydia*.

- Routine test-of-cure laboratory examination is not recommended by the CDC for gonorrhea infections unless therapeutic compliance is in question, symptoms persist, or reinfection is suspected.[8,10]
- However, patients who have symptoms that persist after treatment of gonorrhea should be evaluated by culture for *N. gonorrhoeae*, and any gonococci isolated should be tested for antimicrobial susceptibility.[8]

PATIENT EDUCATION

The Centers for Disease Control and Prevention (CDC) recommends the following for patients diagnosed with gonorrhea:[1]

- Return for evaluation if the symptoms persist or return after therapy is completed.
- Abstain from sexual intercourse until 7 days after starting therapy, symptoms have resolved, and sexual partners have been adequately treated.
- Undergo testing for other STDs, including HIV and syphilis.
- Advise sexual partners of the need for treatment and/or take medications directly to them using EPT.

181 SYPHILIS

Richard P. Usatine, MD
Heidi Chumley, MD

PATIENT STORY

A young woman presents to the office with a total body rash for one week (**Figure 181-1**). She denies other symptoms and the rash does not itch. Upon examination, tattoos on her hands are visible and she does admit to experimenting with crack and IV heroine. The physician suspects that she may have secondary syphilis and she admits to many sexual partners especially while using drugs. She is given a shot of 2.4 million units of benzathine penicillin IM in the office and her blood is drawn for an RPR and an HIV test. The RPR and HIV tests come back positive along with a treponemal specific confirmatory test. The patient is called to return to the office for some serious counseling and a referral to an infectious disease specialist. The ID specialist is called on the phone to see if he wants to admit her for a lumbar puncture or if he will do this as an outpatient. She needs investigation for neurosyphilis due to her positive HIV status.

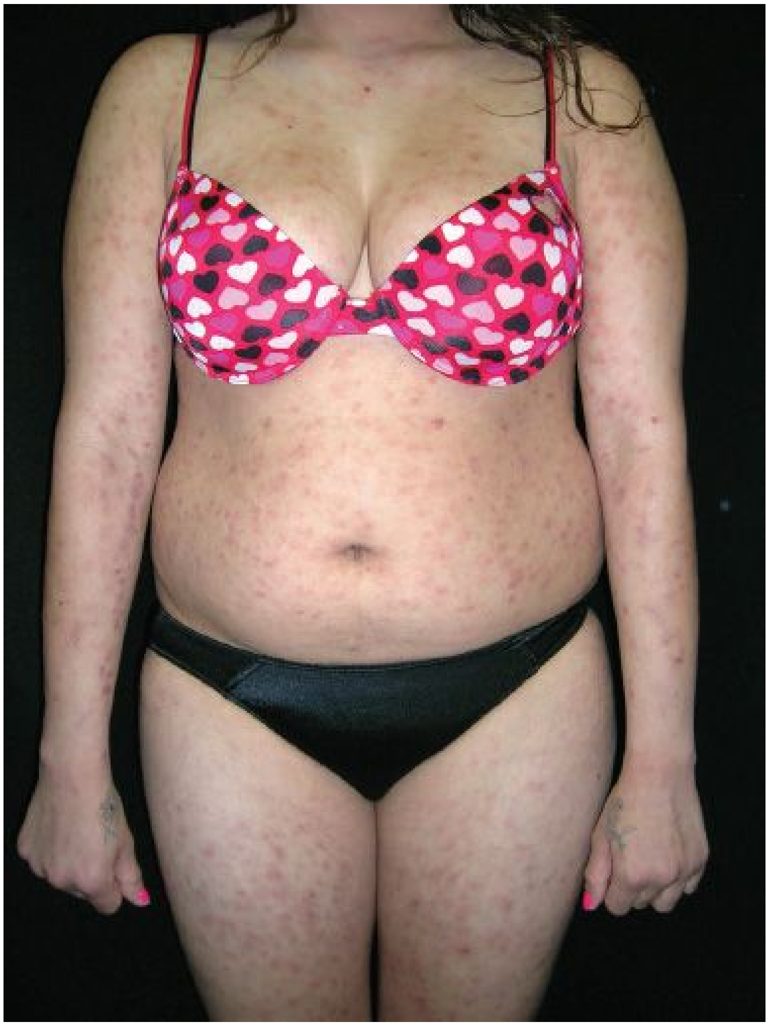

FIGURE 181-1 Secondary syphilis in a young woman with a history of injection drug use and multiple sexual partners. Her HIV test was also positive so she was worked up for neurosyphilis. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Syphilis, caused by *Treponema pallidum*, is a systemic disease characterized by multiple overlapping stages: primary syphilis (ulcer), secondary syphilis (skin rash, mucocutaneous lesions, or lymphadenopathy), tertiary syphilis (cardiac or gummatous lesions), and early or late latent syphilis (positive serology without clinical manifestations). Neurosyphilis can occur at any stage. Diagnosis is made using treponemal and nontreponemal tests. Treatment is penicillin; the dose and duration depend on the stage.

SYNONYMS AND ACRONYMS

Lues is another word for syphilis.

NONTREPONEMAL TESTS

- VDRL—Venereal Disease Research Laboratory.
- RPR—Rapid Plasma Reagin.

TREPONEMAL TESTS

- EIA—Enzyme immunoassay.
- TPPA—*T. pallidum* particle agglutination.
- FTA-ABS—Fluorescent treponemal antibody absorption.
- MHA-TP—Microhemagglutination assay for *T. pallidum*.

EPIDEMIOLOGY

- Primary and secondary (P&S) syphilis cases reported to CDC increased from 11,466 in 2007 to 13,970 in 2011, an increase of 22 percent.[1] The rate of P&S syphilis in the US in 2011 (4.5 cases per 100,000 population) was 2.2 percent lower than the rate in 2009 (4.6 cases). This is the first overall decrease in P&S syphilis in 10 years.[1]
- The prevalence of P&S syphilis per 100,000 population is extremely low in ages 0 to 4 (0.0), 5 to 9 (0.0), and 10 to 14 (0.1) year olds, with only 25 reported cases in 2011.[1]

- The prevalence of P&S syphilis per 100,000 between the ages of 15 and 19 is 3.9, and is higher in males (5.4) than females (2.4).[1]
- Syphilis in persons ages 15 to 19 differs by races/ethnicities. In 2011, prevalence per 100,000 was 16.7 in black, 2.5 in Hispanic, and 0.9 in white persons.[1]
- In 2008, 63 percent of the reported cases of P&S (adolescents and adults combined) were in men who have sex with men (MSM).[2]
- HIV-infected patients were found to have syphilis rates of 62.3 per 1000 compared to 0.8 per 1000 in HIV-uninfected patients in a population study of adults in California.[3]
- In 2011, there were 362 reported cases of congenital syphilis, 8.4 per 100,000 live births.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Syphilis is caused by the spirochete *T. pallidum* and contracted through direct sexual contact with primary or secondary lesions.
- Congenital syphilis can be contracted across the placenta. Seventy-five percent to 95 percent of fetuses are infected when untreated maternal syphilis was contracted within 2 years. Thirty-five percent of fetuses are infected when maternal syphilis was contracted more than 2 years before pregnancy.

RISK FACTORS

- Sexual contact with a person with primary or secondary syphilis.
- Gay males.
- Prostitution.
- Sex for drugs.

- HIV/AIDS.

DIAGNOSIS

CLINICAL FEATURES

- Primary syphilis is associated with a chancre—Usually a nonpainful ulcer (**Figures 181-2** and **181-4**). The presence of pain does not rule out syphilis, and the patient with a painful genital ulcer should be tested for both syphilis and herpes.

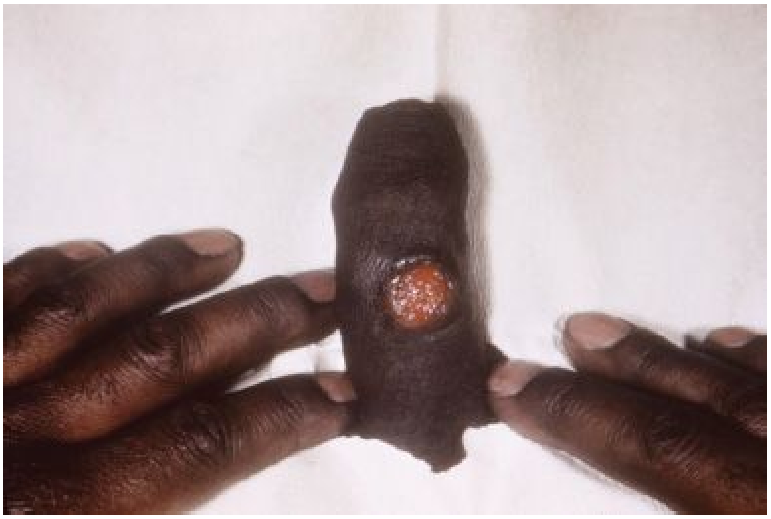

FIGURE 181-2 A painless chancre at the location of treponemal entry. (*Used with permission from the Public Health Image Library, Centers for Disease Control and Prevention*.)

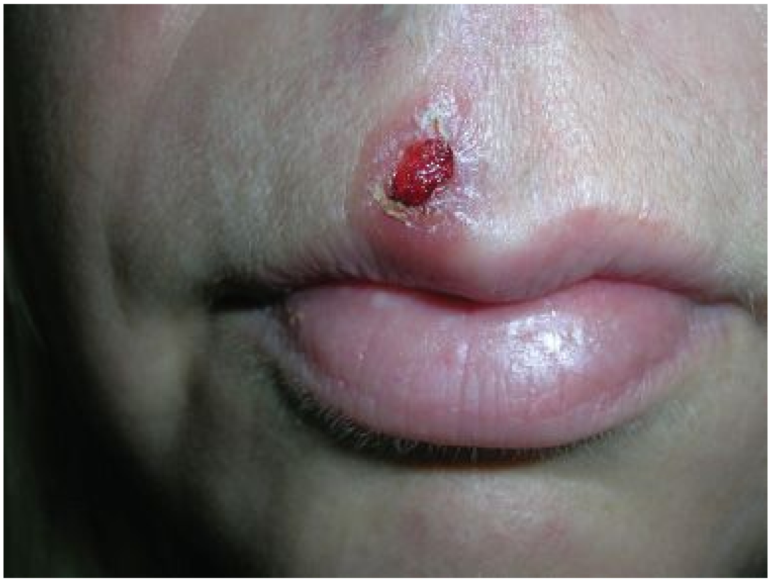

FIGURE 181-4 Primary syphilis with a chancre over the lip of a young woman. (*Used with permission from Richard P. Usatine, MD*.)

- Secondary syphilis occurs when the spirochetes become systemic and may present as a rash with protean morphologies, condyloma lata, and/or mucous patches (**Figures 181-5** to **181-7**).

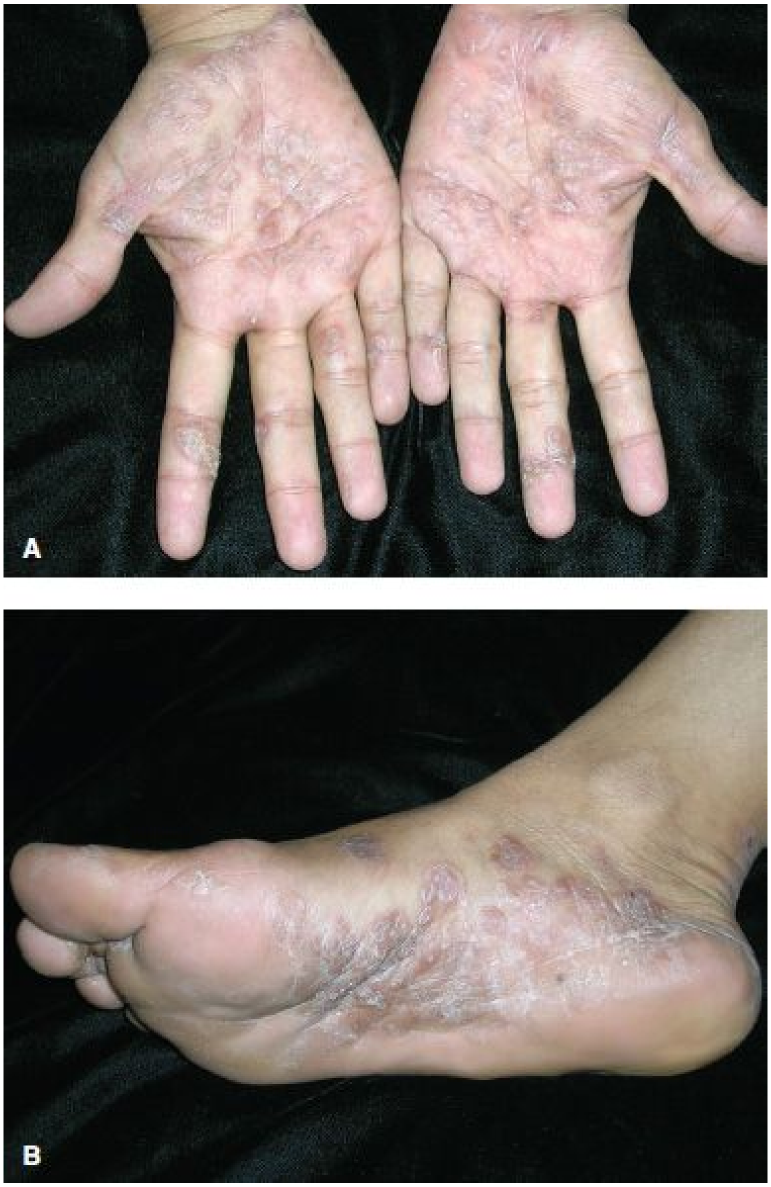

FIGURE 181-5 Secondary syphilis in a pregnant patient. **A.** Typical palmar lesions. **B.** Typical lesions on the sole. C. Mucous patches on the labia. (*Used with permission from Richard P. Usatine, MD.*)

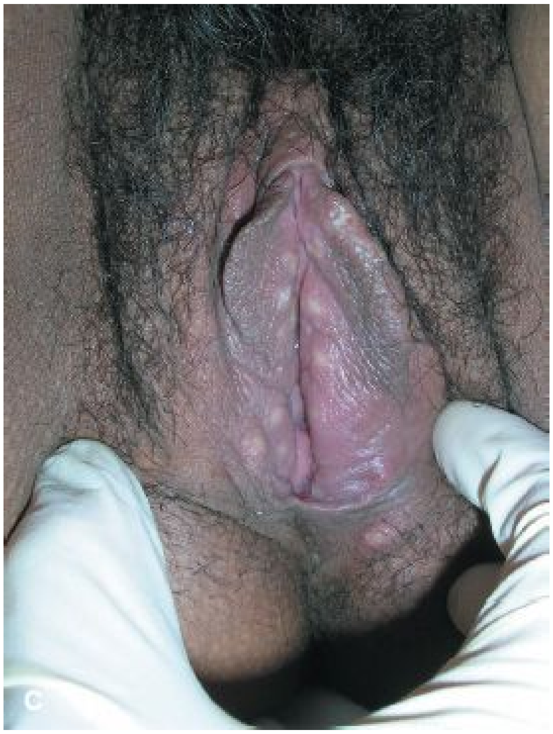

FIGURE 181-6 Pink macules on the feet and wrists of a patient with secondary syphilis. (*Used with permission from Richard P. Usatine, MD.*)

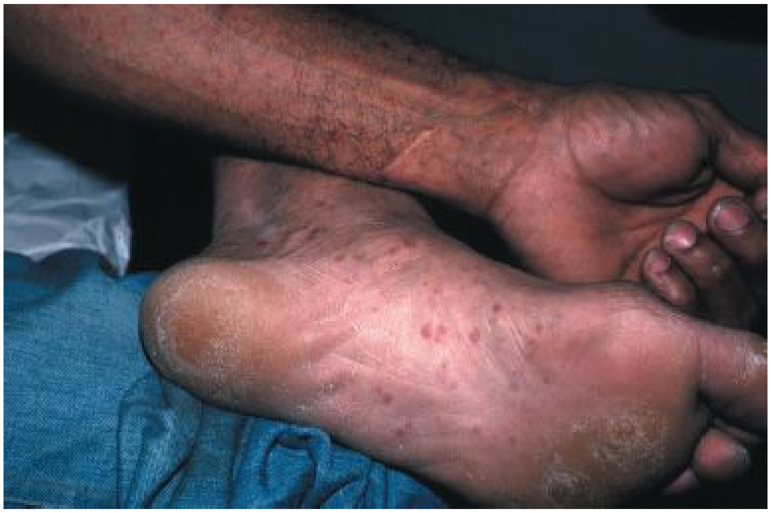

FIGURE 181-7 Condylomata lata (*arrows*) on the vulva of a patient with secondary syphilis. (*Used with permission from Richard P. Usatine, MD.*)

- Tertiary syphilis may be visualized with gummas on the skin, but many of the manifestations are internal such as the cardiac and neurologic diseases that occur (e.g., aortitis, tabes dorsalis, and iritis). As tertiary syphilis takes years to develop and penicillin treatment is readily available, it is unlikely to ever see this in a child.

- Neurosyphilis can occur at any stage. Clinical symptoms include cognitive dysfunction, vision or hearing loss, uveitis or iritis, motor or sensory abnormalities, cranial nerve palsies, or symptoms of meningitis.
- Congenital syphilis.
  - Early manifestations (within 2 years, typically by 2 to 3 months) include rhinitis, mucocutaneous lesions, bone changes, hepatosplenomegaly, lymphadenopathy, anemia and jaundice (**Figures 181-8** and **181-9**).

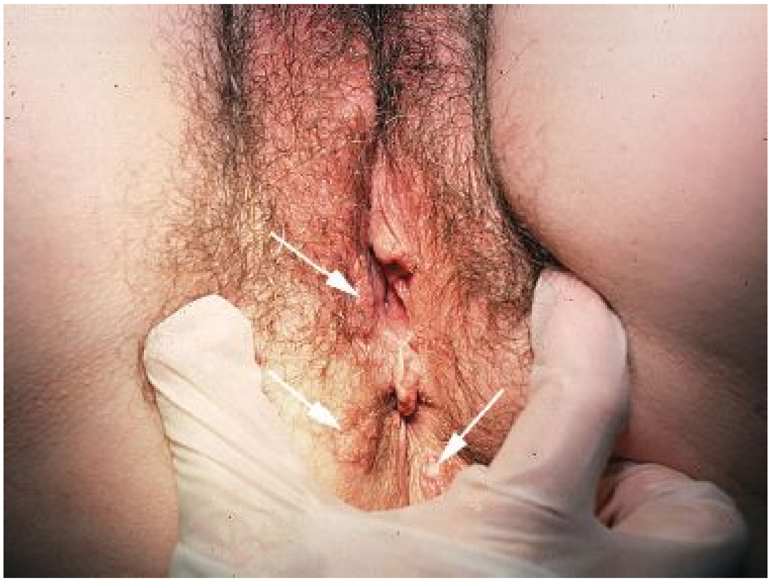

FIGURE 181-8 Congenital syphilis in a newborn infant with snuffles (mucous discharge from the nose). (*Used with permission from the CDC/Dr. Norman Cole*.)

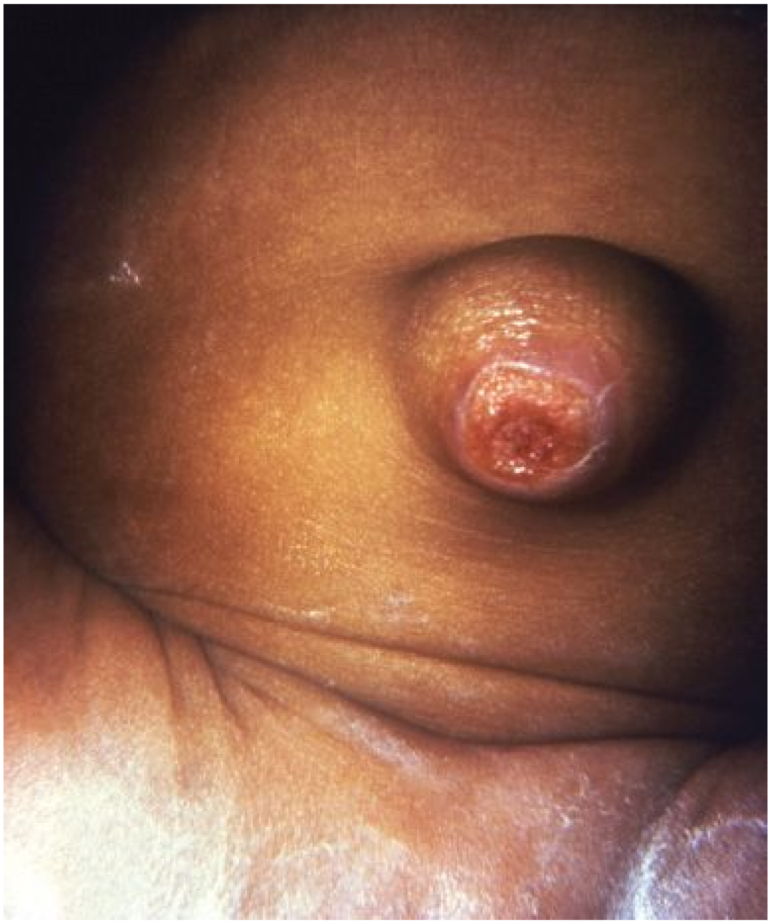

FIGURE 181-9 Congenital syphilis presenting with an inflamed lesion on the umbilicus. Dark field examination revealed the presence of Treponema pallidum spirochetes. (*Used with permission from the Public Health Image Library, Centers for Disease Control and Prevention*.)

- Late manifestations (after 2 years of age, without treatment) include interstitial keratitis, eight-nerve deafness, recurrent arthropathy, saber shins, saddle nose, tooth abnormalities, and neurosyphilis (**Figures 181-10** to **181-12**).

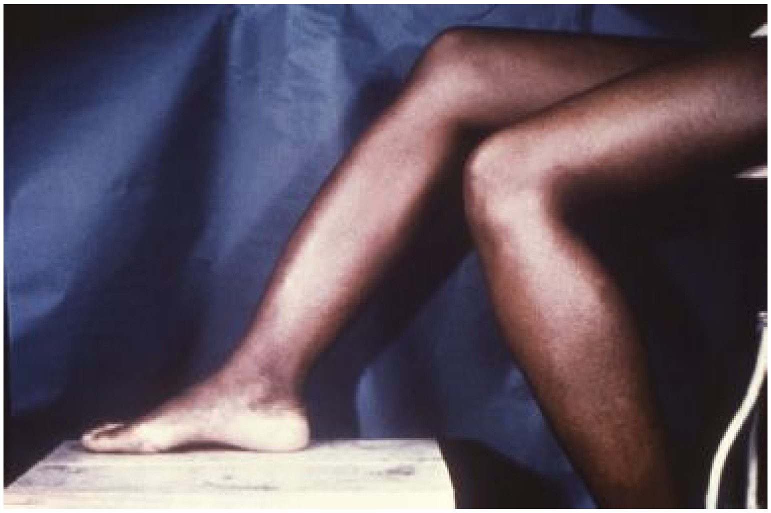

FIGURE 181-10 Saber shins or osteoperiostitis of the tibia is a result of untreated congenital syphilis. (*Used with permission from the CDC/Robert E. Sumpter*.)

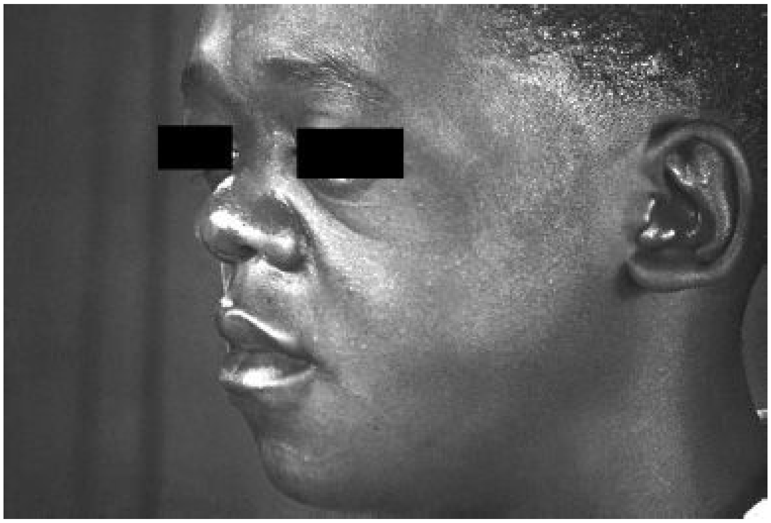

FIGURE 181-11 Saddle nose deformity in a 16-year-old patient due to congenital syphilis. (*Used with permission from the Public Health Image Library, Centers for Disease Control and Prevention*.)

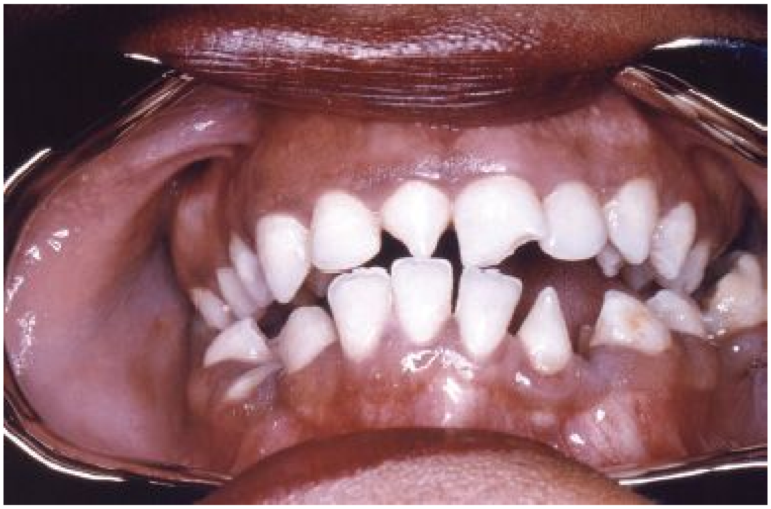

FIGURE 181-12 Hutchinson incisors caused by a congenital syphilis infection. Triangular appearing teeth are Hutchinson incisors, a known manifestation of congenital syphilis. (*Used with permission from the CDC/Robert E. Sumpter*.)

TYPICAL DISTRIBUTION

- Primary syphilis is usually a single ulcer (chancre) that is not painful in the genital region (**Figures 181-2** and **181-3**). A chancre can be seen on the lip (**Figure 181-4**).

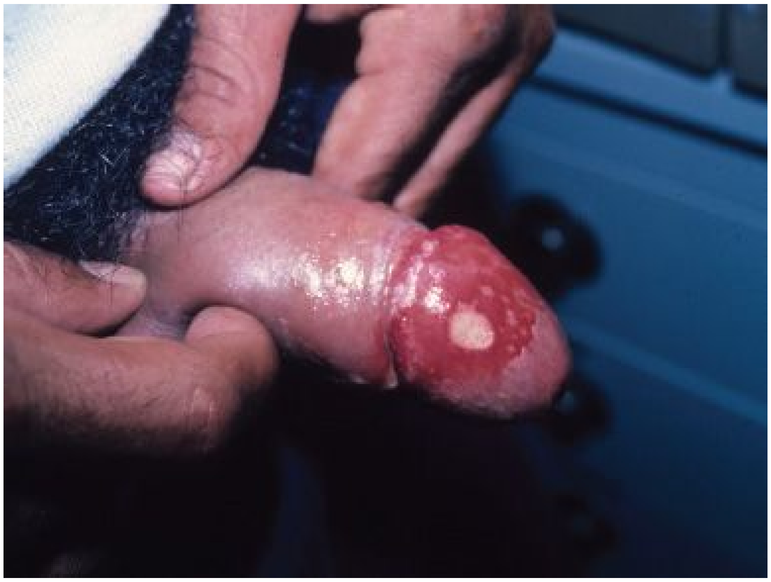

FIGURE 181-3 Primary syphilis with a large chancre on the glands of the penis. The multiple small surrounding ulcers are part of the syphilis and not herpes. (*Used with permission from Richard P. Usatine, MD.*)

- Secondary syphilis may present with various eruptions on the trunk, palms, and soles (**Figures 181-5** to **181-7**).
- Mucous patches of secondary syphilis are found on the genitals or in the mouth (**Figure 181-5C**).

LABORATORY TESTING

- Serologic tests are either nontreponemal (RPR or VDRL), which measure anticardiolipin antibodies, or treponemal (EIA, TPPA, FTA-ABS, or MHA-TP), which measure antibodies to *T. pallidum*.
- There are two algorithms for laboratory testing currently in use around the world:
    1. Start with a low-cost nontreponemal test and confirm a positive result with a treponemal test.
    2. Start with the EIA treponemal test, followed by a nontreponemal test for confirmation.
- In 2008, the Centers for Disease Control and Prevention (CDC) recommended a treponemal EIA initially, with positive results followed by a nontreponemal test for confirmation, a strategy that detected an additional 3 percent of positive samples not identified in the nontreponemal–treponemal sequence.[4]
- A nontreponemal test is required for confirmation, as a treponemal EIA indicates exposure but not active infection.
- A positive EIA with a negative RPR can be a previous treated or untreated infection, a false positive, or early primary syphilis. In this case, retest with a second treponemal test.
- Dark-field microscopy is useful in evaluating moist cutaneous lesions, such as chancre, mucous patches, and condyloma lata (**Figure 181-13**).

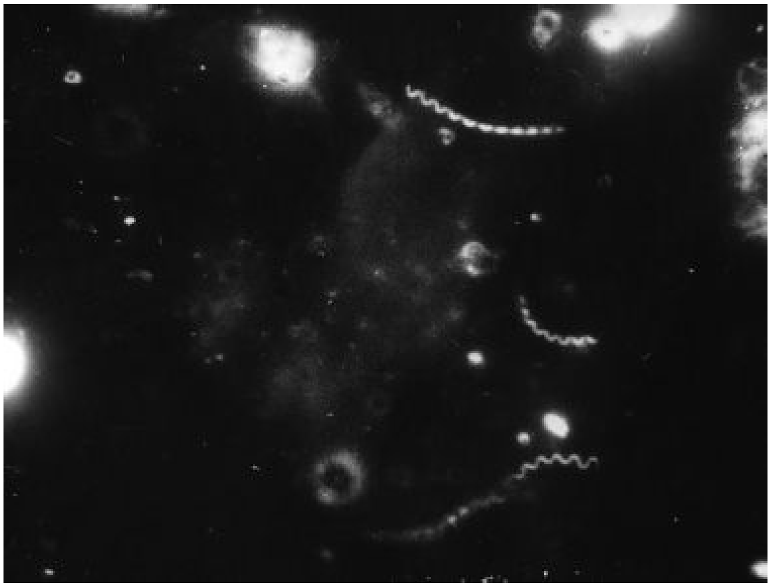

FIGURE 181-13 Live spirochetes of *T. pallidum* seen in a darkfield preparation. (*Used with permission from the Public Health Image Library, Centers for Disease Control and Prevention*.)

- Test all patients with syphilis for HIV (**Figure 181-14**).

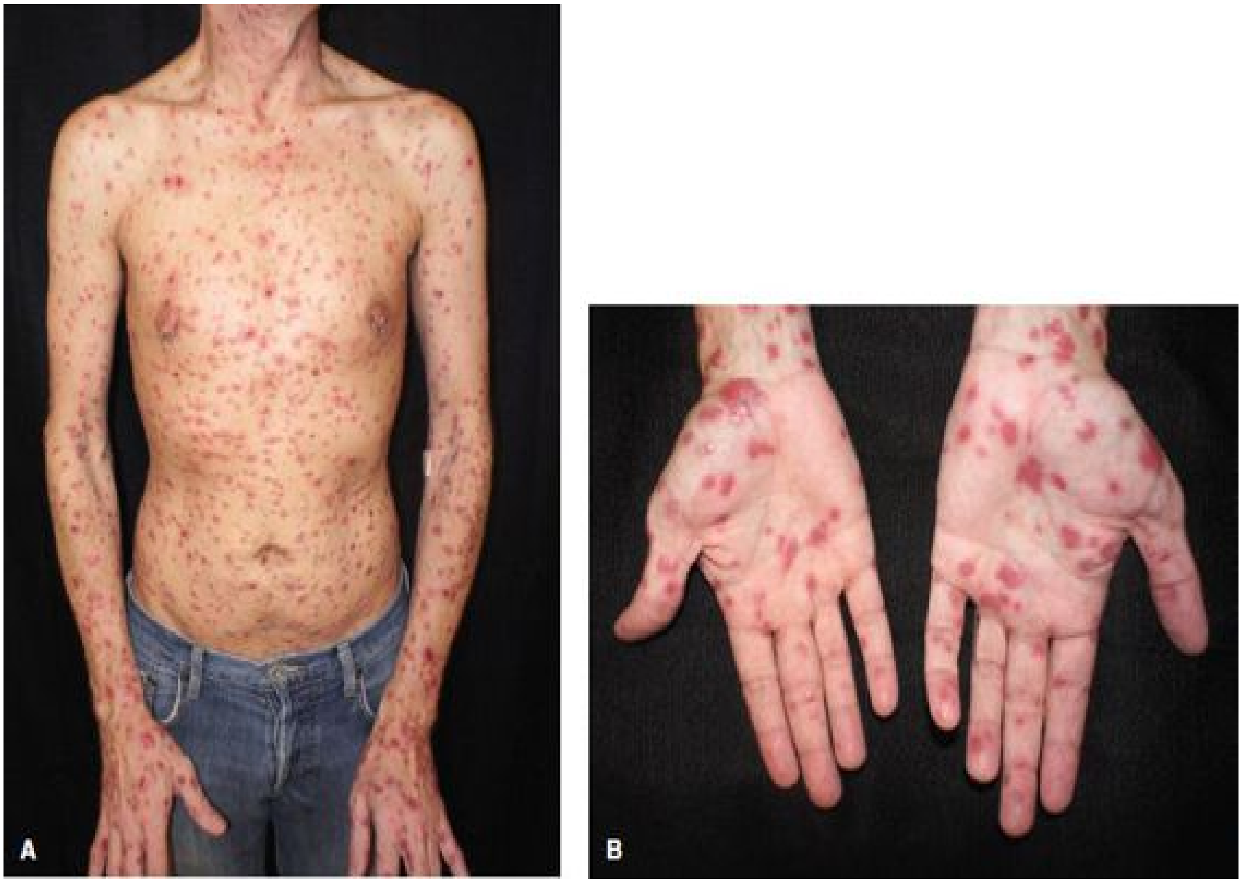

FIGURE 181-14 Secondary syphilis in a young man with known HIV/AIDS **A.** Impressive red papulosquamous eruption from head to toe is present. **B.** Close-up showing the palmar patches and plaques. (*Used with permission from Jonathan B. Karnes, MD.*)

- Patients with syphilis who have any signs or symptoms suggesting neurologic disease including vision or hearing need a cerebrospinal fluid (CSF) exam, a slit-lamp ophthalmologic examination, and an otologic examination to determine if neurosyphilis is present.

DIFFERENTIAL DIAGNOSIS

- Herpes simplex—Most common cause of genital ulcers in the US. These ulcers are painful and often start as vesicles (see Chapter 114, Herpes Simplex).

- Chancroid—Painful beefy red ulcers on the penis or vulva (**Figure 181-15**). It is less common than syphilis but in the early stage of the ulceration can resemble primary syphilis. If the RPR in a patient with a presumed syphilis chancre is negative and remains negative, bacterial cultures of the ulcer for *Haemophilus ducreyi* should be submitted. Chancroid is also known to cause large painful inguinal adenopathy (bubo; **Figure 181-16**). (See Chapter 75, Mucosal Ulcerative Disorders.)

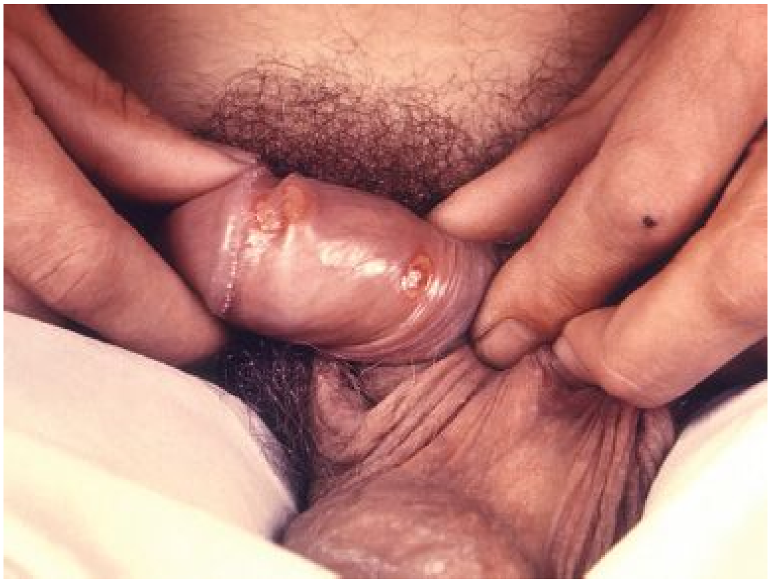

FIGURE 181-15 Chancroid ulcers caused by the bacterium, *Haemophilus ducreyi*. The patient was originally thought to have syphilis. Chancroidal ulcers are classically painful and beefy but chancroid should be considered on the differential diagnosis of any sexually acquired genital ulcer. (*Used with permission from CDC/Dr. Pirozzi*.)

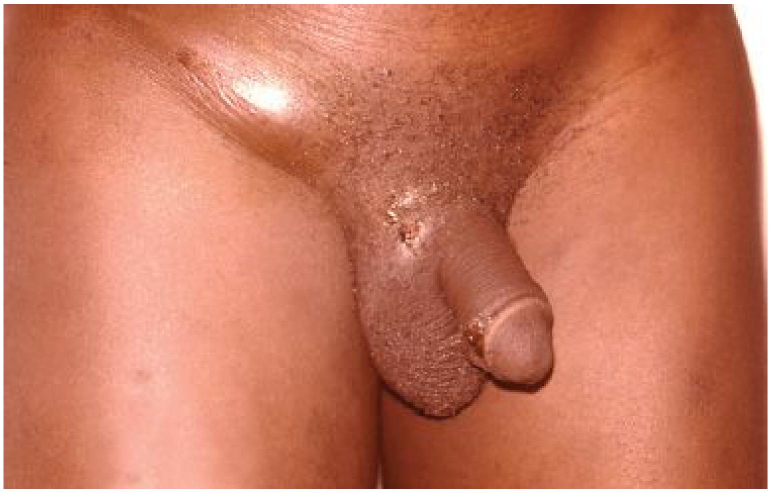

FIGURE 181-16 Chancroid lesions of the groin and penis affecting the ipsilateral inguinal lymph nodes. (*Used with permission from CDC/J. Pledger*.)

- Drug eruptions—Can be on the genital area such as seen in a fixed drug eruption. Also whole-body drug eruptions can appear similar to secondary syphilis (see Chapter 154, Cutaneous Drug Reactions).
- Erythema multiforme—Can look like the rash of secondary syphilis but may have target lesions (see Chapter 151, Erythema Multiforme, Stevens-Johnson Syndrome, and Toxic Epidermal Necrolysis).
- Pityriasis rosea—A self-limited cutaneous eruption that often begins with a herald patch and may have a Christmas tree distribution on the back (see Chapter 137, Pityriasis Rosea).
- The differential diagnosis for congenital syphilis includes other congenital infections such as rubella, cytomegalovirus, herpes simplex virus, and toxoplasmosis (see Chapter 187, Congenital Infections). Erythroblastosis fetalis is also on the differential diagnosis for congenital syphilis.

MANAGEMENT

MEDICATIONS

Benzathine penicillin is the treatment of choice for all stages of syphilis. Dose and duration depend on stage. The following treatment information is from the CDC.[5]

- Primary, secondary, and early latent (immunocompetent and nonpregnant):
    - Children older than 1 month with acquired primary or secondary—Benzathine penicillin 50,000 U/kg IM up to 2.4 million U one time.
- Penicillin allergy:
    - Doxycycline 100 mg twice daily × 14 days (For children 8 years of age and older) or
    - Ceftriaxone 1 γ IM/IV daily × 10 to 14 days (limited studies) or

  - Azithromycin 2 γ single oral dose; however, azithromycin resistance has been documented in several areas of the US. Use only when penicillin or doxycycline cannot be used. Do not use in gay males.
- Late latent syphilis or syphilis of unknown duration.
  - Children—Benzathine penicillin 50,000 U/kg IM (up to 2.4 million U) every week for 3 weeks.
- Penicillin allergy—Doxycycline is the only acceptable alternative available (for children 8 years of age and older).
- For the management of congenital, tertiary, and neurosyphilis, see the *Sexually Transmitted Diseases Treatment Guidelines* published by the CDC in 2010—www.cdc.gov/std/treatment/2010/genital-ulcers.htm#syphilis.

REFERRAL OR HOSPITALIZATION

- Refer patients when the stage of syphilis is unclear. Consider referral to an infectious disease specialist in children younger than 1 month of age, pregnant women with a penicillin allergy, patients with tertiary or neurosyphilis, or patients who have failed treatment.

PREVENTION

PRIMARY PREVENTION

Safe sex practices—Sexual transmission occurs when mucocutaneous syphilitic lesions are present.

SECONDARY PREVENTION

- Treat presumptively (regardless of serology) sexual partners who were exposed within 90 days of the partner’s diagnosis of primary, secondary, or early latent syphilis.

- Consider presumptive treatment when exposure was greater than 90 days before partner’s diagnosis if serology is unavailable or follow-up is uncertain.[5]

Primary prevention of congenital syphilis: Screen all pregnant patients and treat as soon as possible when positive. Treatment before the 16th week of pregnancy prevents fetal damage in most cases.

PROGNOSIS

When syphilis is recognized and appropriately treated, the prognosis is excellent.

FOLLOW-UP

- Reexamine clinically and serologically at 6 and 12 months. Consider treatment failure if signs and/or symptoms persist or the nontreponemal test titer does not decline by 2 dilutions after 6 to 12 months of therapy. Fifteen percent will not achieve this decline in titer after 1 year.[5]
- For treatment failures—Retest for HIV and perform a lumbar puncture for CSF analysis and treat for neurosyphilis if positive.

PATIENT EDUCATION

Condoms can prevent the spread of syphilis. Patients should be advised to get HIV testing and need to know that syphilis is a risk factor for the spread of HIV. HIV/AIDS is also a risk factor for acquiring syphilis (**Figure 181-14**). Patients should be advised of the importance of completing treatment and follow-up to prevent complications.

182 PEDIATRIC HUMAN IMMUNODEFICIENCY VIRUS (HIV) INFECTION

Rebecca Schein, MD

PATIENT STORIES

A 6-month-old girl is seen by her pediatrician for because her mother is concerned about a white coating on the infant’s tongue and poor feeding. On exam, the child appears cachectic and has thrush visible throughout her oropharynx (**Figure 182-1**). Palpable cervical and axillary lymph nodes are noted as well. A human immunodeficiency virus (HIV) antibody test is obtained and is positive. Diagnosis is confirmed with a HIV DNA polymerase chain reaction (PCR). The mother of the baby also tests positive for HIV. The child is treated with antiretroviral (ARV) therapy and improves with treatment.

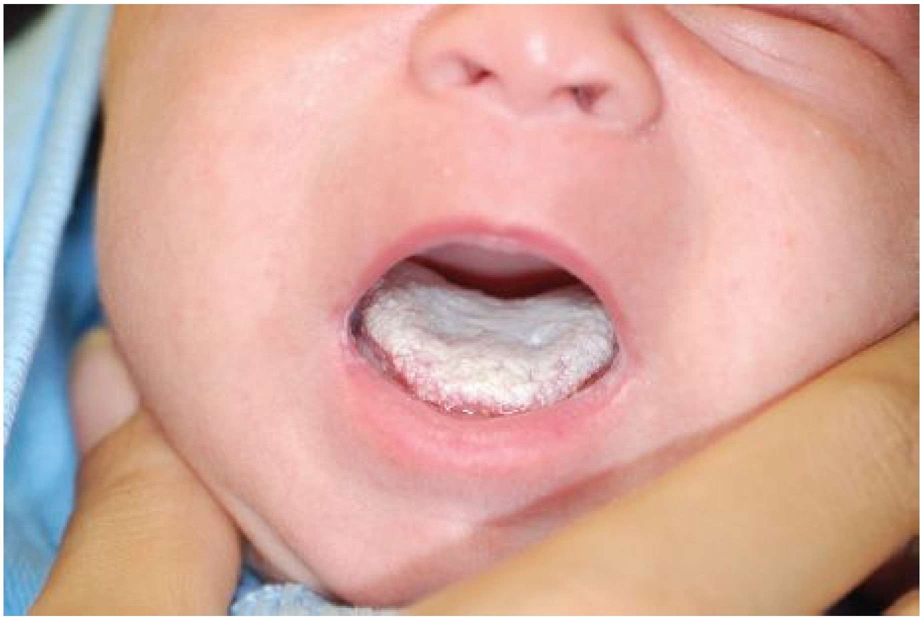

Figure 182-1 Oral thrush in an infant with human immunodeficiency virus (HIV) infection. (*Used with permission from David Effron, MD.*)

A 15-year-old male presents to a community clinic with penile discharge and anal itching due to anal warts (**Figure 182-2**). On further questioning, he admits to being homeless. He supports himself through commercial sex work, mainly with male partners. A urine nucleic acid test is positive for chlamydia and the oral rapid HIV antibody test is positive as well. Diagnosis of HIV is confirmed via Western Blot testing.

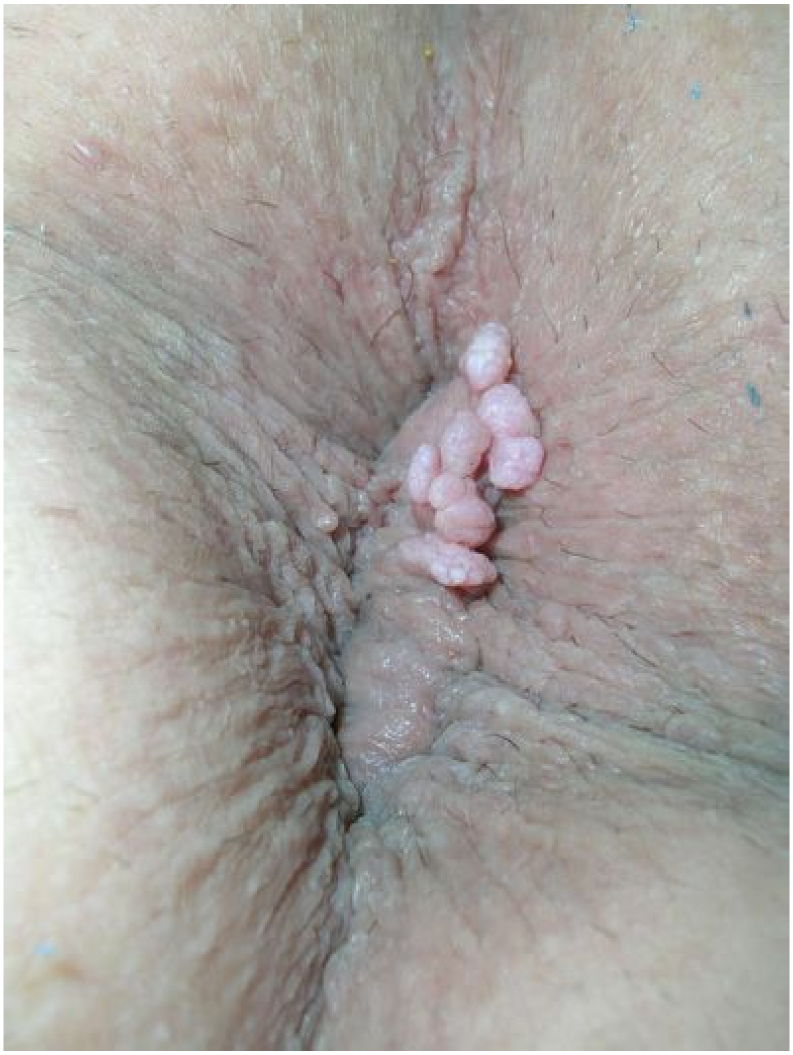

FIGURE 182-2 Anal warts (condyloma) caused by Human Papilloma Virus in an adolescent male with HIV infection and a history of anal receptive intercourse. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

HIV is a retrovirus that causes disseminated infection resulting in suppression of T-cell mediated immunity and development of opportunistic infections.

SYNONYMS

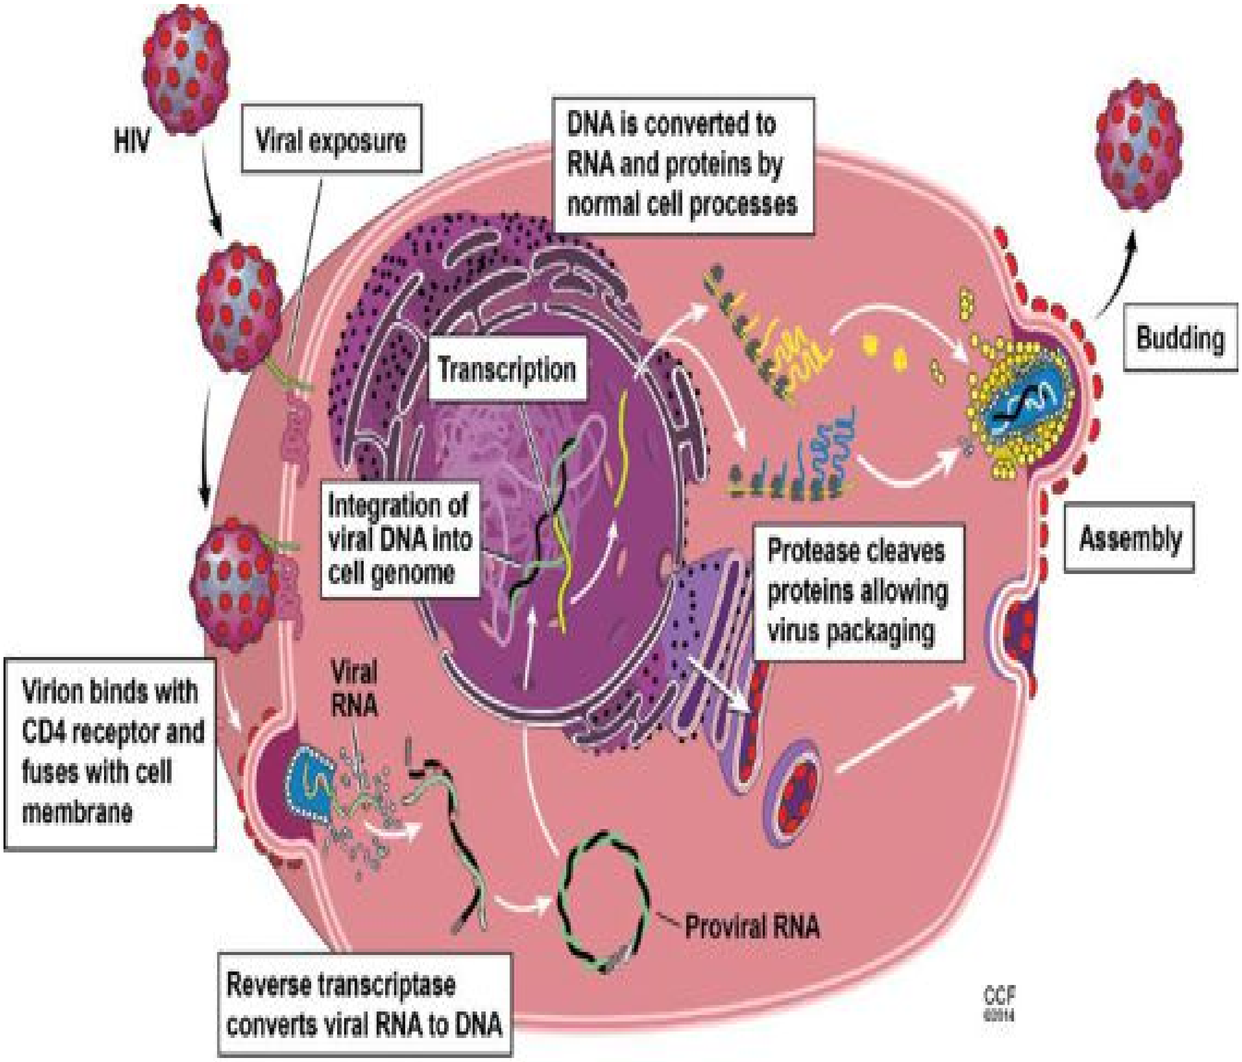
Acquired Immunodeficiency Syndrome (AIDS) refers to clinical syndrome seen with advanced disease.[1]

EPIDEMIOLOGY

- Humans are the only known reservoir for HIV-1 and HIV-2.
- HIV lives in peripheral blood mononuclear cells, brain cells, bone marrow, and genital tract cells.
- Transmission occurs via sexual contact, blood exposure, mucous membrane exposure to blood or breast milk, and mother to child transmission.[2]
- Risk of mother to child transmission at birth without intervention is approximately 30 percent;[2] with current therapy this risk is now 1 to 2 percent in the US. High maternal HIV viral load at delivery, primary maternal infection during pregnancy, and breast feeding all increase transmission risk.[3]
- Risk of sexual transmission varies from 0.1 to 30 percent per encounter with highest risk from receptive anal sex.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Lentivirus of the family *Retroviridae*.
- Two forms—HIV-1 and HIV-2. HIV-2 causes a milder form of disease and is found predominantly in West Africa.
- RNA virus that requires conversion of viral RNA to DNA to incorporate into host cell genome.[2]
- Major enzymes and regulatory genes required for replication, assembly, and release viral particles are encoded in the viral genome including Reverse Transcriptase, Integrase, and Protease enzymes (**Figure 182-3**). See Diagram.



HIV
Viral exposure
DNA is converted to RNA and proteins by normal cell processes
Budding
Transcription
Integration of viral DNA into cell genome
Assembly
Protease cleaves proteins allowing virus packaging
Viral RNA
Virion binds with CD4 receptor and fuses with cell membrane
Proviral RNA
Reverse transcriptase converts viral RNA to DNA

RISK FACTORS

- Unprotected sexual intercourse particularly receptive anal sex, genital ulcers or concomitant sexually transmitted diseases, intravenous drug use, maternal HIV, contaminated blood transfusion, and rarely needle stick injury.[2]

DIAGNOSIS

CLINICAL FEATURES

- Fevers, generalized lymphadenopathy, hepatosplenomegaly, failure to thrive, recurrent oral thrush, persistent diarrhea, interstitial pneumonia, invasive bacterial infection, and/or other opportunistic infection (OI).[2]
- OIs include respiratory or esophageal candidiasis, cryptococcosis (**Figure 182-4**), disseminated endemic fungal infection, cytomegalovirus (**Figure 182-5**), chronic herpes simplex (**Figure 182-6**), progressive multifocal leukoencephalopathy caused by JC virus (**Figure 182-7**), Kaposi's sarcoma caused by HHV 8 (**Figure 182-8**), *Mycobacterium avium-intracellulare*, other mycobacterial disease, cryptosporidium, *Pneumocystic jirovecii* (**Figure 182-9**), and toxoplasmosis.[5]

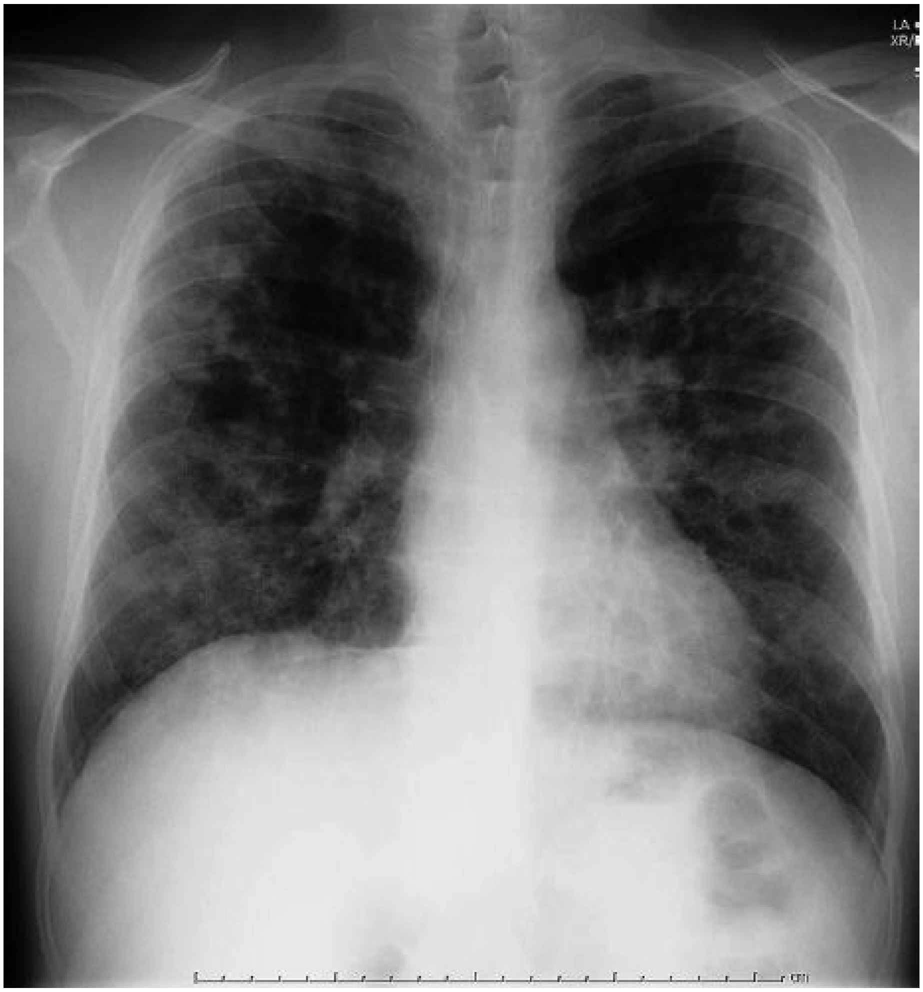

FIGURE 182-9 *Pneumocystis jirovecii* Pneumonia on chest x-ray. (*Used with permission from Rebecca Schein, MD*.)

- Children may also present with more severe presentations of common childhood infections (**Figures 182-10** and **182-11**).

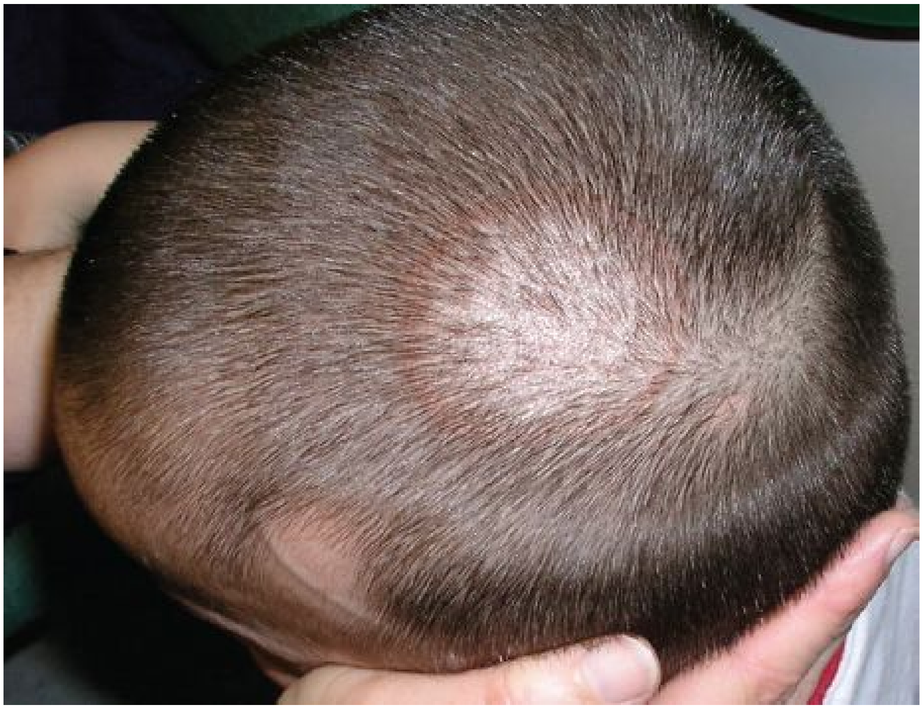

FIGURE 182-10 Tinea capitis in a child with human immunodeficiency virus infection. (*Used with permission from Ann Petru, MD*.)

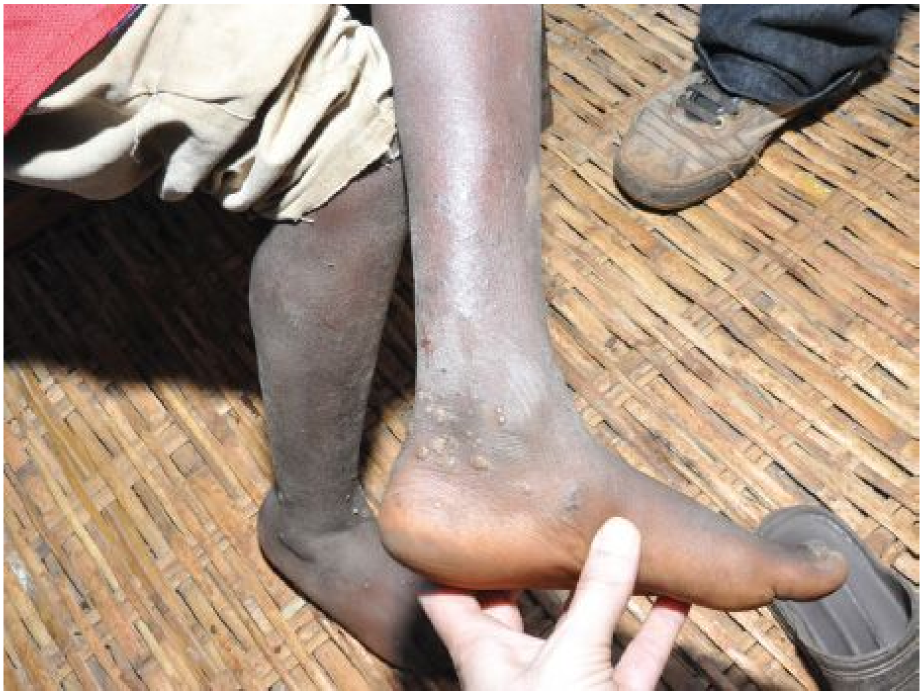

FIGURE 182-11 The cluster of warts on the foot of this African boy prompted an HIV test, which was positive. While warts alone are very common in children, the large cluster of warts was a stimulus to ask about HIV in the family. The mother knew that she was positive for HIV but had resisted having her son tested until this time. (*Used with permission from Richard P. Usatine, MD.*)

- Cervical lymphadenopathy not resolving should prompt the clinician to check for generalized lymphadenopathy and to consider HIV on the differential diagnosis (**Figure 182-12**).

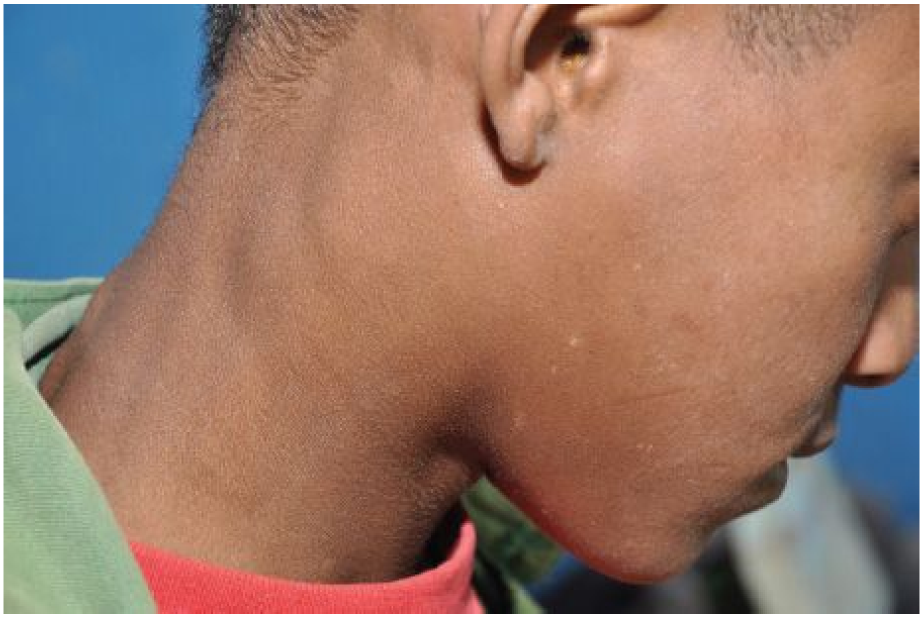

FIGURE 182-12 Cervical lymphadenopathy in an 12-year-old African boy with perinatal HIV infection. (*Used with permission from Richard P. Usatine, MD.*)

LABORATORY TESTING

- Neonates.
    - Diagnosis in this age group is via HIV DNA PCR because passively acquired maternal antibodies can persist until 18 months of age. Two negative PCR tests after 2 weeks of age effectively rules out infection.[6]
- Adolescents and children >18 months of age.
    - Initial screen is an HIV antibody test via enzyme immunoassay. Rapid testing is available and may be performed on blood or saliva. Confirmation of positive antibody testing is via Western blot.[1]
    - US Preventative Services Task Force recommends one time screening for HIV of all persons 15 to 65 years of age.

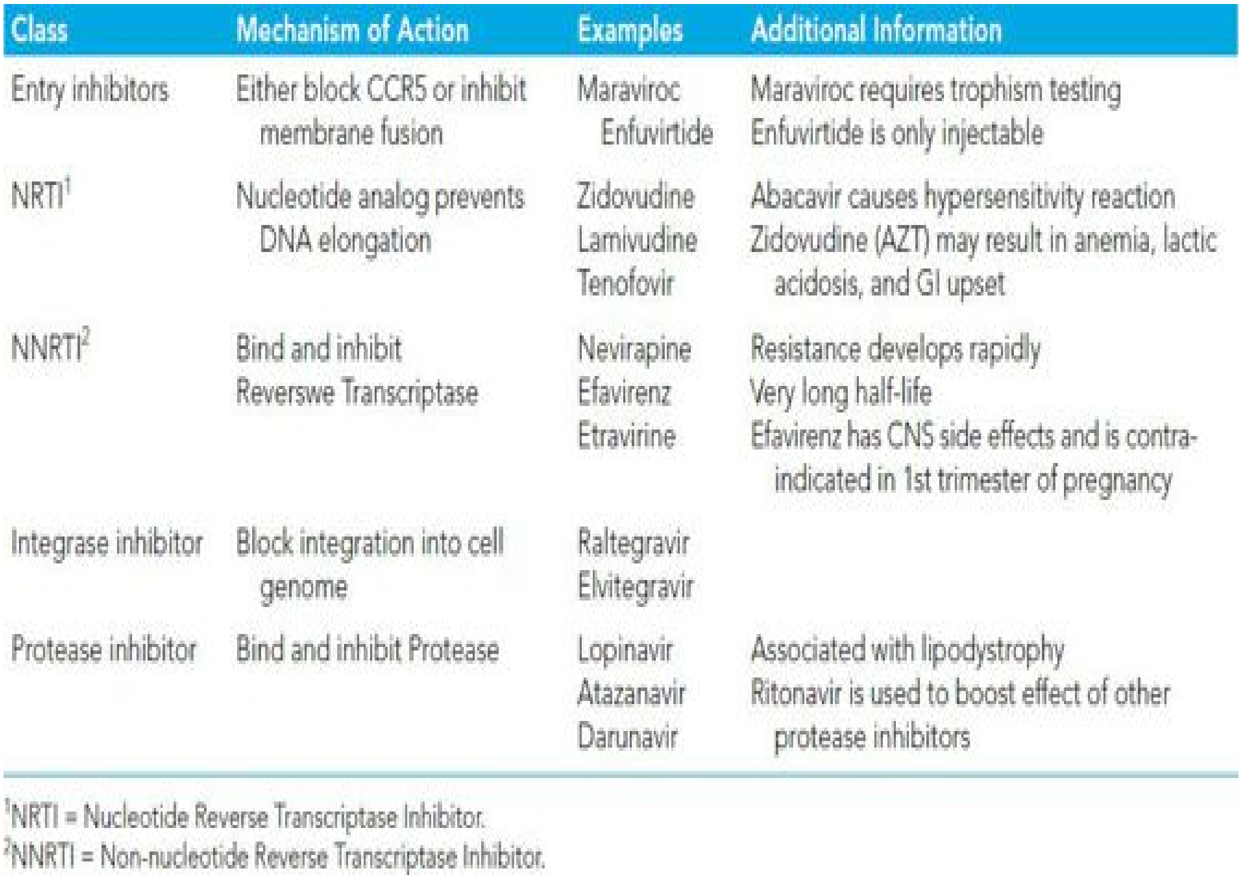
MANAGEMENT

- Current therapy consists of a combination of ARV agents and current recommendations can be found on the National Institutes of Health AIDSinfo website—http://aidsinfo.nih.gov/.
- HIV therapy is based on frequently revised guidelines, viral resistance patterns, and adverse effects of medications. Management in collaboration with experts in pediatric and adolescent HIV care is recommended.
- Treatment is currently recommended for all persons with HIV regardless of CD4 count. Therapy requires a multidisciplinary approach that includes medical care, mental health care, and social support programs.[7]

MEDICATIONS

- Highly Active Anti-Retroviral Therapy or HAART is defined as 3 or more drugs in 2 or more classes.
- ARV agents are directed at blocking viral infection and/or replication and are characterized by their mechanism of action. See **Table 182-1** for further information.[7]

TABLE 182-1 Anti-Retroviral Agents



Class	Mechanism of Action	Examples	Additional Information
Entry inhibitors	Either block CCR5 or inhibit membrane fusion	Maraviroc Enfuvirtide	Maraviroc requires trophism testing Enfuvirtide is only injectable
NRTI[1]	Nucleotide analog prevents DNA elongation	Zidovudine Lamivudine Tenofovir	Abacavir causes hypersensitivity reaction Zidovudine (AZT) may result in anemia, lactic acidosis, and GI upset
NNRTI[2]	Bind and inhibit Reverswe Transcriptase	Nevirapine Efavirenz Etravirine	Resistance develops rapidly Very long half-life Efavirenz has CNS side effects and is contra-indicated in 1st trimester of pregnancy
Integrase inhibitor	Block integration into cell genome	Raltegravir Elvitegravir	
Protease inhibitor	Bind and inhibit Protease	Lopinavir Atazanavir Darunavir	Associated with lipodystrophy Ritonavir is used to boost effect of other protease inhibitors

[1] NRTI = Nucleotide Reverse Transcriptase Inhibitor.

[2] NNRTI = Non-nucleotide Reverse Transcriptase Inhibitor.

PREVENTION AND SCREENING

- Maternal-Child transmission.
  - All pregnant women should be tested for HIV in the first trimester and women with high-risk behaviors should be retested in the third trimester or at delivery.[3] HIV positive women are treated with HAART. Newborn infants are treated with a minimum of six weeks of oral zidovudine (AZT). SOR A Additional therapy is recommended on a case by case basis.[8]
- Sexual transmission.
  - Limit numbers of sexual partners, encourage condom use, treat sexually transmitted infections, and encourage partner notification.
  - Combination tenofovir plus emtricitabine has been shown to decrease transmission in discordant couples and may be used for preexposure

prophylaxis or PrEP.[9] SOR Ⓑ

- Injection drug use transmission.
    - Encourage use of clean needle programs and avoid needle sharing, methadone maintenance programs, and bleach to disinfect drug paraphernalia.
- Postexposure prophylaxis.
    - If exposure occurs despite interventions then combination antiretroviral therapy may be used in high-risk cases to prevent infection. Typically treatment should be initiated within 72 hours of exposure and is continued for 28 days.[4] SOR Ⓑ

PROGNOSIS

- With early and appropriate treatment HIV has become a chronic disease. Further studies are in progress on the long-term effects of the various ARVs. In general, patients are expected to lead full lives.

FOLLOW-UP

- Patients are typically followed at 3- to 4-month intervals. CD4 counts and HIV viral loads are followed to determine response to therapy and additional testing is tailored to evaluate for medication toxicity.[7]

PATIENT EDUCATION

- Counsel patients and their parents regarding the importance of adherence to medication and the risk of resistance of medications.

- Counsel adolescent patients regarding the need and methods to prevent transmission, as previously outlined.

183 LYME DISEASE

Thomas J. Corson, DO
Richard P. Usatine, MD
Camille Sabella, MD

PATIENT STORY

On a warm, summer afternoon an 11-year-old girl presents having had low-grade fevers for 4 days and a rash. On physical examination, the pediatrician notes annular eruptions with erythema on her shoulder and legs (**Figure 183-1**). The mother states that the rash has gotten progressively larger during the last 3 days and her daughter complains of intermittent joint pain. She does not recall being bitten by an insect. She denies taking medications within the last month and has no known allergies. When asked about recent travel, the mother admits to taking the family on a camping trip in eastern Massachusetts with a return of 5 days ago. The patient was diagnosed with Lyme borreliosis (acute Lyme disease) and started on doxycycline 100 mg twice daily for 14 days. She responded quickly to the antibiotics and never developed the late stage of Lyme disease.

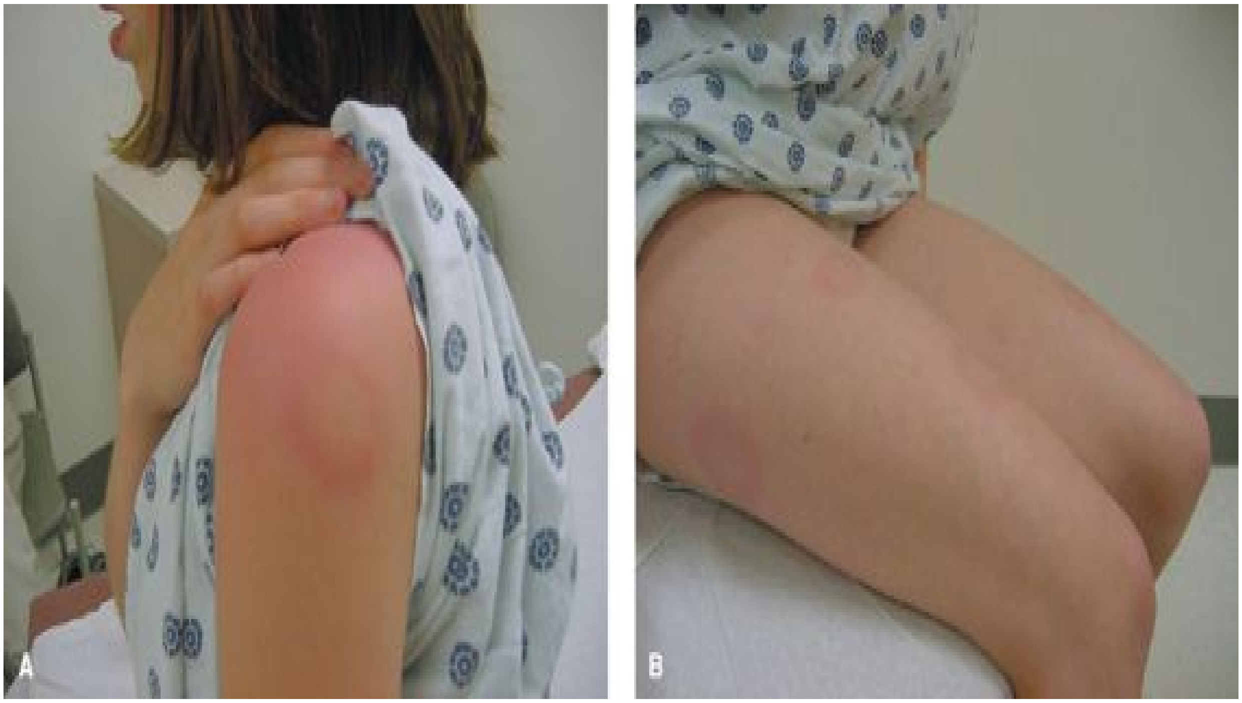

FIGURE 183-1 An 11-year-old girl with early disseminated Lyme disease presenting with multiple erythema migrans (EM) lesions, low grade fever and some intermittent joint pain. **A.** EM with its annular configuration on her shoulder. **B.** Multiple rings of EM on her legs. (*Used with permission from Jeremy Golding, MD*.)

INTRODUCTION

Lyme disease is an infection caused by the spirochete *Borrelia burgdorferi*, transmitted via tick bite. Most cases of Lyme disease occur in the northeast between April and November. Patients experience flu-like symptoms and may develop the pathognomonic rash, erythema migrans. Lyme disease is prevented by avoiding exposure to the tick vector using insect repellent and protective clothing.

EPIDEMIOLOGY

- In 1977, clusters of patients in Old Lyme, Connecticut, began reporting symptoms originally thought to be juvenile rheumatoid arthritis.[1]
- In 1981, American entomologist, Dr. Willy Burgdorfer, isolated the infectious pathogen responsible for Lyme disease from the midgut of *Ixodes scapularis* (a.k.a., black-legged deer ticks; **Figure 183-2**), which serve as the primary transmission vector in the US.[1]

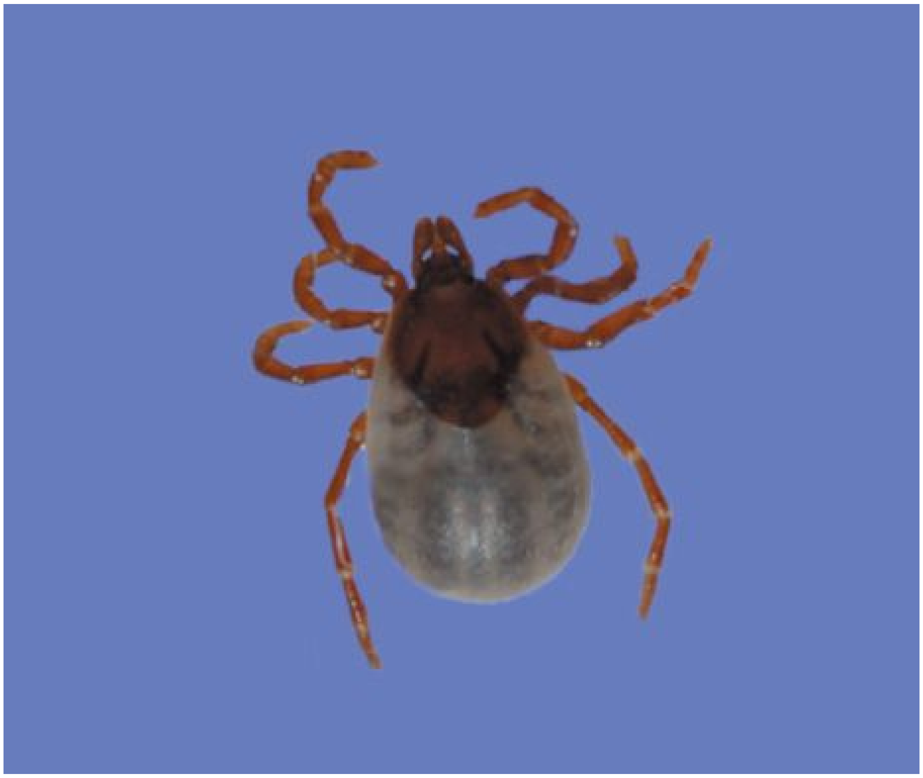

FIGURE 183-2 The deer tick transmits the *Borrelia* spirochete. This is an unengorged female black-legged deer tick. The tick is tiny and can be undetected in its unengorged state. (*Used with permission from Thomas Corson, MD*.)

- It was identified as a bacterial spirochete and named *B. burgdorferi* in honor of its founder.
- Based on Centers for Disease Control and Prevention (CDC) data reported in 2007, Lyme disease (or Lyme borreliosis) is the most common tickborne illness in the US, with an overall incidence of 7.9 per 100,000 persons.[2]

- In 2010, 94 percent of Lyme disease cases were reported from 12 states: Connecticut, Delaware, Maine, Maryland, Massachusetts, Minnesota, New Jersey, New Hampshire, New York, Pennsylvania, Virginia, and Wisconsin.[3]
- Patients living between Maryland and Maine accounted for 93 percent of all reported cases in the US in 2005, with an overall incidence of 31.6 cases for every 100,000 persons.[2]
- The incidence is highest among children 5 to 14 years of age, and more than 90 percent of cases report onset between April and November.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- *B. burgdorferi* begins to multiply in the midgut of *I. scapularis* ticks upon attaching to humans.
- Migration from midgut to salivary glands of ticks requires 24 to 48 hours.
- Prior to this migration, host infection rarely occurs.
- Common hosts include field mice, white-tailed deer, and household pets.
- Ticks must feed on infested hosts in order to infect humans.
- Thirty percent of infected patients do not recall being bitten.[4]
- Once a human is infected, disease progression is categorized into three clinical stages: early localized, early disseminated, and late disseminated.

DIAGNOSIS

CLINICAL FEATURES

Early Localized (3 to 32 days after tick bite)

- Erythema migrans (formerly known as erythema chronicum migrans)—This pathognomonic finding occurs in roughly 68 percent of Lyme disease cases.[4] Described as a “bull’s-eye” eruption (**Figures 183-1** and **183-3**), this nonpruritic, maculopapular lesion typically occurs near the site of infection. The erythematous perimeter migrates outward over several days while the central area clears. Erythema migrans can persist for 2 to 3 weeks if left untreated.

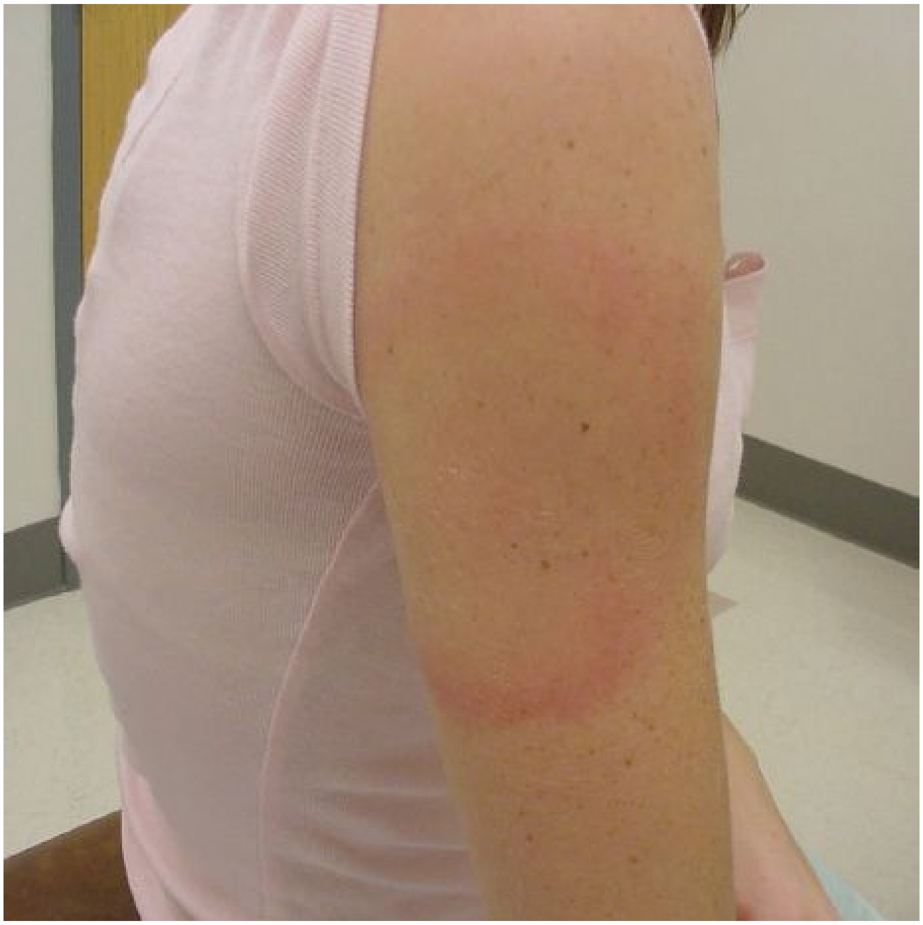

FIGURE 183-3 A 12-year-old girl with erythema migrans eruption on her right arm. The annular border is somewhat raised and there is central clearing. (*Used with permission from Jeremy Golding, MD.*)

- Flu-like symptoms—Roughly 67 percent of patients will develop flu-like symptoms that can include fever, myalgias, headache, malaise, and lymphadenopathy. Symptoms usually subside within 7 to 10 days.

Early Disseminated (3 to 10 weeks after tick bite)

- *Erythema migrans*—Multiple lesions (**Figure 183-4**).

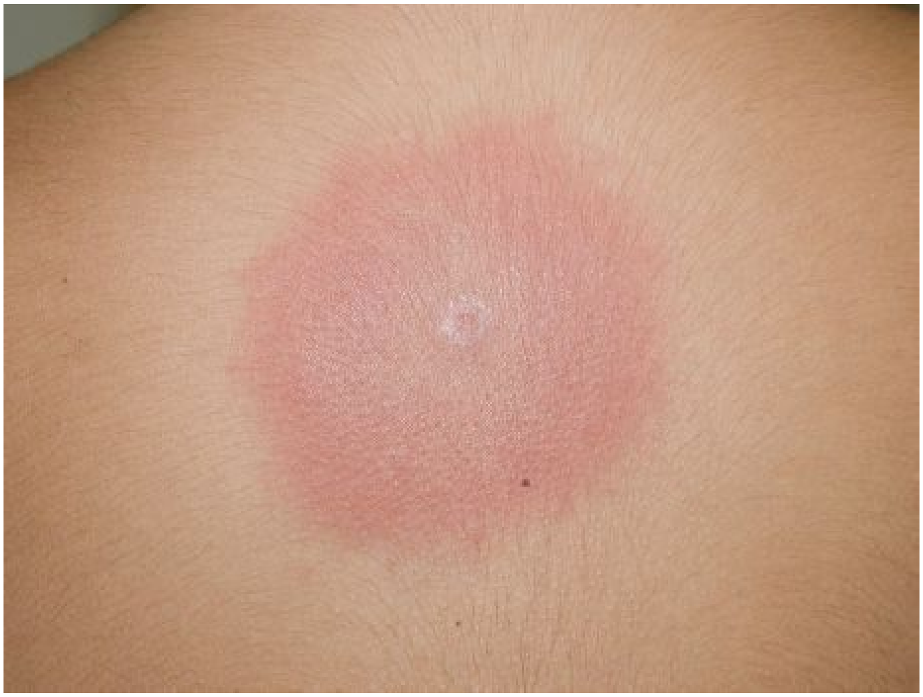

FIGURE 183-4 Erythema migrans on the back of an 11-year-old boy who was camping in Western Pennsylvania. The central papule/excoriated lesion is the site of the bite and some central clearing is visible. (*Used with permission from Charles B. Foster, MD.*)

  - May develop as a consequence of bacteremic dissemination to multiple sites.
  - About 25 percent of children are first diagnosed with Lyme disease based on these lesions.
  - Lesions are usually smaller than primary lesions and often accompanied by flu-like symptoms.
- Cranial nerve palsy—Bell's palsy (seventh cranial nerve) is the most common neurologic manifestation of Lyme disease, occurring in 3 to 5 percent of children with Lyme disease. However, nearly every cranial nerve has been reported to be involved. Facial nerve palsy is a lower motor neuron lesion that results in weakness of both the lower face and the forehead. Lasting up to 8 weeks, the resolution of symptoms is gradual, begins shortly after initial onset, and does not appear to be influenced by antimicrobial therapy (see Chapter 202, Bell's Palsy).

- Aseptic meningitis—Patients may present with complaints similar to bacterial meningitis (photophobia, nuchal rigidity, and headache), but symptoms are generally less severe in nature. This can also occur with or without concomitant cranial nerve palsy.[4]
- Atrioventricular blockade—This is a very uncommon finding in children with Lyme disease. When it does occur, syncope, lightheadedness, and dyspnea are classic symptoms consistent with atrioventricular (AV) dysfunction.[3] However, patients can be completely asymptomatic. The degree of Lyme-associated blockade varies so that symptoms are generally episodic. Most cases resolve spontaneously within 1 week.[4]
- All of the following can be accompanied by nonspecific signs and symptoms as fatigue, myalgia, headache, fever, and lymphadenopathy.

Late Disseminated Disease (2 to 12 months after tick bite)

- Arthritis—This is generally a monoarticular arthritis involving the knee (90%), although other sites such as the shoulder, ankle, elbow, or wrist may be involved. Approximately 7 percent of children with Lyme disease will have this as their presenting manifestation.[4] Swelling and tenderness of the joint, along with an effusion is most common. With treatment, the arthritis resolves over days to weeks, although recurrence occurs in 5 to 10 percent of treated patients and usually resolves with retreatment. An immune mediated chronic arthritis has been rarely associated in adults with Lyme disease but is extremely rare in children.[5]
- Children who are adequately treated for Lyme disease in the early stages almost never develop late manifestations.

LABORATORY TESTING

Diagnosing Lyme disease is generally based on pertinent history findings and/or the presence of an erythema migrans lesion, especially in endemic areas. In cases where an erythema migrans lesion is absent, serologic testing may be warranted utilizing the following tests:

- Enzyme-linked immunosorbent assay (ELISA; sensitivity: 94%, specificity: 97%)[6]—Used as a *screening* test in patients lacking physical signs of erythema migrans. Up to 50 percent of patients with early infection can have a false-negative result. Thus, serologic testing is generally not recommended in the first 4 weeks of the illness. If strong suspicion remains, convalescent titers should be obtained in 6 weeks.[6] Prior infection does not indicate immunity. Lyme titers may be falsely positive in patients with mononucleosis, periodontal disease, connective tissue disease, and other less common conditions.[7]

- Western blot (immunoglobulin [Ig] M and IgG for *B. burgdorferi*)—If ELISA test yields a positive result, Western blot test is used as a *confirmatory* test. IgM antibodies are detectable between 2 weeks and 6 months after inoculation. IgG may be present indefinitely after 6 weeks, despite appropriate antibiotic therapy. Once it is determined that a person is seropositive for Lyme disease, antibiotic therapy should be initiated promptly. Repeat testing to assess for success of therapy should not be performed, as positive serologic tests may persist indefinitely.
- Because of the frequency of false positive serologic results of Lyme testing, the American Academy of Pediatrics state that, “The widespread practice of ordering serologic tests for patients with nonspecific symptoms, such as fatigue or arthralgia, who have a low probability of having Lyme disease or because of parental pressure, is discouraged. Almost all positive serologic test results in these patients are false-positive results. In areas with endemic infection, subclinical infection and seroconversion also can occur, and the patient’s symptoms merely are coincidental. Patients with acute Lyme disease almost always have objective signs of infection (e.g., erythema migrans, facial nerve palsy, arthritis). Nonspecific symptoms commonly accompany these specific signs but almost never are the only evidence of Lyme disease.”[8]

Empiric antibiotic therapy (no test necessary) should be considered in any of the following clinical presentations: presence of EM rash, flu-like symptoms (in absence of upper respiratory infection [URI] or GI symptoms) after known tick bite, Bell’s palsy in endemic areas, especially between June and September, and tick bites occurring during pregnancy.

CHARACTERISTIC LABORATORY FINDINGS

- Complete blood count (CBC)—Leukocytosis (11,000 to 18,000/µL). Anemia and thrombocytopenia are rare.
- Elevated erythrocyte sedimentation rate (ESR) (>20 mm/h).
- Elevated γ-glutamyltransferase (GGT) and aspartate aminotransferase (AST).
- Cerebrospinal fluid—Pleocytosis and elevated protein levels if central nervous system (CNS) is involved. Spirochete antibodies may be detectable.
- Blood culture—Low yield; not recommended.
- Nerve conduction studies and EM—Useful in patients with paresthesias or radicular pain.

DIFFERENTIAL DIAGNOSIS[9]

- Cellulitis—Spreads more rapidly than Lyme disease. Induration and tenderness are more common (see Chapter 103, Cellulitis).
- Urticaria—Can resemble erythema migrans when the urticarial lesions are annular. Urticaria is generally more widespread and the wheals come and go over time whereas the lesion of EM is more fixed (see Chapter 134, Urticaria and Angioedema).
- Rocky Mountain spotted fever—Associated with *Dermacentor variabilis* (American dog) tick; rash is petechial and the spots are widely distributed over the body (see Chapter 175, Henoch Schonlein Purpura, **Figure 175-5**). Patients often appear toxic.
- Cutaneous fungal infections—Usually pruritic and may be annular; associated with scaling, which is not characteristic of erythema migrans; and spreads slowly if at all. The similarity is that the annular appearance of tinea corporis can mimic EM (see Chapter 123, Tinea Corporis).
- Local reaction to tick bites—Tick bites may cause a local reaction in skin and do not expand with time; generally less than 2 cm in diameter, and are usually papular.

- Febrile viral illnesses (particularly enteroviruses during summer)—Rash, myalgias, arthralgias, and headache; GI symptoms; sore throat and/or cough.
- Facial nerve palsy—May be bilateral in Lyme disease. This is uncommon in facial nerve palsy not associated with Lyme disease (see Chapter 202, Bell’s Palsy).
- Viral meningitis—Lymphocytic (aseptic) meningitis caused by viral infection generally results in transient illness that resolves within several days, usually after a monophasic course.
- Juvenile idiopathic arthritis may be indistinguishable from acute arthritis associated with Lyme disease. Serologic testing and clinical history can help to discriminate (see Chapter 172, Juvenile Idiopathic Arthritis).

MANAGEMENT

MEDICATIONS

▶ Early localized disease

- Eight years of age and older—Doxycycline 4 mg/kg divided twice a day up to 100 mg/dose for 14 to 21 days.[5] SOR Ⓐ
- Younger than 8 years of age or for those who can’t tolerate Doxycycline—Amoxicillin 50 mg/kg divided 3 times a day up to 500 mg per dose or cefuroxime 30 mg/kg divided twice a day up to 1000 mg per dose for 14 to 21 days.

▶ Early disseminated disease and late disease

- Multiple erythema migrans—Same oral regimen as for early localized disease, but for 21 days.
- Isolated facial palsy—Same oral regimen as for early localized disease, but for 14 to 21 days.

- Arthritis—Same oral regimen as for early localized disease, but for 28 days.
- Persistent or recurrent arthritis—Ceftriaxone sodium, 50 to 75 mg/kg, IV, once a day (maximum 2 g/day) for 14 to 28 days.
    - Alternatives: Penicillin, 200 000 to 400 000 U/kg per day, IV, given in divided doses every 4 h (maximum 18 to 24 million U/day) for 14 to 28 days.
    - Cefotaxime 150 to 200 mg/kg per day, IV, divided into 3 or 4 doses (maximum 6 g/day) for 14 to 28 days.
    - Same oral regimen as for early disease (retreatment) but for 28 days.

Atrioventricular heart block or carditis

- Oral regimen as for early disease if asymptomatic but for 14 to 21 days. Ceftriaxone or penicillin IV for symptomatic: see persistent or recurrent arthritis for dosing, but for 14 to 21 days.

Meningitis

- Ceftriaxone 50 to 75 mg/kg IV up to a maximum of 2 g/day for 14 days; alternative therapy cefotaxime 150 to 200 mg/kg per day up to a maximum of 6 g/day, divided into 3 to 4 doses per day.[5] SOR B
- Doxycycline (oral) 100 to 200 mg twice a day for 14 days.[5] SOR B

REFERRAL OR HOSPITALIZATION

- Consider referring patients in whom the diagnosis is unclear, have severe clinical manifestations, or who do not respond to initial therapy.

PREVENTION

- Avoid exposure to ticks by using protective clothing and tick repellant. If hiking in tick-infested areas check body daily for ticks and promptly remove any attached ticks.
- Prophylactic doxycycline (1 dose of 200 mg) is recommended only if the tick is identified as an adult or nymphal *I. scapularis* tick that has been attached for at least 36 hours; medication can be started within 72 hours of tick removal; local rate of infection of ticks with *B. burgdorferi* is at least 20 percent; and doxycycline is not contraindicated.[5]

PROGNOSIS

- The outcome for children who receive conventional appropriate antimicrobial therapy is excellent.
- Non-specific symptoms such as fatigue, arthralgia or myalgia may continue after appropriate treatment, but will resolve over weeks to months. This is not due to persistence of the organism and repeated courses of antibiotics are not effective in hastening resolution of these symptoms.[3]
- True treatment failures are uncommon and prolonged oral or parenteral antibiotic courses are emphatically discouraged. In patients who continue to present with residual subjective symptoms, providers should seek alternate diagnoses and/or referral to an appropriate specialist.

FOLLOW-UP

Follow patients during antibiotic therapy through recovery.

PATIENT EDUCATION

Prevention is accomplished by reducing exposure to ticks. If you live in an area that has Lyme disease then use protective clothing, tick repellent, tick checks, and other simple measures to prevent tick bites. This is especially important during the high-risk months of April through November. Patients should know the early signs of Lyme disease so that they can get care early when it is most curable.

If a tick is found on the skin, remove it early using fine-tipped tweezers. See the following patient resources.

184 EPSTEIN BARR VIRUS INFECTIONS (INFECTIOUS MONONUCLEOSIS)

Blanca E. Gonzalez, MD

PATIENT STORY

A 16-year-old boy comes to see his pediatrician because of a 7-day history of intense sore throat, fever, malaise, and abdominal pain. He also complains of bilateral neck swelling and tenderness. On examination, he has markedly enlarged tonsils with bilateral whitish exudates, and very large lymph nodes palpable in the posterior neck bilaterally (**Figure 184-1**). In addition, his spleen is palpable at 1 cm below the left costal margin. A heterophile antibody test (monospot) is positive and he is offered symptomatic treatment. His symptoms persist for about 10 days, after which he recovers completely.

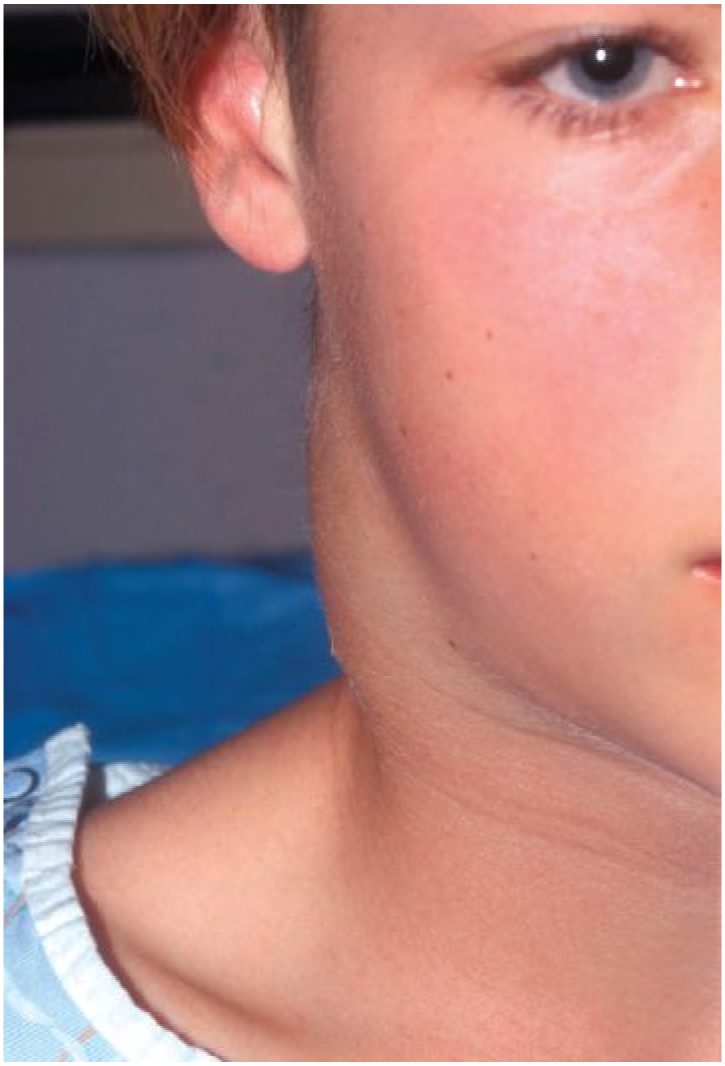

FIGURE 184-1 Posterior cervical lymphadenopathy in an adolescent with infectious mononucleosis. (*Used with permission from Johanna Goldfarb, MD*.)

INTRODUCTION

Epstein Barr virus (EBV) is a DNA virus that belongs to the Herpes virus family. It is the most common etiological agent of infectious mononucleosis, a clinical syndrome characterized by fever, pharyngitis and cervical lymphadenopathy. Rarely, encephalitis, myocarditis, and hemolytic anemia can develop as a consequence of EBV infections.[1] In the immunocompromised host, this virus can cause life-threatening infections.[2]

SYNONYMS

EBV infection is synonymous with infectious mononucleosis although infectious mononucleosis can be caused by other viruses such as cytomegalovirus (CMV). Other terms associated with EBV are glandular syndrome and human herpes virus 4. It is referred to as “the kissing disease” in the popular vernacular.

EPIDEMIOLOGY

- Ubiquitous in the environment.
- In developed countries, EBV infections are not common in infants and young children. In contrast, in developing nations, 90 percent of children less than 6 years of age have been exposed to the virus.[1,3,4]
- The majority of primary infections occur in adolescents and young adults.
- By adulthood, greater than 90 percent have serological evidence of previous EBV exposure.
- The virus has no defined seasonal variations and occurs year round with slightly higher incidence during summer months.[56–7]
- Oral secretions are the main source of transmission; that is, deep kissing, toddlers sharing toys.[8]
- In childhood, EBV infections may be asymptomatic.
- EBV infection results in infectious mononucleosis in 30 to 40 percent of adolescents.
- Incubation 30 to 50 days.

ETIOLOGY AND PATHOPHYSIOLOGY

- The virus infects epithelial cells in the tonsillar crypts and B lymphocytes.[2]
- The virus is disseminated throughout the reticuloendothelial system (tonsils, spleen, and lymph nodes) by the infected B cells.
- CD4 and CD8 T cell responses are activated.
- The virus establishes permanent latent infections in the host.
- Disease severity may be related to high numbers of NK and $CD8^+$ T cells and elevated blood viral loads.[8]

RISK FACTORS

- In developed countries, teenagers and college students are the highest risk group. Behaviors such as “deep kissing”[8] and sexual activity are risk factors for primary EBV infections.
- Immunocompromised hosts, including patients with diabetes, HIV, transplant patients, and patients on immunomodulators are at risk of developing severe manifestations of EBV infections.

DIAGNOSIS

- Infectious Mononucleosis—The classical presentation consists of the triad of fever, exudative pharyngitis and lymphadenopathy.
- Younger children may present with mild symptoms, or may present with fever as their only sign of infection.

- Constitutional symptoms such as fever, myalgias, malaise, and headache may precede the lymphadenopathy and pharyngitis by 3 to 5 days.
- Cervical lymphadenopathy can be significant and give the neck the appearance of “bull’s neck.” The posterior cervical chains are commonly involved. Epitrochlear nodes can also be enlarged (**Figure 184-1**).[9,10] Splenomegaly occurs in 80 percent of the patients and may lead to splenic rupture after mild trauma.[11,12]
- Hepatomegaly is less common.
- Fatigue is a common feature and often persists throughout the course of illness.

OCULAR MANIFESTATIONS

- Periorbital edema may be the presenting sign of infectious mononucleosis and can be confused with cellulitis.[13,14]
- Oculo-glandular syndromes (eyelid swelling with non-tender pre-auricular lymphadenopathy).[15,16]
- Less commonly keratitis, uveitis and acute retinal necrosis.[17,18]

DERMATOLOGICAL MANIFESTATIONS

- A rash may be present in 10 percent of the patients. The rash is morbilliform and usually is present over the trunk and arms (**Figure 184-2**). Occasionally the rash may be urticarial or petechial.[1920–21]

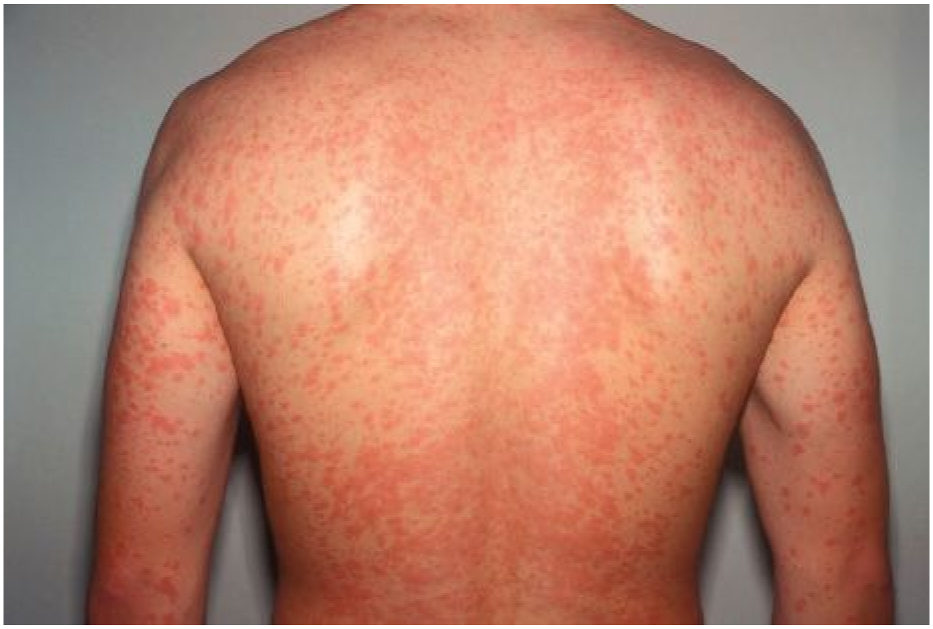

FIGURE 184-2 Morbilliform rash in an adolescent with infectious mononucleosis. (*Used with permission from Johanna Goldfarb, MD.*)

- Over 90 percent will develop a rash if exposed to ampicillin.[20]
- Papular acrodermatitis, also known as Gianotti-Crosti syndrome, has been associated with EBV.[21] It tends to occur in infancy and early childhood (**Figure 184-3**).

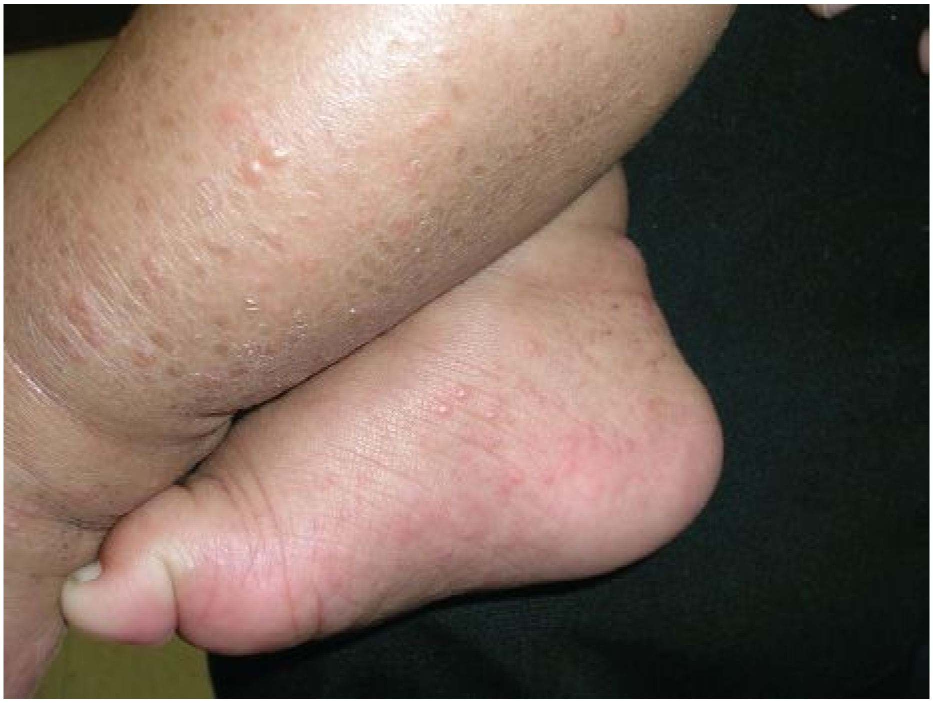

FIGURE 184-3 Papular acrodermatitis (also known as Gianotti-Crosti syndrome) in an infant. (*Used with permission from Richard P. Usatine, MD*.)

- Erythema nodosum (**Figure 184-4**).

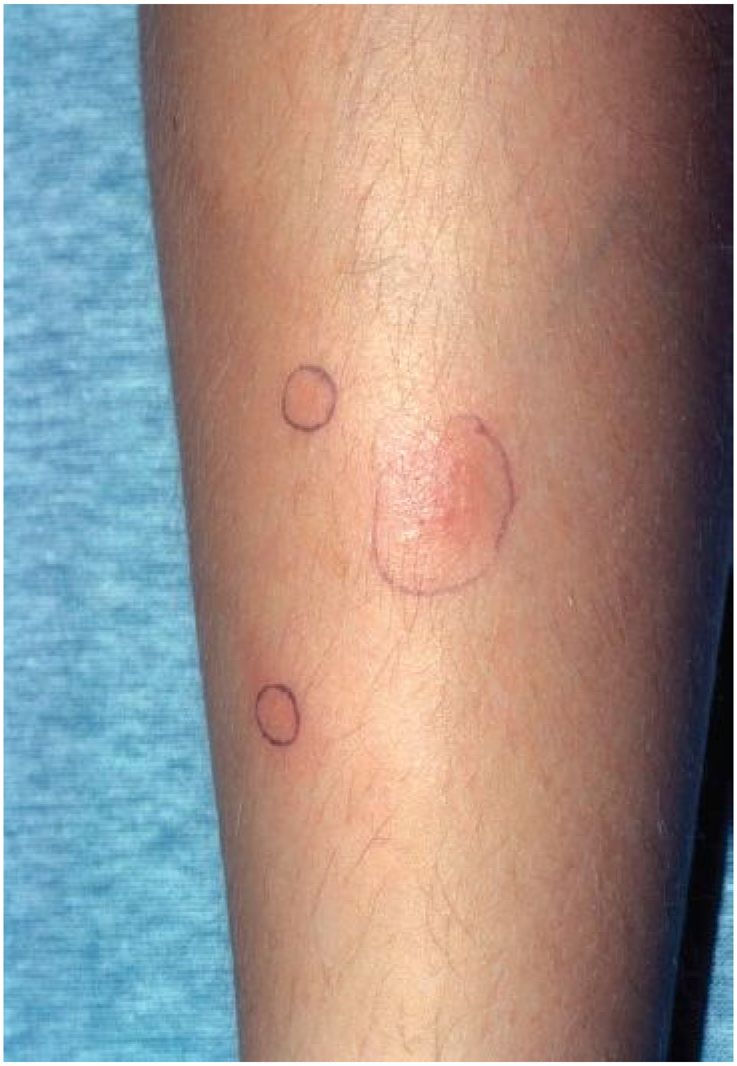

FIGURE 184-4 Erythema nodosum distributed over the shins of this adolescent. These are painful nodules and are associated with many infections, including EBV infection. (*Used with permission from Camille Sabella, MD.*)

- Genital ulcerations in adolescent girls can be seen in conjunction with EBV infections (Ulcus Vulvae Acutum). They can be single or multiple and very painful.[22,23]

CENTRAL NERVOUS SYSTEM MANIFESTATIONS

- The virus may affect central and peripheral and nervous system and has been associated with encephalitis, meningitis, encephalomyelitis, and radiculitis.[24]
- Acute disseminated encephalomyelitis (ADEM; **Figure 184-5**).[25]

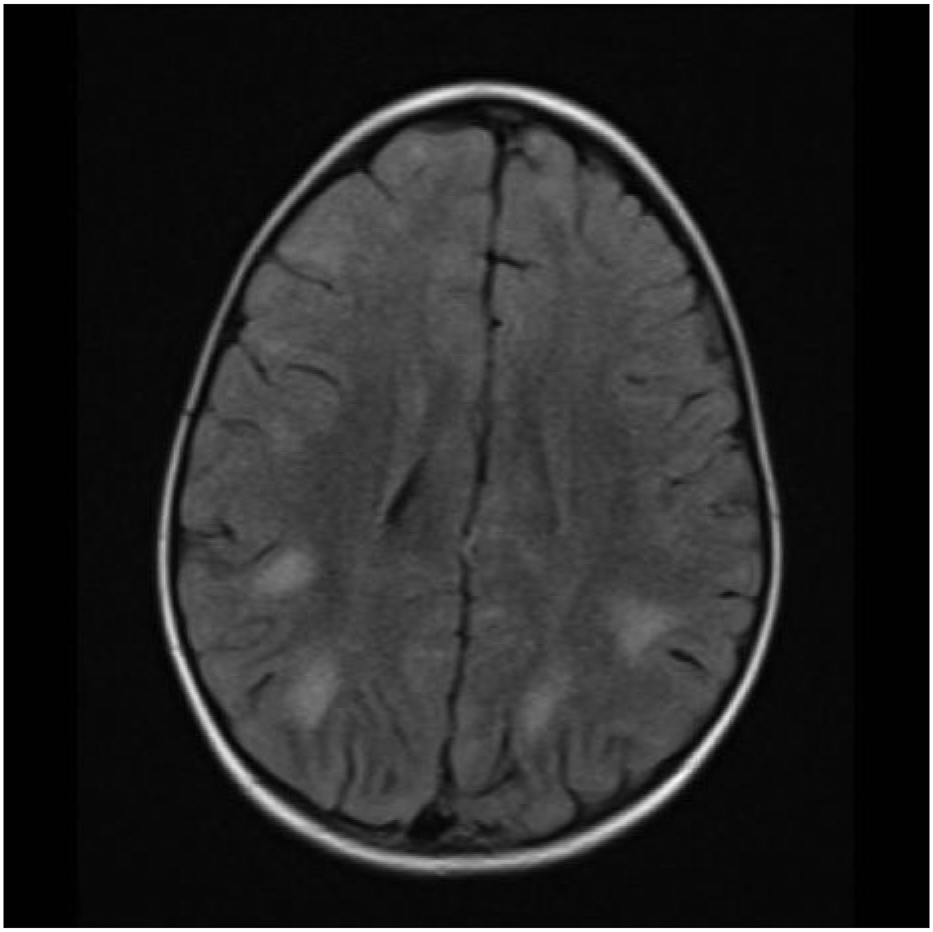

FIGURE 184-5 Acute disseminated encephalomyelitis. Note the hypodense areas in the occipital and parietal areas. Many different etiologic agents have been associated with ADEM, including EBV infections. (*Used with permission from Neil Friedman, MD*.)

- Alice in Wonderland syndrome—Associated with EBV and consists of abnormal perceptions where patients experience distortions of forms, size, or colors. Children will say objects look long, or small or different. This condition usually transient and improves with the improvement of the infectious mononucleosis.[26]

OTHER MANIFESTATIONS OF EBV INFECTIONS[1,2]

- Carditis, pericarditis.
- Pneumonia.
- Hemolytic anemia.
- Transient thrombocytopenic purpura.
- Interstitial nephritis.

ASSOCIATED MALIGNANT PROCESSES WITH EBV IN CHILDREN[2]

- Burkitt's lymphoma.
- Hodgkin's disease (**Figure 184-6**).

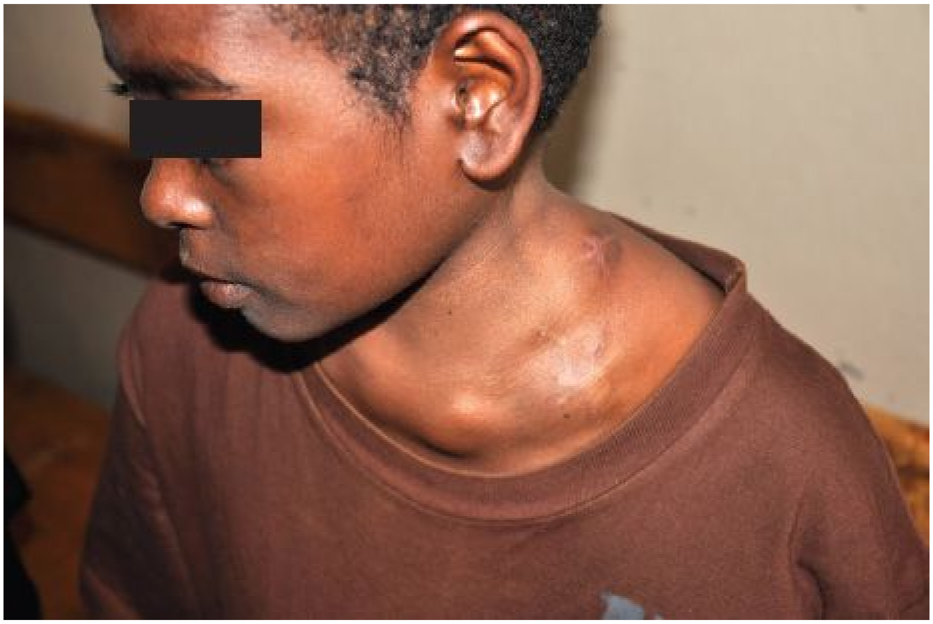

FIGURE 184-6 Cervical and supraclavicular lymphadenopathy in a boy with Hodgkin's disease. (*Used with permission from Richard P. Usatine, MD.*)

- X-linked lymphoproliferative syndrome (XLPS).
- Leiomyosarcoma in children with Human Immunodeficiency virus (HIV) or immunodeficiencies (i.e., transplant) and post-transplant lymphoproliferative disorder (PTLD) after organ transplantation.

LABORATORY TESTING

- Atypical lymphocytes—Reactive lymphocytes that are larger and with dents in the cytoplasm (**Figure 184-7**). They are also present with CMV infections. Less commonly present in other viral illnesses.[27]

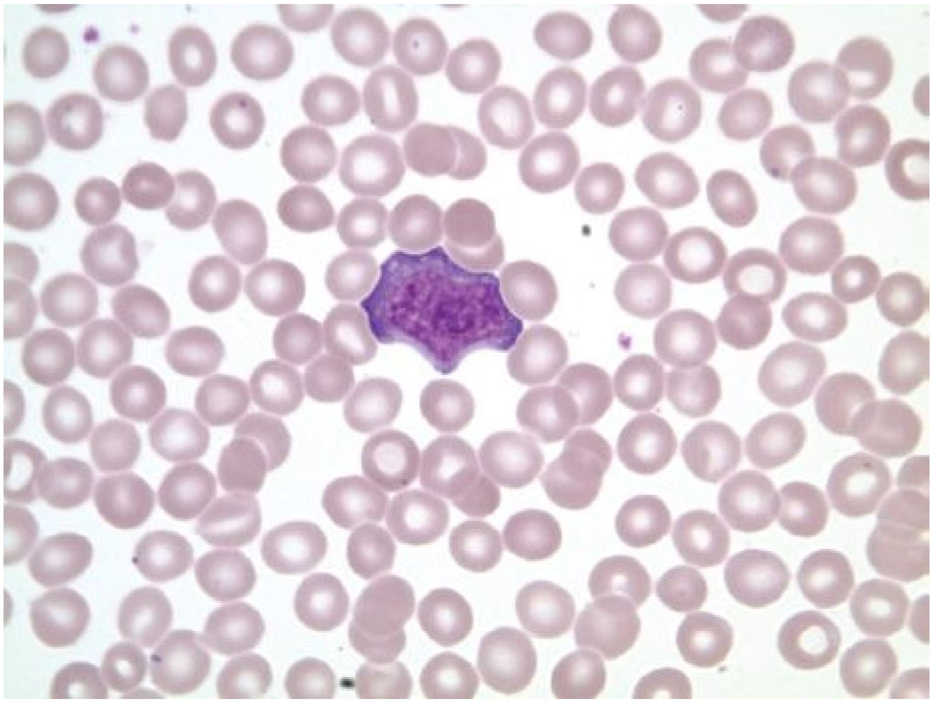

FIGURE 184-7 Atypical lymphocyte with indentation of the nuclei on a peripheral blood smear, characteristic of infectious mononucleosis. (*Used with permission from Eric Hsi, MD.*)

- Heterophile antibody—These are nonspecific antibodies that cross react with many antigens. The monospot detects these antibodies using slide tests with horse or sheep red blood cells. These antibodies are most elevated between 2 to 5 weeks of illness and may be negative in the first weeks of the disease process. The test is usually negative in 10 to 50 percent of children under the age of 4 years. Overall sensitivity of the test is around 80 percent and the specificity is around 89 to 100 percent. Therefore, a negative monospot does not exclude EBV.[1,28]

- Cytomegalovirus associated infectious mononucleosis is monospot negative.[29]
- Serologies—Four specific EBV antibodies are used to establish the diagnosis: Early antigen, viral capsid antibody (VCA) IgM, VCA IgG, and Epstein Barr nuclear antigen (EBNA) IgG (**Figure 184-8**).[30] These are used to make the diagnosis in younger children in whom the heterophile antibody test may negative or when the heterophile antibody test is negative and infectious mononucleosis remains suspected.

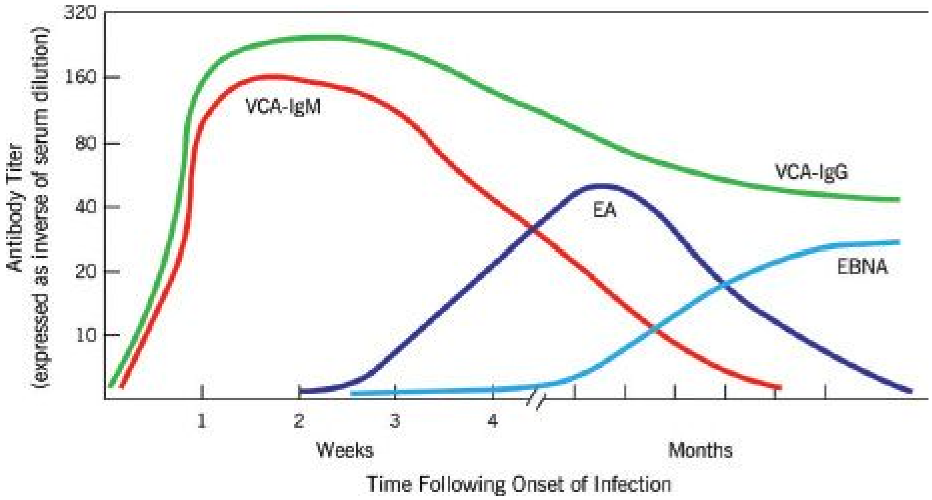

FIGURE 184-8 EBV antibodies during infectious mononucleosis. The first antibodies to appear are IgM and IgG against the viral capside antigen (IgM VCA and IGG VCA). The IgM VCA rises quickly and remains positive for approximately 4 months. The IgG VCA remains positive for life after the infection. The early antigen (EA) antibody follows the VCA antibodies and may remain positive for more than 6 months and in some patients may be positive lifelong. The Epstein Barr nuclear antigen (EBNA) is the last antibody to appear 1 to 3 months after the infection and usually remains positive for life.[1,30]

- Polymerase chain reaction (PCR) is utilized to detect the virus in CSF when central nervous system complications are suspected or to measure the viral load in blood of immunocompromised patients.[31,32]

DIFFERENTIAL DIAGNOSIS[33]

- CMV—Causes a heterophile-negative infectious mononucleosis syndrome and can be indistinguishable from EBV infection. Diagnosis usually made with serology.
- Toxoplasmosis—May present with similar features to EBV infection. The pharyngitis features and less pronounced and splenomegaly often absent.
- Acute retroviral syndrome (acute HIV)—Should be suspected as a cause of heterophile-negative infectious mononucleosis syndrome, especially if there is a history of possible epidemiological exposure.
- Hepatitis A—Commonly causes fever, nausea and jaundice, but not often with pharyngitis and lymphadenopathy.
- Adenovirus—Usually more acute presentation and not associated with splenomegaly.
- Enterovirus—Common cause of fever in infants and young children and may present similarly to EBV infection at these ages. Often have herpangina or hand-foot-mouth disease (see Chapter 113, Hand Foot Mouth Syndrome).
- HHV6—Very common cause of fever with/without rash in infants and thus in the differential diagnosis of EBV infection in young infants.
- Mycoplasma—Common in adolescents, who usually have respiratory manifestations as the primary focus of infection.
- Group A streptococcal infection—Common cause of pharyngitis and lymphadenopathy and can occur concurrently with EBV infection. It can be excluded with appropriate microbiologic testing of the pharynx (see Chapter 29, URI Including Pharyngitis).
- Hodgkin’s lymphoma (Hodgkin’s disease)—Can present with lymphadenopathy, fever, night sweats, and fatigue similar to mononucleosis. These children may have larger more tender lymph nodes but any systemic illness with these features should prompt consideration of Hodgkin’s disease as well as mononucleosis (**Figure 184-6**). Hodgkin’s disease may even follow an episode of mononucleosis.

MANAGEMENT

- Mainly supportive: hydration, rest.
- Antibiotics have no role and may cause rash (amoxicillin). If there is coexisting strep pharyngitis use penicillin (not amoxicillin) as treatment to avoid the common amoxicillin mononucleosis exanthem (see Chapter 154, Cutaneous Drug Reactions).
- Routine therapy with corticosteroids is not indicated. They may offer benefit in reducing edema when there is airway compromise.[34] SOR C
- Contact sports should be avoided until the spleen is no longer palpable because of risk of splenic rupture.
- Acyclovir and ganciclovir are active against the virus in vitro by means of inhibition of the lytic phase but there is limited or no evidence that they improve symptoms of infectious mononucleosis. Antiviral treatment is reserved for immunocompromised patients.[35]

RADIOLOGY

- Ultrasound technique may be used to assess the size of the spleen and help determine when a child can go back to participate in contact sports; however, there are no well-defined norms related to a normal spleen size are available (**Figure 184-9**).[363738–39]

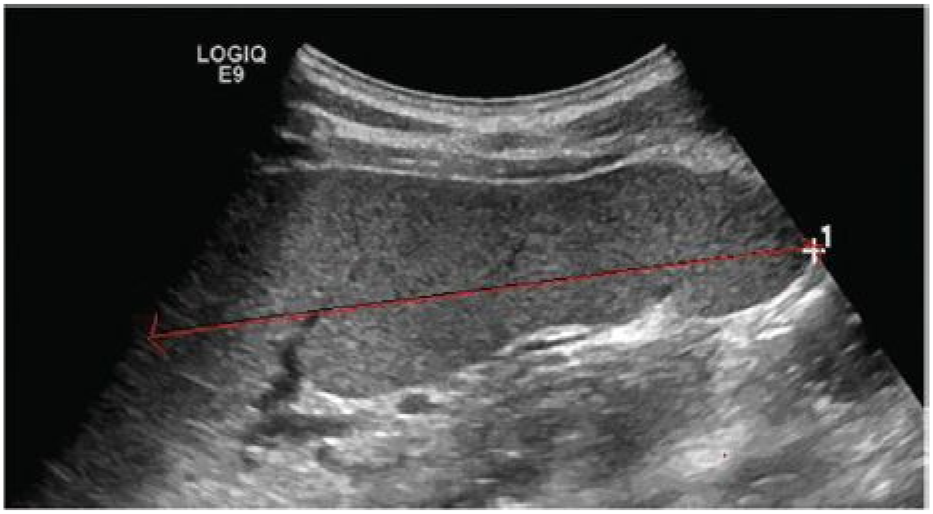

FIGURE 184-9 Splenomegaly on ultrasound of the spleen in a 16 year-old-patient with infectious mononucleosis. The spleen measures 17cm. Even though there are no clearly defined norms of splenic size in adolescents, measurement closer to 12 to 13 are considered normal for this age group.[37, 38] The disruption in the splenic perimeter at the bottom left portion of this enlarged spleen is due to a splenic vessel and not a splenic rupture. (*Used with permission from Blanca Gonzalez, MD*.)

SURGERY

- Surgery may be indicated in splenic rupture, although conservative approaches have also been successful in treating splenic rupture associated with EBV infectious mononucleosis.[40]
- Spontaneous splenic rupture, though rare, can occur most frequently within the first 2 weeks of illness.[39]
- Late ruptures are associated with trauma.

PREVENTION

- Because the virus may persist in saliva for a long time and patients may be infectious prior to the onset of symptoms, prevention strategies are difficult; nevertheless, patients should avoid deep kissing and sharing food or utensils during the acute phase of the disease.

PROGNOSIS

- The fatigue that patients experience may persist for up to 6 months.[41] Fatigue and non-specific symptoms persisting longer than this cannot be attributed to active viral infection and other diseases such as Hodgkin's lymphoma should be considered.
- Chronic EBV infections are a very rare occurrence and manifest as persistent symptoms of infectious mononucleosis for more than 6 months with evidence of other organ involvement (i.e., Hepatitis, hemolytic anemia).[42]
- EBV infection confers lifelong immunity to re-infection.
- Even though reactivations may occur, they tend to be asymptomatic in the immune competent host.
- Lymphomas and epithelial malignancies may develop in some patients.[2]
- In the transplant patient, EBV reactivation may lead to the development of PTLD.[43]

FOLLOW-UP

- Follow-up with primary physician for clearance for participation in sports.
- Generally, once the acute manifestations and splenomegaly on physical exam have resolved, the patient may return to sports participation. A 6-week period from the onset of symptoms is often used as a guideline.

PATIENT EDUCATION

- The expected course of illness should be discussed with the patient and the family.
- After an initial period of rest, a return to school and noncontact activities is important to re-establish a normal routine.

185 TOXIC SHOCK SYNDROMES

Camille Sabella, MD

PATIENT STORY

An 11-year-old boy presented to the emergency department with a 12-hour history of fever, rash over his trunk, vomiting, and diarrhea. In the emergency department, he had a fever to 39.3°C., pulse 140/minute, respiratory rate 40/minute, and blood pressure 90/60 mm Hg. He had conjunctival injection and inflamed oral mucus membranes, and intense erythroderma (red skin) on his trunk and back (**Figure 185-1**). Laboratory tests revealed thrombocytopenia, transaminitis, and an elevated creatinine level that was twice normal for his age. He was given fluid resuscitation and was admitted to the pediatric intensive care unit, where he required several fluid boluses and inotropic support to maintain adequate blood pressure and perfusion. He was treated with vancomycin and clindamycin. *Staphylococcus aureus* was isolated from an infected wound on his lower extremity that he sustained from a sports injury a few days prior to his presentation.

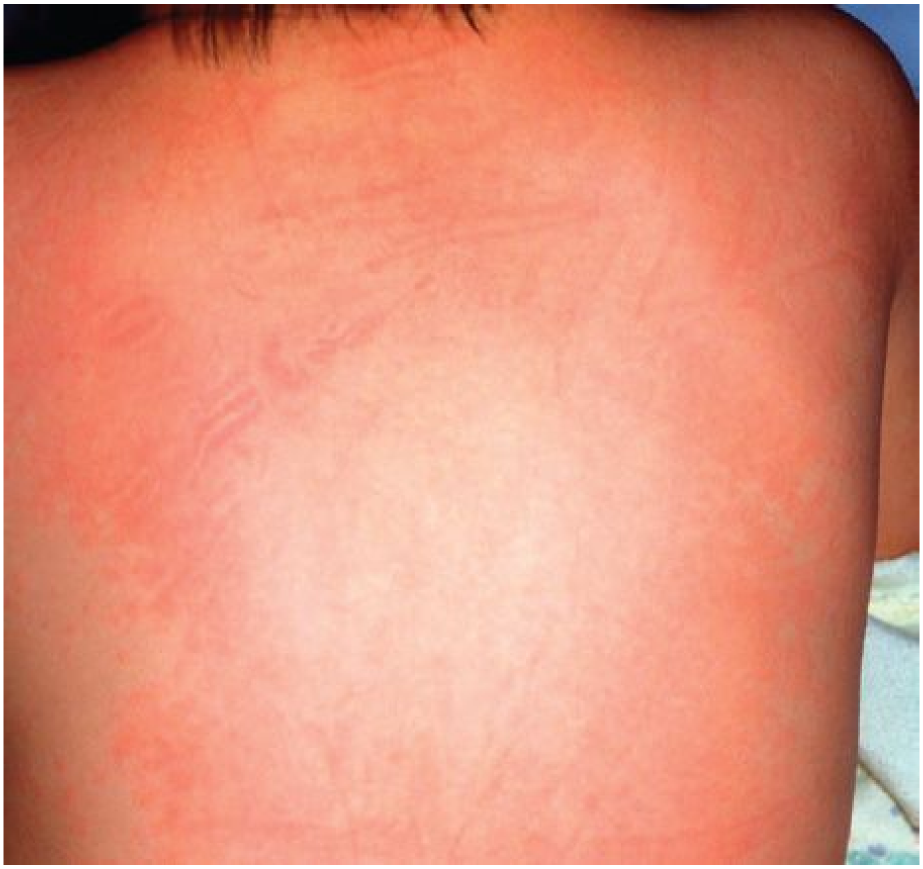

FIGURE 185-1 Erythroderma in a child with toxic shock syndrome. (*Used with permission from Johanna Goldfarb, MD.*)

INTRODUCTION

Toxic shock syndrome (TSS) is an acute illness characterized by fever, rash, hypotension, and multi-organ system involvement that can progress to shock, renal failure, myocardial dysfunction, and adult respiratory distress syndrome. TSS was originally described in 1978 in children who had infection caused by *Staphylococcus aureus*, and has been well described in menstruating females using tampons.[1,2] A similar toxic shock-like syndrome has been described in association with group A streptococcal (GAS) infection.[3,4]

EPIDEMIOLOGY

STAPHYLOCOCCAL TOXIC SHOCK

- There is a strong correlation between menstruation, use of high absorbency tampons, and the development of TSS.[5]
- Sixty percent of TSS cases occur in menstruating women while 40 percent occur in males and nonmenstruating females.[6]
- More likely to occur in younger individuals who have not had previous exposure to TSS toxins and lack neutralizing antibody.[7]
- Young women who have vaginal colonization with toxin-producing strains of *S aureus* and who have no antibody to TSS toxin 1 (TSST-1) are at highest risk of developing TSS during menstruation, especially with tampon use.
- Children who have focal infection caused by *S aureus* can develop TSS. These infections may be clinically apparent, such as wound infections, skin abscesses, cellulitis, tracheitis, or may be occult, such as with sinusitis.

STREPTOCOCCAL TOXIC SHOCK-LIKE SYNDROME

- Usually related to GAS bacteremia, and in many cases often associated with cellulitis and necrotizing fasciitis.[3,4]
- Associated with varicella infections in which GAS secondarily infects skin lesions.

ETIOLOGY AND PATHOPHYSIOLOGY

- TSS is caused by *S aureus* strains that produce TSS toxin 1 or possibly other Staphylococcal enterotoxins.[8]
- TSS toxins are thought to act as superantigens that stimulate the production of inflammatory mediators such as tumor necrosis factor and interleukin 1. These mediators cause capillary leakage that lead to hypotension and multisystem organ dysfunction.[910–11]
- The degree of hypotension predicts the extent of multisystem organ dysfunction.
- Current clones of community-associated strains of methicillin-resistant *S aureus* (MRSA) rarely produce TSS toxin.[12]
- Most cases of GAS toxic shock-like syndrome are due to strains of M types 1 and 3.

RISK FACTORS

- TSS is most common in young menstruating women using high absorbency tampons.
- The lack of antibody to TSS-toxin 1 is a risk factor for infection.
- Varicella infection is an important risk factor for Streptococcal toxic shock-like syndrome (**Figure 185-2**).

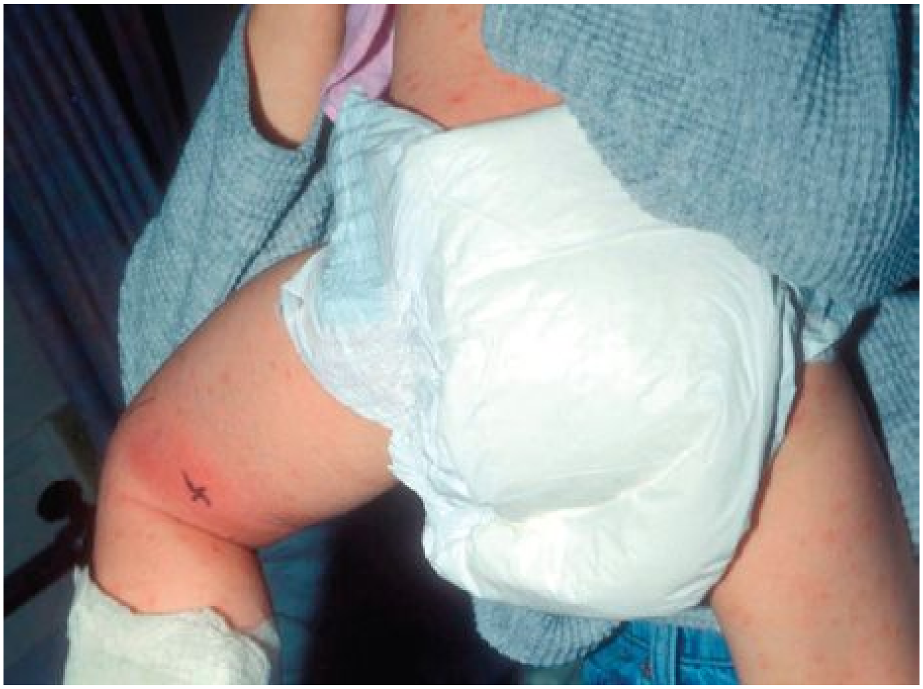

FIGURE 185-2 Child with varicella who developed a secondary bacterial cellulitis caused by group A streptococcus. (*Used with permission from Camille Sabella, MD*.)

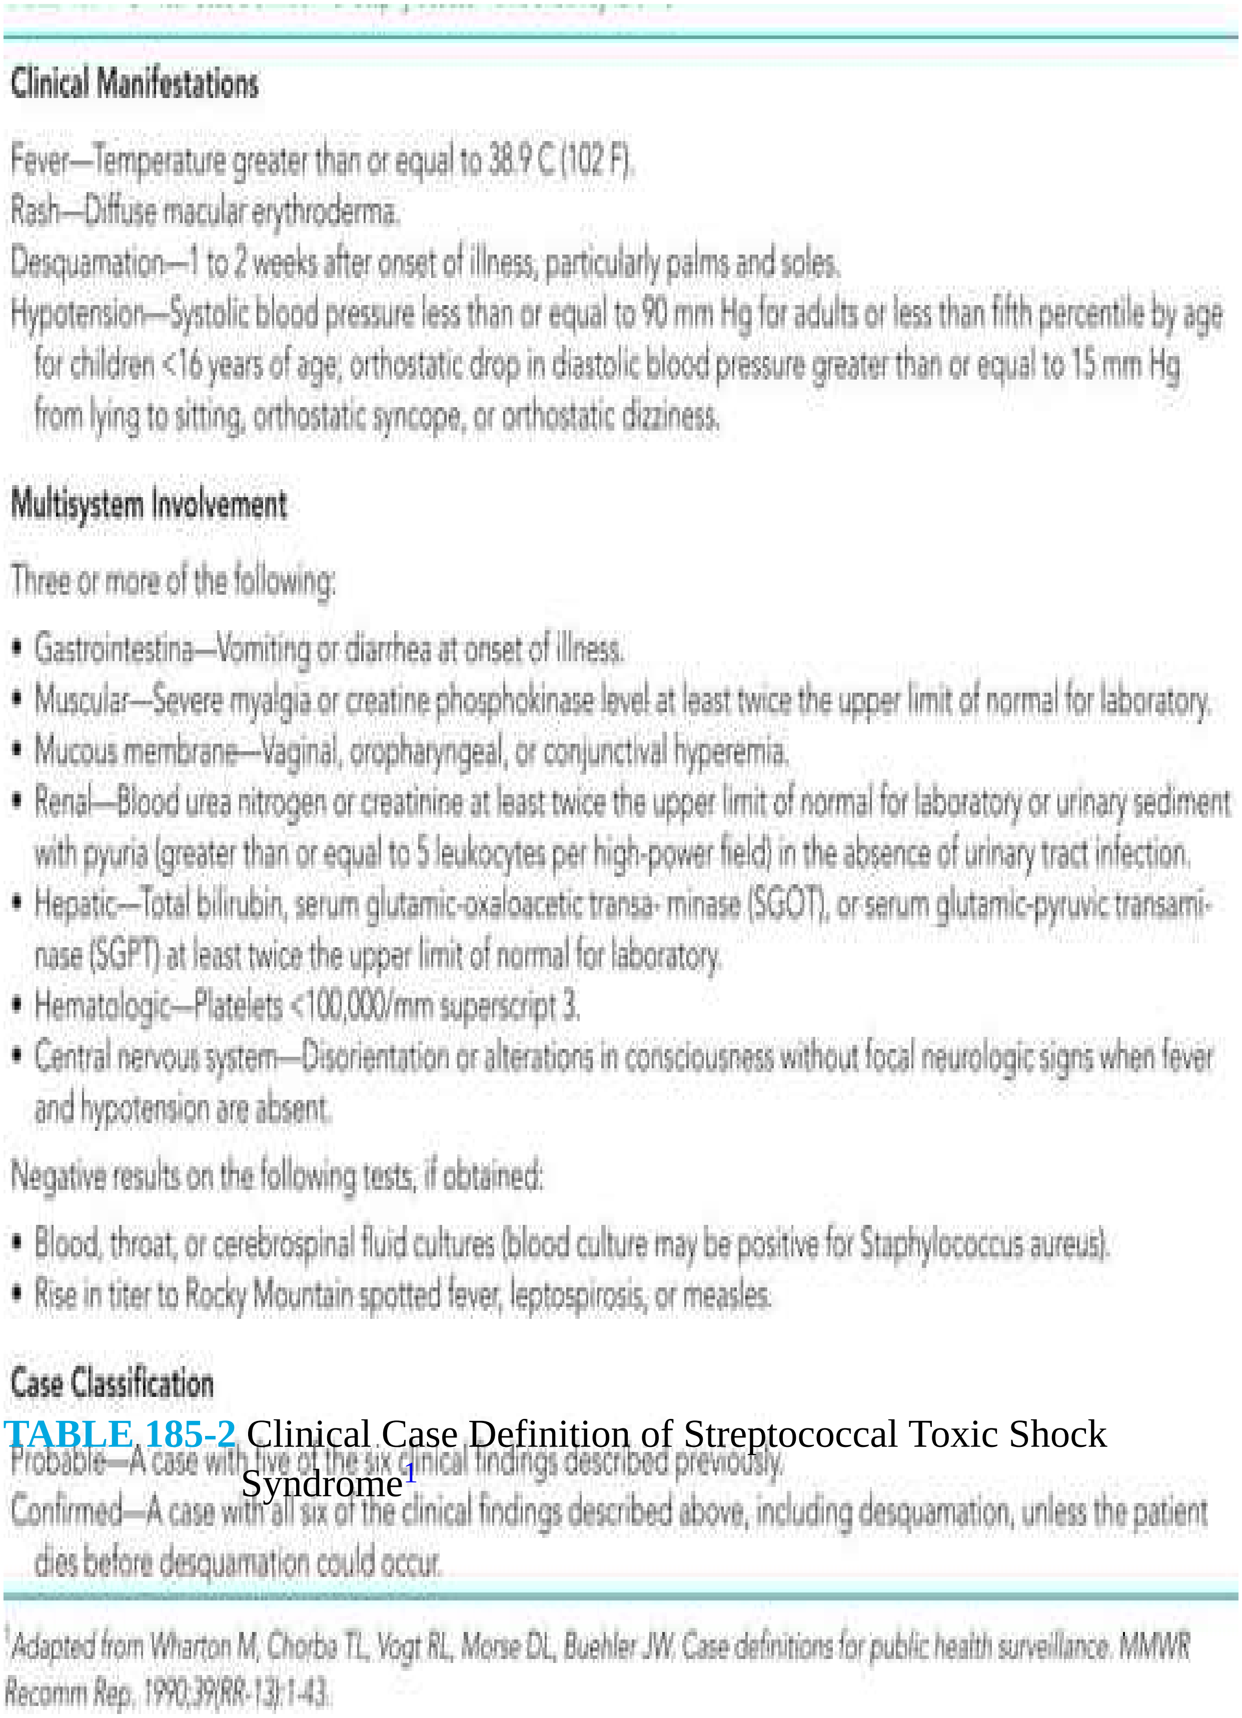
DIAGNOSIS

CLINICAL FEATURES

- Formal case definitions for TSS and Streptococcal toxic shock-like syndrome have been published (**Tables 185-1** and **185-2**).

TABLE 185-1 Clinical Case Definition for Staphylococcal Toxic Shock Syndrome[1]

TABLE 185-2 Clinical Case Definition of Streptococcal Toxic Shock Syndrome[1]



Clinical Manifestations

Fever—Temperature greater than or equal to 38.9 C (102 F).
Rash—Diffuse macular erythroderma.
Desquamation—1 to 2 weeks after onset of illness, particularly palms and soles.
Hypotension—Systolic blood pressure less than or equal to 90 mm Hg for adults or less than fifth percentile by age for children <16 years of age; orthostatic drop in diastolic blood pressure greater than or equal to 15 mm Hg from lying to sitting, orthostatic syncope, or orthostatic dizziness.

Multisystem Involvement

Three or more of the following:

- Gastrointestina—Vomiting or diarrhea at onset of illness.
- Muscular—Severe myalgia or creatine phosphokinase level at least twice the upper limit of normal for laboratory.
- Mucous membrane—Vaginal, oropharyngeal, or conjunctival hyperemia.
- Renal—Blood urea nitrogen or creatinine at least twice the upper limit of normal for laboratory or urinary sediment with pyuria (greater than or equal to 5 leukocytes per high-power field) in the absence of urinary tract infection.
- Hepatic—Total bilirubin, serum glutamic-oxaloacetic transa- minase (SGOT), or serum glutamic-pyruvic transaminase (SGPT) at least twice the upper limit of normal for laboratory.
- Hematologic—Platelets <100,000/mm superscript 3.
- Central nervous system—Disorientation or alterations in consciousness without focal neurologic signs when fever and hypotension are absent.

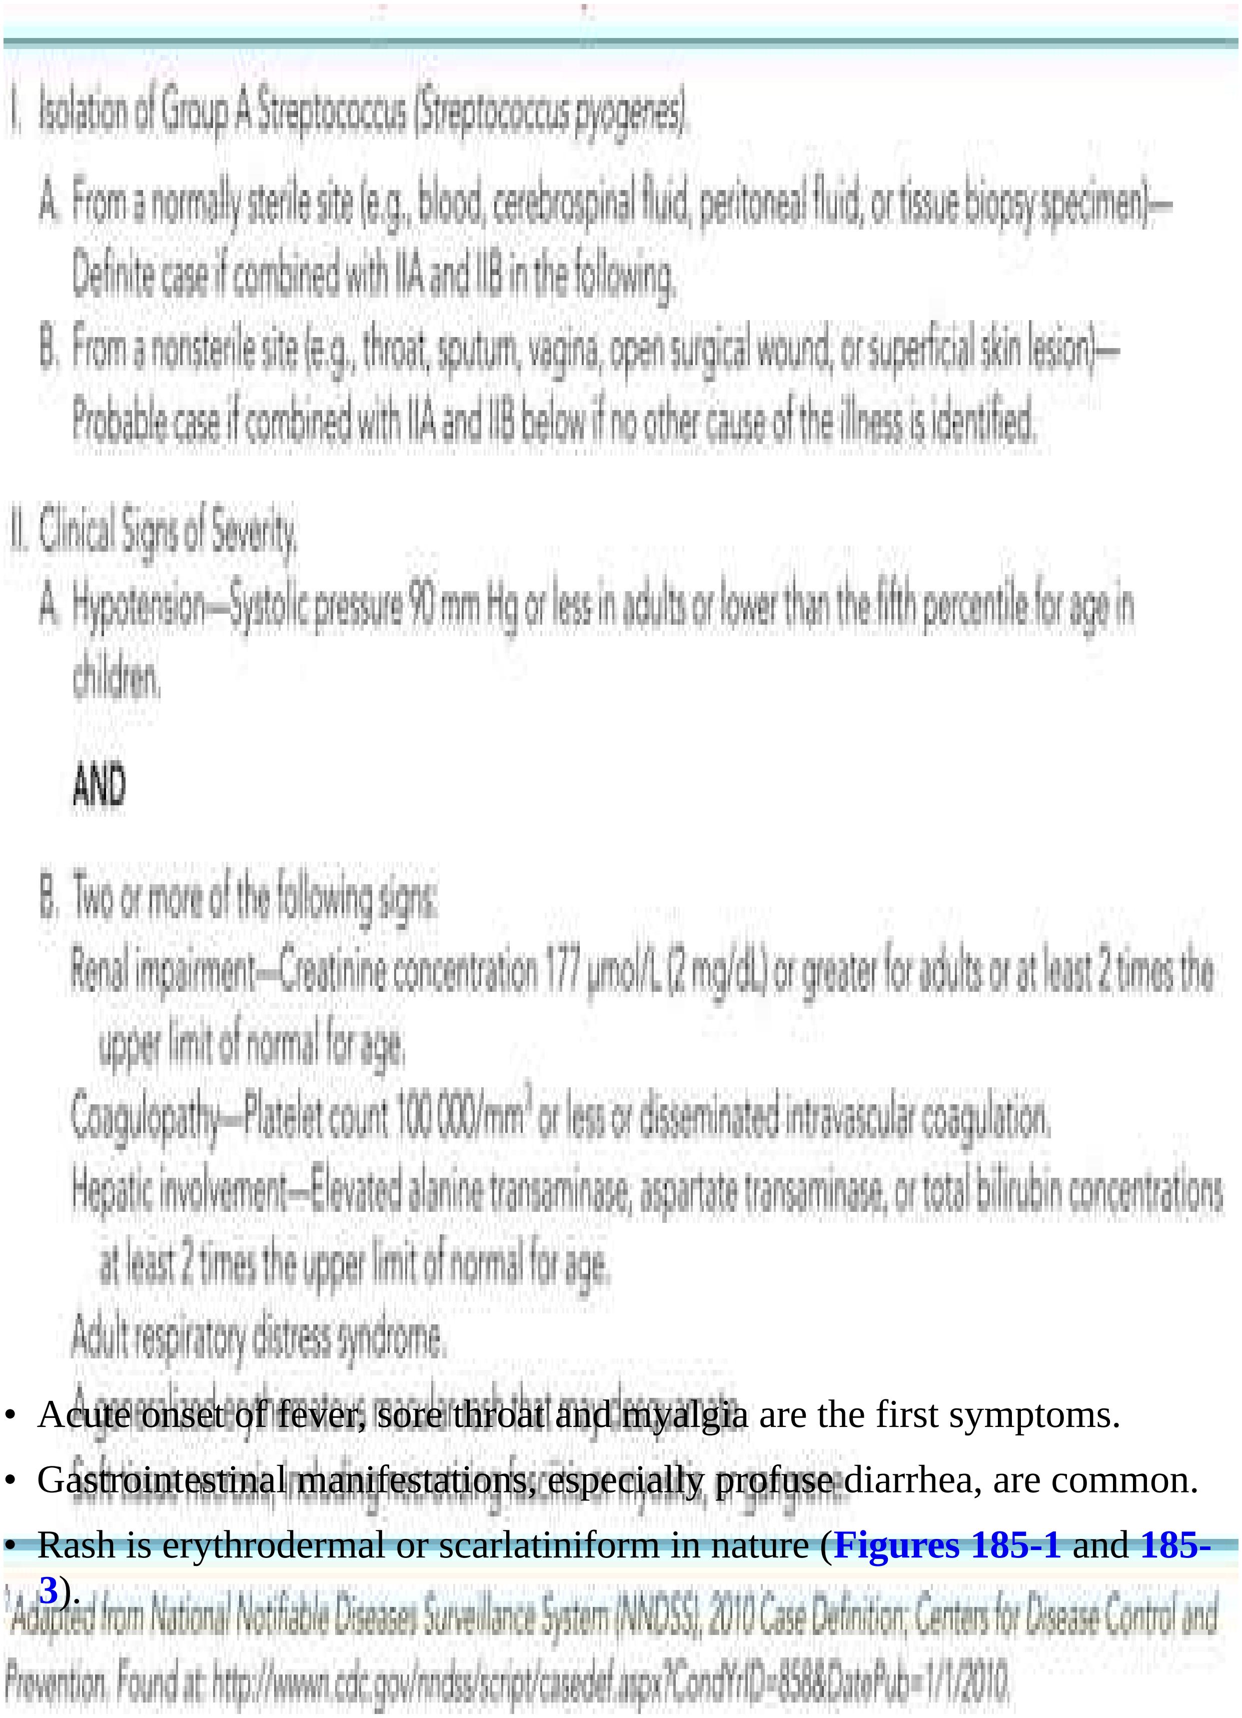
Negative results on the following tests, if obtained:

- Blood, throat, or cerebrospinal fluid cultures (blood culture may be positive for Staphylococcus aureus).
- Rise in titer to Rocky Mountain spotted fever, leptospirosis, or measles.

Case Classification

Probable—A case with five of the six clinical findings described previously.
Confirmed—A case with all six of the clinical findings described above, including desquamation, unless the patient dies before desquamation could occur.

[1] *Adapted from Wharton M, Chorba TL, Vogt RL, Morse DL, Buehler JW. Case definitions for public health surveillance. MMWR Recomm Rep. 1990;39(RR-13):1-43.*



I. Isolation of Group A Streptococcus (*Streptococcus pyogenes*)

A. From a normally sterile site (e.g., blood, cerebrospinal fluid, peritoneal fluid, or tissue biopsy specimen)—Definite case if combined with IIA and IIB in the following.

B. From a nonsterile site (e.g., throat, sputum, vagina, open surgical wound, or superficial skin lesion)—Probable case if combined with IIA and IIB below if no other cause of the illness is identified.

II. Clinical Signs of Severity

A. Hypotension—Systolic pressure 90 mm Hg or less in adults or lower than the fifth percentile for age in children.

AND

B. Two or more of the following signs:

Renal impairment—Creatinine concentration 177 μmol/L (2 mg/dL) or greater for adults or at least 2 times the upper limit of normal for age.

Coagulopathy—Platelet count 100 000/mm^3 or less or disseminated intravascular coagulation.

Hepatic involvement—Elevated alanine transaminase, aspartate transaminase, or total bilirubin concentrations at least 2 times the upper limit of normal for age.

Adult respiratory distress syndrome.

A generalized erythematous macular rash that may desquamate.

Soft-tissue necrosis, including necrotizing fasciitis or myositis, or gangrene.

[a] Adapted from National Notifiable Diseases Surveillance System (NNDSS), 2010 Case Definition; Centers for Disease Control and Prevention. Found at: http://wwwn.cdc.gov/nndss/script/casedef.aspx?CondYrID=858&DatePub=1/1/2010.

- Acute onset of fever, sore throat and myalgia are the first symptoms.
- Gastrointestinal manifestations, especially profuse diarrhea, are common.
- Rash is erythrodermal or scarlatiniform in nature (**Figures 185-1** and **185-3**).

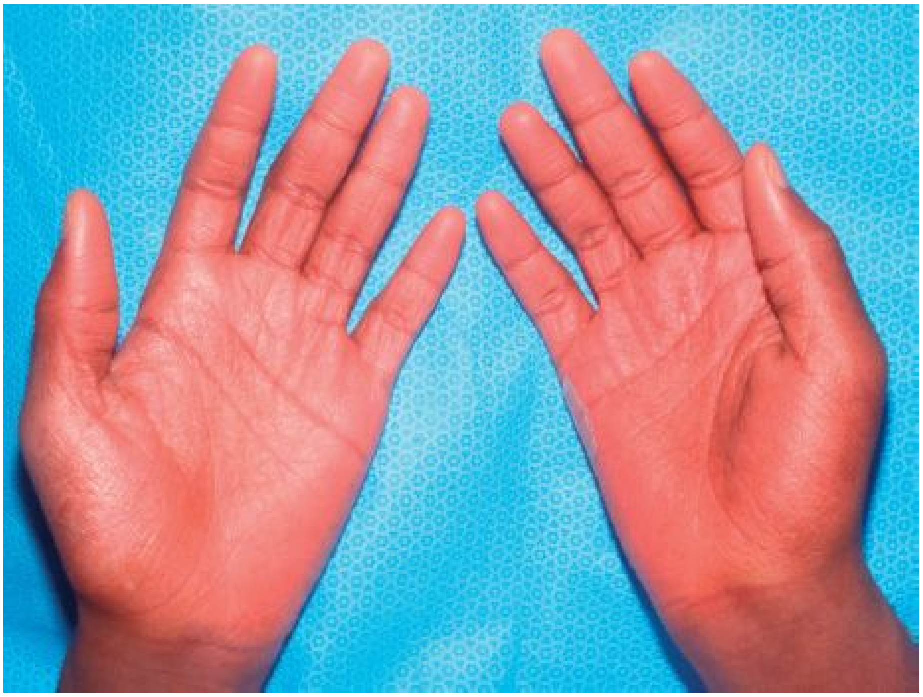


FIGURE 185-3 Child with palmar erythema characteristic of early toxic shock syndrome. (*Used with permission from Camille Sabella, MD*.)

- Symptoms of hypotension are often present (dizziness or fainting).
- “Strawberry tongue” (**Figure 185-4**), nonpurulent conjunctival injection (**Figure 185-5**), and pharyngeal inflammation are common features on physical examination.

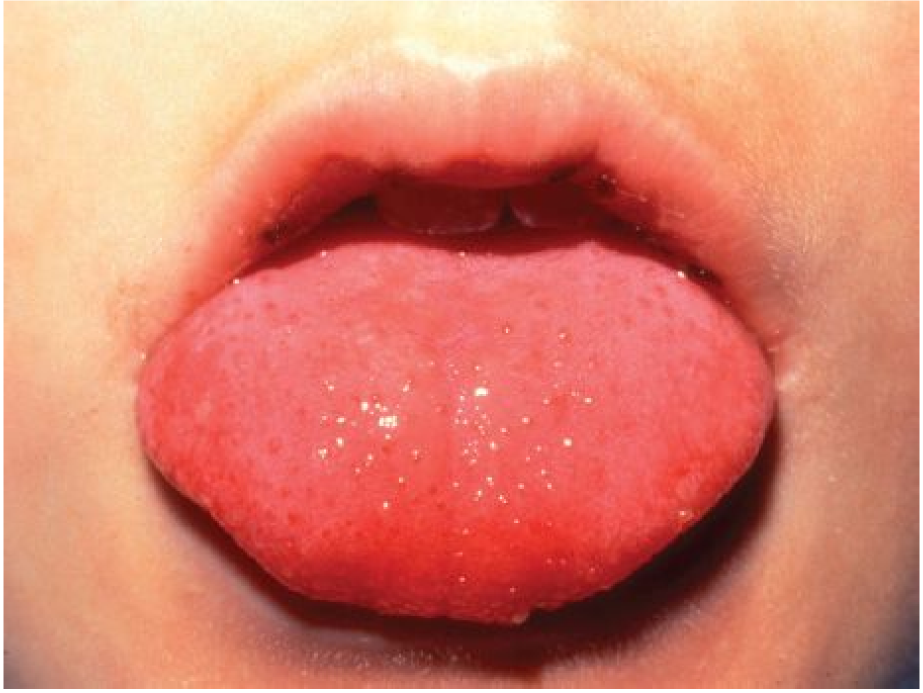

FIGURE 185-4 Strawberry tongue, which is one of the features of toxic shock syndrome. (*Used with permission from Johanna Goldfarb, MD.*)

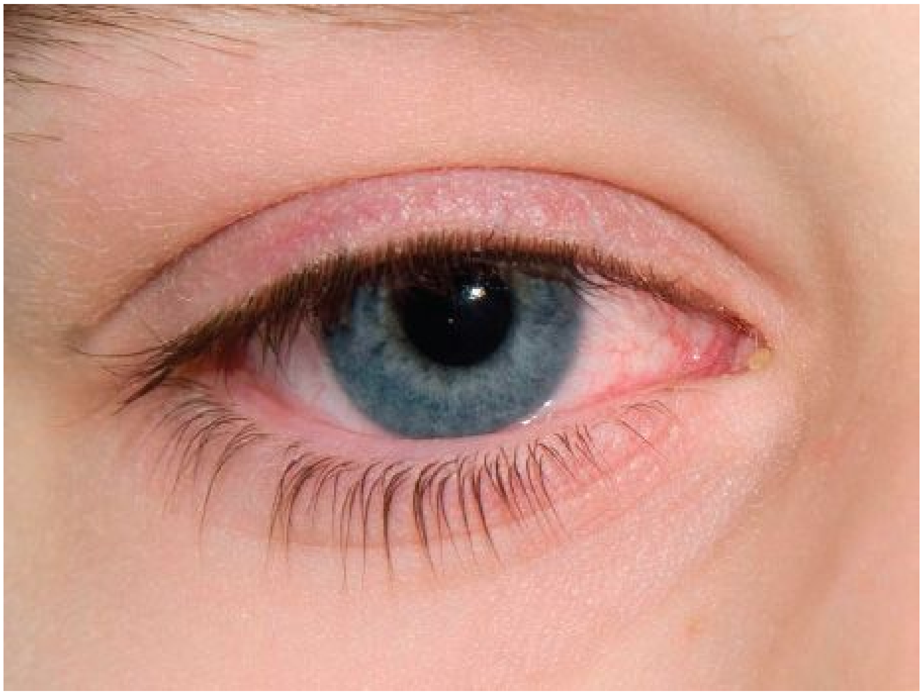

FIGURE 185-5 Conjunctival hyperemia in a child with toxic shock syndrome. (*Used with permission from Camille Sabella, MD.*)

- Altered consciousness is a sign of hypotension.
- Desquamation of the skin occurs 7 to 21 days after the onset of illness; this commonly occurs in a full-thickness, sheet like manner (**Figure 185-6**).

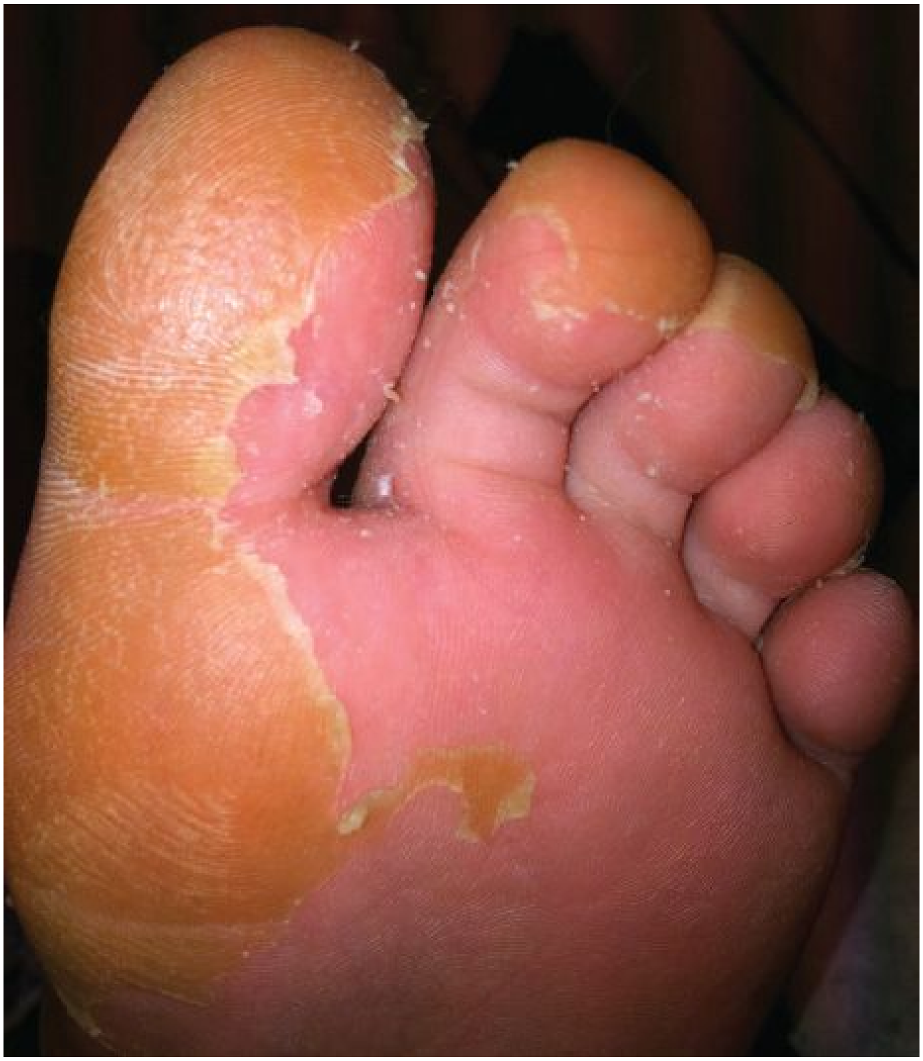

FIGURE 185-6 Sheet-like desquamation, which occurs 7 to 10 days after the onset of toxic shock syndrome. (*Used with permission from Camille Sabella, MD*.)

- The clinical features of GAS toxic shock-like syndrome are similar to that of Staphylococcal toxic shock; however, GAS toxic shock is more often preceded by wound infection, cellulitis or pneumonia (**Figure 185-7**).

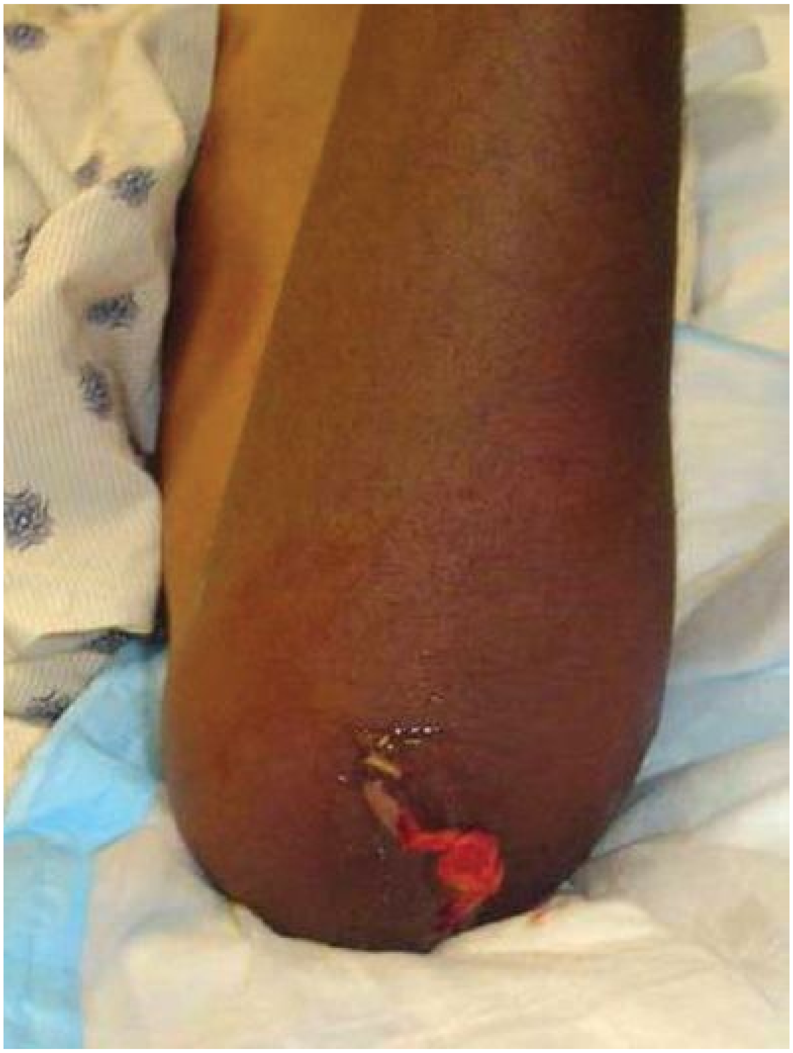

FIGURE 185-7 Wound infection caused by group A streptococcus as a risk factor for streptococcal toxic shock-like syndrome. (*Used with permission from Camille Sabella, MD.*)

DISTRIBUTION

- Rash is more prominent on the trunk than on the extremities, except in the presence of severe hypotension.
- Desquamation of the digits, palms, and soles is most common.

LABORATORY TESTING

- Leukocytosis with a predominance of neutrophils and premature forms are common.
- Hepatic dysfunction is common and usually heralded by mildly elevated serum transaminases and disproportionately elevated conjugated bilirubin levels.
- Renal function is often compromised.
- Consumption coagulopathy may occur.
- Isolation of *S aureus* is not required to make the diagnosis of TSS, but every effort should be made to identify and drain any focus of infection.
- A definitive diagnosis of GAS toxic shock-like syndrome requires meeting the clinical case definition plus isolation of GAS from the blood or other sterile body site (probable case if GAS isolated from nonsterile body site).

DIFFERENTIAL DIAGNOSIS

- TSS should be considered in the differential of fever, rash (erythroderma), and hypotension.
- Kawasaki disease has many similar findings as TSS but the prolonged fever, absence of gastrointestinal symptoms, and lack of hypotension in most cases of Kawasaki disease helps to differentiate these entities.
- Septic shock caused by organisms other than *S. aureus* can usually be differentiated on the basis of positive blood cultures, purpuric rather than an erythrodermal rash, and lack of conjunctivitis and mucositis.
- Other toxin-mediated illnesses such as Staphylococcal scalded skin syndrome and scarlet fever are not usually associated with the toxicity and hypotension of TSS.

MANAGEMENT

NONPHARMACOLOGIC

- Vigorous administration of intravenous fluids to correct the hemodynamic compromise is critical.
- Inotropic support may be necessary depending on the degree of hemodynamic compromise and myocardial dysfunction.
- Drainage of any foci of infection is important in limiting the amount of toxin produced by the organism.
- Any foreign material that may be contributing to the infection, such as a tampon or other vaginal foreign body, should be removed.

MEDICATIONS

- Empiric therapy for TSS is recommended to eradicate the organism and prevent relapses and should include coverage against *S. aureus* and GAS. SOR Ⓒ
- The combination of vancomycin and clindamycin is an appropriate empiric choice to cover *S. aureus*, including MRSA and GAS. SOR Ⓒ
- Clindamycin is useful as an adjunctive agent because of its ability to inhibit toxin production. SOR Ⓒ
- For cases caused by GAS, treatment with a penicillin and clindamycin are often used once the organisms is isolated; clindamycin in these situations is advantageous because of its superior activity against high inoculum, low-replication setting of GAS skin and soft tissue infection, as well as its anti-toxin effects.[13,14]
- Corticosteroids and intravenous immunoglobulin (IVIG) may be considered in severe cases of staphylococcal toxic shock, although data from clinical trials showing clear benefit are lacking.[15,16] SOR Ⓒ
- IVIG may be useful for severe refractory GAS toxic shock.[17,18] SOR Ⓑ

SURGERY

- Drainage of purulent foci of infection and removal of any infected foreign material should be undertaken.
- Early surgical exploration and debridement of infected skin and soft tissues is especially critical in cases of GAS toxic-shock like syndrome that involve severe cellulitis and necrotizing fasciitis.

REFERRAL

- Children who manifest signs of TSS or who are suspected of having TSS should be admitted to the hospital and managed in a pediatric intensive care unit.

PREVENTION AND SCREENING

- The routine use of age-appropriate varicella vaccination for all children decreases the risk of varicella and bacterial superinfection, which is an important risk factor for TSS.
- Women who develop menses-associated TSS should be counseled to not use tampons for several menstrual cycles and to use pads instead of tampons at night.[19]
- Routine screening for *S aureus* carriage in patients who have recovered from TSS is controversial and not routinely recommended.

PROGNOSIS

- Most patients improve with aggressive fluid resuscitation, drainage of any purulent material, and appropriate antimicrobial therapy.[15]
- The case fatality rate for TSS is lower in children than in adults.
- Causes of fatalities in patients with TSS include myocardial dysfunction, refractory shock, and adult respiratory distress syndrome.

FOLLOW-UP

- Recurrence of TSS can occur especially in women who continue to use tampons. Close follow-up of these patients is warranted.

PATIENT EDUCATION

Parents should be advised to seek care for high fever and rash in any child who has a wound or skin infection.

186 PEDIATRIC TUBERCULOSIS

Nazha Abughali, MD
Jessie Maxwell, MD
Frits van der Kuyp, MD

PATIENT STORY

A 17-month-old Hispanic boy presented to the emergency department with a 2-week history of cough, wheezing, fever, and weight loss. The child was born in the US and lives with his dad and uncle, both employed as migrant farm workers. He was admitted to the hospital with the diagnosis of bacterial pneumonia and asthma exacerbation. His initial chest radiograph (CXR) showed right upper and lower lobe infiltrates (**Figure 186-1**). He continued to have high grade fever despite intravenous antibiotics. After further history revealed that his mother recently died of tuberculosis (TB), he was immediately placed in respiratory isolation. A tuberculin skin test (TST) was positive with a 17 mm of induration, and a computed tomography (CT) of the chest showed a large lymph node compressing the trachea and the right main bronchus (**Figure 186-2**). Gastric aspirates for acid fast bacilli (AFB) stain and culture were obtained and he was started on anti-TB medications. The culture was positive for *Mycobacterium tuberculosis*. His father, sister and uncle all had a positive TST and evidence of active pulmonary TB. They were referred expeditiously for evaluation and treatment.

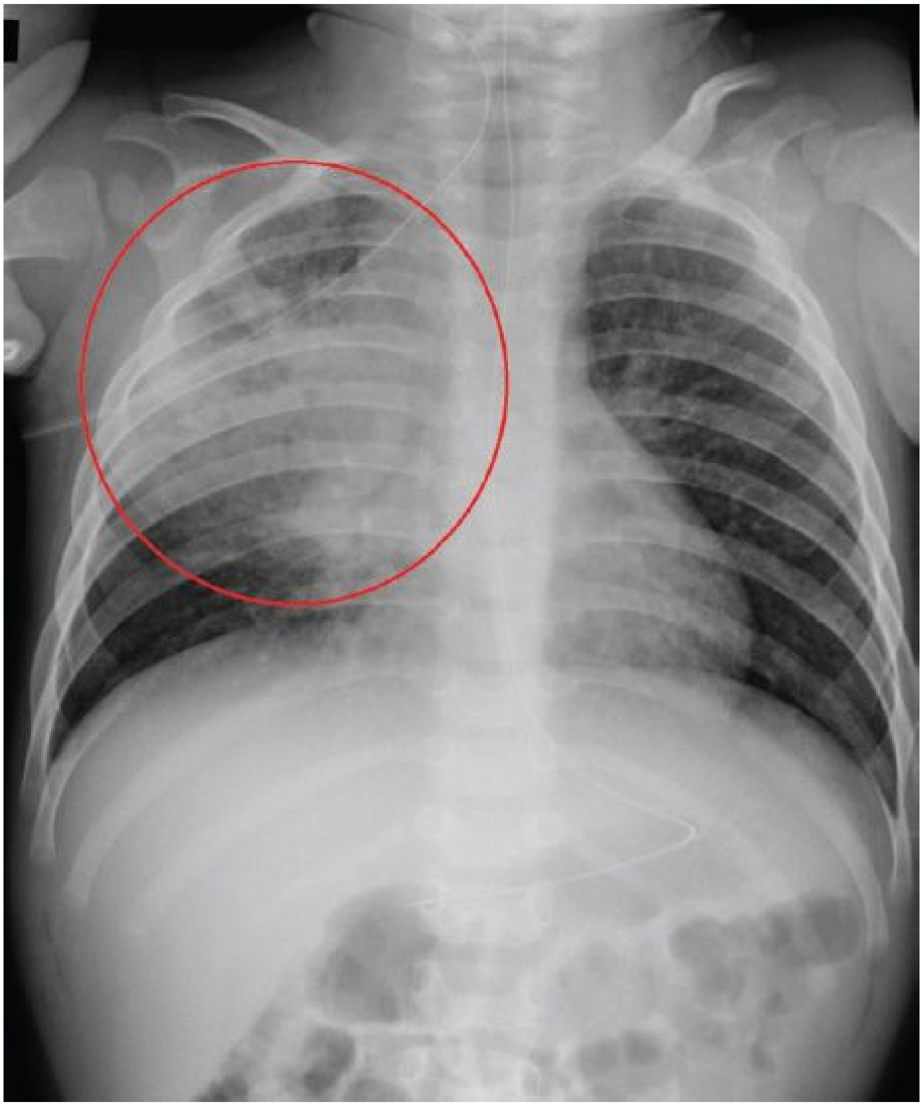

FIGURE 186-1 Right, upper, and middle lobe infiltrates (circled) due to primary pulmonary tuberculosis on chest x-ray of a 17-month-old boy. (*Used with permission from Nazha Abughali, MD*.)

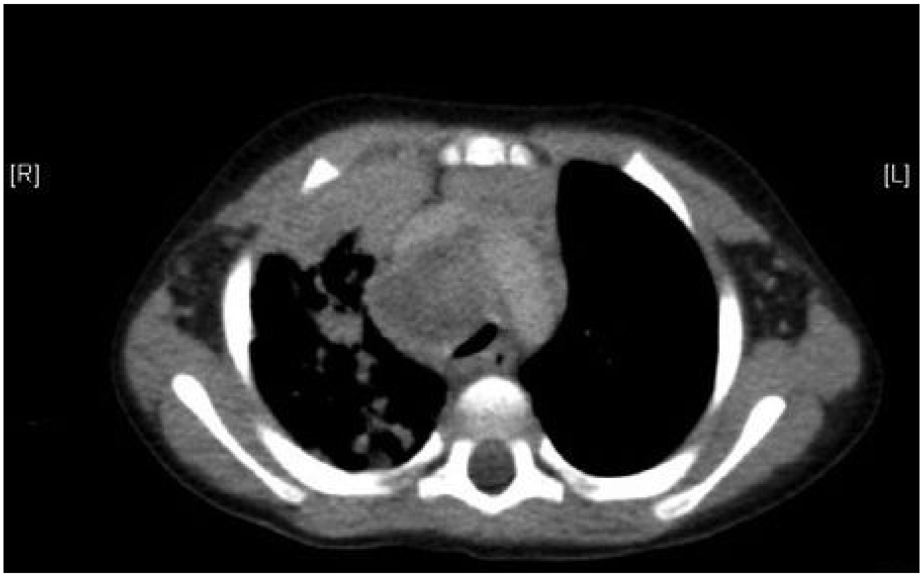

FIGURE 186-2 Compression of the trachea and right main stem bronchus due to an enlarged and necrotic lymph node on chest CT of the boy in Figure 186-1 with primary pulmonary tuberculosis. (*Used with permission from Nazha Abughali, MD*.)

INTRODUCTION

Despite the significant decrease in TB rates in the US and other developed countries, tuberculosis continues to be a major cause of morbidity in developing countries. It is estimated that one third of the world's population is currently infected with TB, with 90 percent occurring in developing countries. Diagnosis of TB in children can be very challenging due to its non-specific clinical presentation and its paucibacillary nature coupled with the decrease in TB expertise among practitioners in developed countries. Without timely diagnosis and prompt institution of appropriate antituberculous therapy, TB in children can be associated with significant morbidity as well as mortality.

SYNONYMS

Tuberculosis: Phthisis, Consumption, Wasting disease, White plague. Scrofula: TB adenitis, usually affecting the cervical lymph nodes. Pott's disease: Tuberculosis of the spine.

EPIDEMIOLOGY

- Worldwide, around 9 million new cases of tuberculosis and approximately 1.5 million deaths are annually reported by the world health organization (WHO), with an estimated 500,000 cases and 64,000 deaths occurring among children <15 years of age.[1]
- In spite of the steady decrease in TB rates in the US among adults and children, tuberculosis continues to occur especially among certain ethnic and racial groups as well as among foreign-born individuals.
- Currently, more than 60 percent of the total TB cases occur among the foreign born persons in the US.[2]
- In children, specific groups with greater TB infection and disease rates include immigrants, international adoptees, and refugees from or travelers to high-prevalence regions.

ETIOLOGY AND PATHOPHYSIOLOGY

- Tuberculosis is caused by aerobic, fastidious, acid fast bacilli belonging to the *M. tuberculosis* complex group, which is composed of multiple species.
- The most important species include *Mycobacterium tuberculosis* (M.tb) that causes the majority of human tuberculosis and *Mycobacterium bovis* that could causes disease in humans by consumption of unpasteurized milk.[3]

TRANSMISSION

- Mainly airborne with inhalation of droplet nuclei containing tubercle bacilli.
- Transmission to a pediatric patient occurs from an adult or adolescent with active TB disease.
- Occurs during coughing, sneezing, and singing.
- Young children are rarely contagious.
- Infection is usually transmitted from a close adult contact.

PATHOPHYSIOLOGY

- Tubercle bacilli are deposited in the alveoli where they multiply forming the initial pulmonary focus or the “Ghon focus.” Infection is spread to the regional lymph nodes (hilar, mediastinal, paratracheal, or subcarinal). The initial pulmonary focus and the draining regional nodes forms what is known as the “primary complex” that is more likely to be seen radiographically in children compared to adults.
- Occult mycobacterial lymphohematogenous spread could occur at this initial phase of infection with possible dissemination throughout the body, including the lymph nodes, kidneys, bones, brain, and the lungs. This provides a nidus for subsequent progressive disease or reactivation disease.
- The incubation period from the initial infection to the development of tuberculin hypersensitivity is around 2 to 10 weeks and can be demonstrated by either a positive tuberculin skin test (TST) or interferon γ release assay (IGRA) blood test.

RISK FACTORS

RISK FACTORS FOR TB INFECTION

- The ultimate risk for TB infection in a child is contact with an adult with untreated or inadequately treated pulmonary TB.
- Epidemiologic risk factors—Foreign birth, history of travel to high TB prevalent areas or history of incarceration. Also, history of exposure to adults with the following risk factors: foreign birth, abuse of intravenous drugs, dwellers of homeless shelters, and migrant farm workers.

RISK FACTORS FOR PROGRESSION FROM TB INFECTION TO DISEASE (TUBERCULOSIS)

- Recent infection—Risk for progression to TB in immunocompetent individuals is 5 to 10 percent during their whole life spans with 50 percent of this risk occurring within the first two years after infection.
- Age—Young infants and adolescents are especially at risk for TB progression. Children <1 year of age with TB infection have 40 percent risk of progression to disease.
- Immunosuppressive conditions—HIV infection, prolonged use of high dose steroids, and use of tumor necrosis factor-alpha (TNF-alpha) antagonists.
- Chronic conditions—Diabetes, renal failure, malnutrition, lymphoma.

DIAGNOSIS

DEFINITIONS

- Tuberculosis Exposure—Patient with history of exposure to suspected contagious TB case, with negative IGRA and negative TST, with no clinical, physical or radiological findings that are consistent with TB.

- Latent TB infection (LTBI)—Patient with a positive IGRA and/or TST, with no clinical, physical or radiological findings that are consistent with TB. These patients are non-contagious. The onset of the hypersensitivity reaction could be associated with erythema nodosum (**Figure 186-3**) or phlyctenular keratoconjunctivitis.

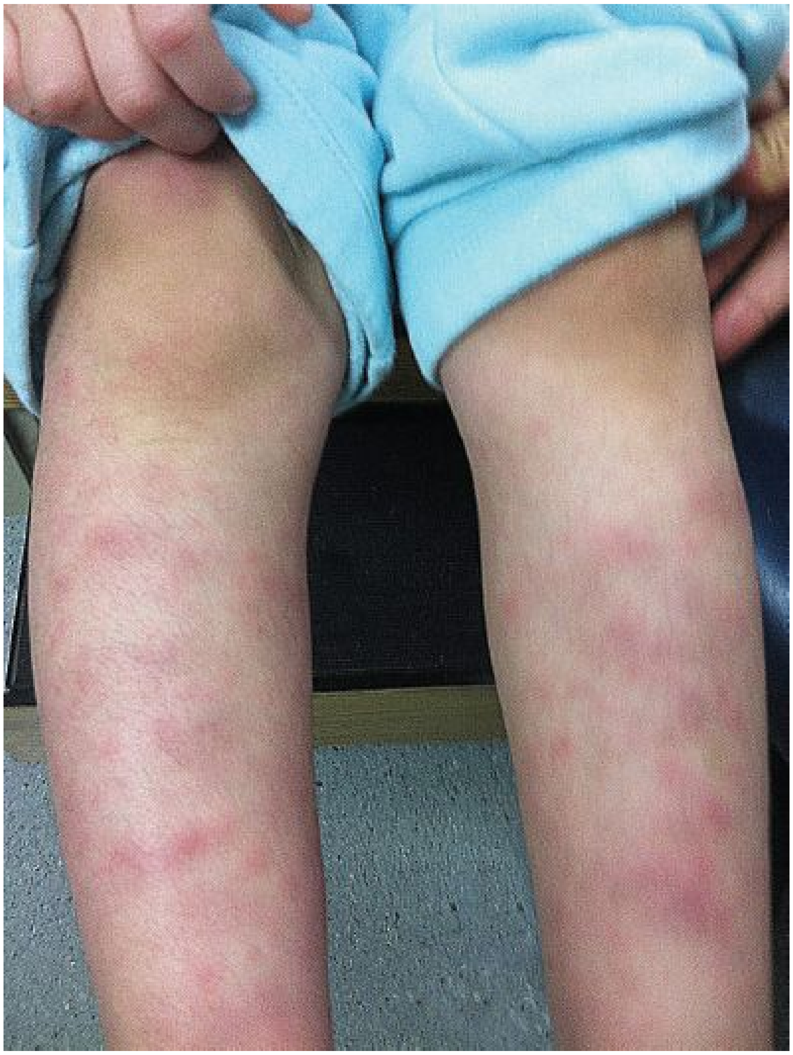

FIGURE 186-3 Erythema nodosum seen in a young patient diagnosed with TB infection. (*Used with permission from Nazha Abughali, MD*.)

- Tuberculosis disease (Tuberculosis)—Patient with a positive TST and/or IGRA with clinical symptoms or signs (physical, radiological, bacteriologic, or histological examination) that are consistent with tuberculosis.

CLINICAL FEATURES

- In general, pulmonary disease predominates in both adults and children.
- TB can develop in any organ system; however, both the frequency and severity of extrapulmonary TB are increased among children. Different manifestations of TB disease tend to occur after different periods of latency in children (**Figure 186-4**).[4]

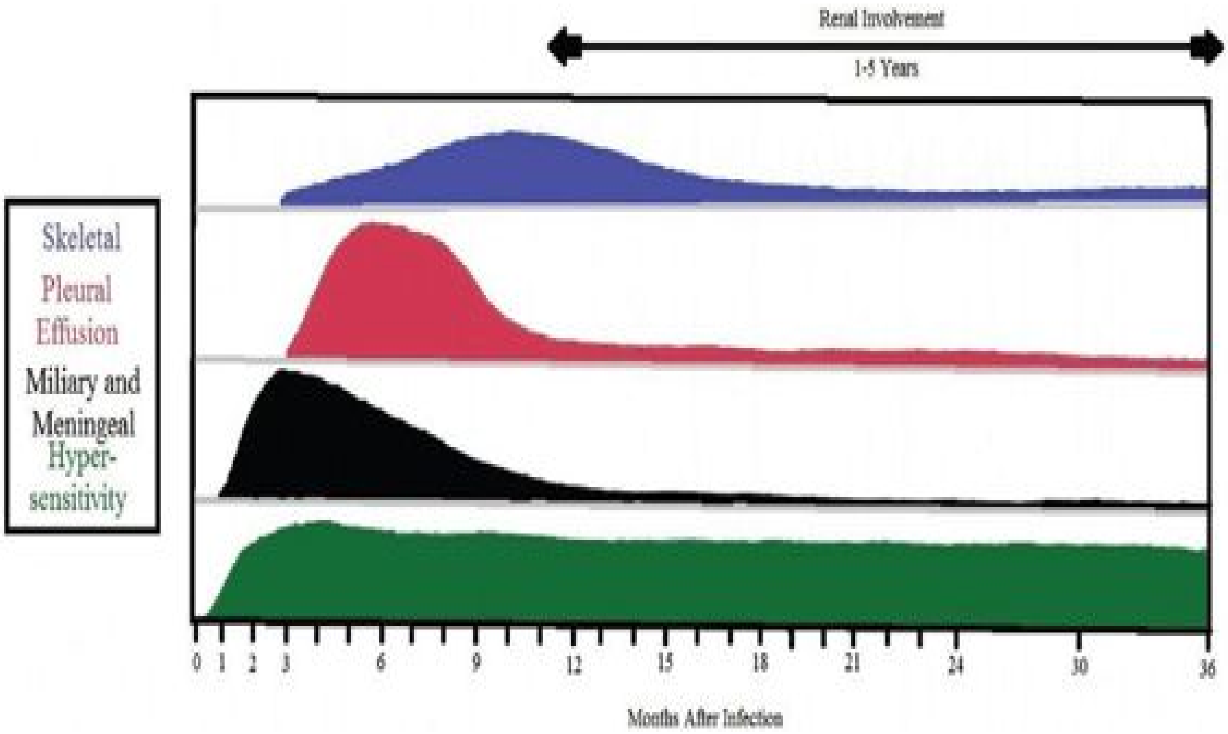

FIGURE 186-4 The clinical manifestations of tuberculosis occur at different times in the disease course in children. Renal involvement is the last manifestation to occur typically. (*Adapted from Marais, BJ, Gie, RP, Schaaf, HS, et al. The natural history of childhood intra-thoracic tuberculosis: A critical review of the pre-chemotherapy literature. Int. J. Tuberc. Lung Dis. 8:392-402, 2004. "Reprinted with permission of the International Union Against Tuberculosis and Lung Disease. Copyright © The Union."*)

- Signs and symptoms of TB in children depend on the organ of involvement.

DISTRIBUTION

▶ Pulmonary disease

Primary tuberculosis

- The most common type of TB in children.
- Children are mostly asymptomatic, but could present with fever, persistent cough, and weight loss.
- Typically diagnosed in an asymptomatic child who has a positive TST/IGRA and an abnormal CXR, which shows intrathoracic lymph node enlargement especially of the hilar or mediastinal nodes (**Figures 186-1**, **186-2**, and **186-5**).

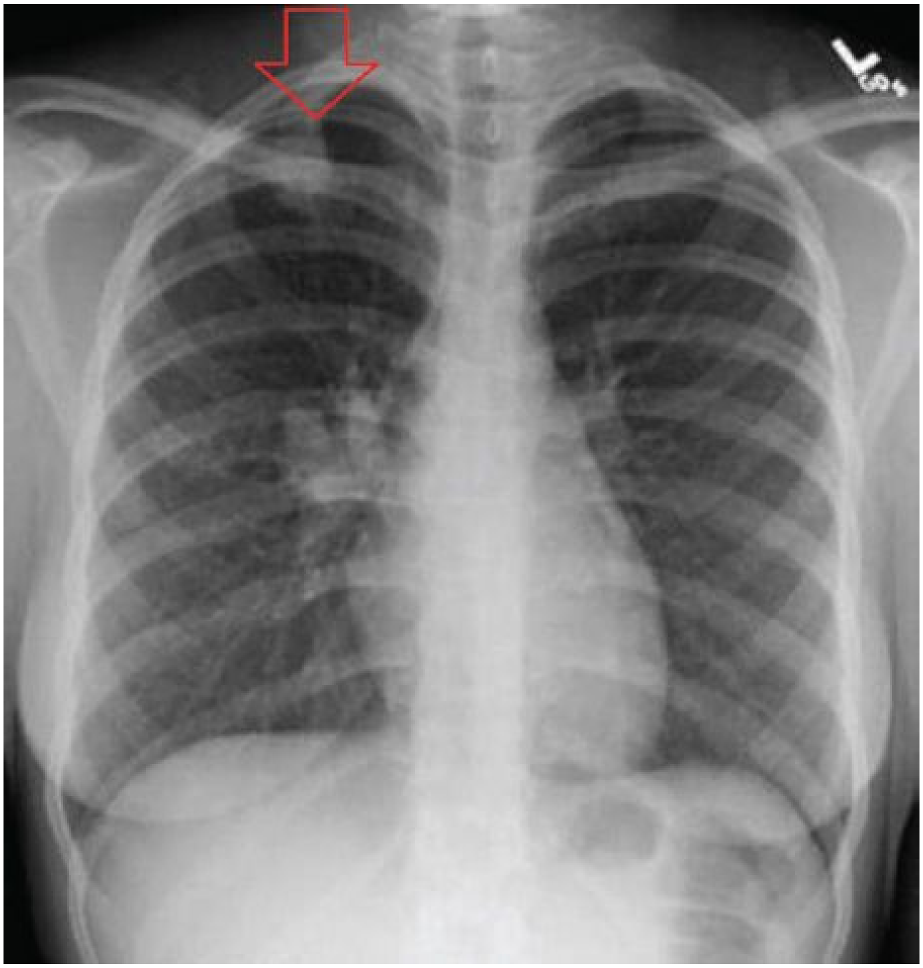

FIGURE 186-5 Right hilar lymphadenopathy with infiltrates in the right middle and upper lobes (arrow) on chest x-ray (CXR) of an 18-year-old female with primary tuberculosis. (*Used with permission from Nazha Abughali, MD.*)

- Bronchial compression and Endobronchial disease—Enlarged nodes may cause compression or obstruction of adjoining airways (**Figure 186-2**). In addition, bronchial obstruction may be caused by severe tuberculous disease secondary to invasion by an infected node into the bronchus (**Figure 186-6**). Children may present with persistent cough, wheezing or recurrent localized bacterial pneumonia.

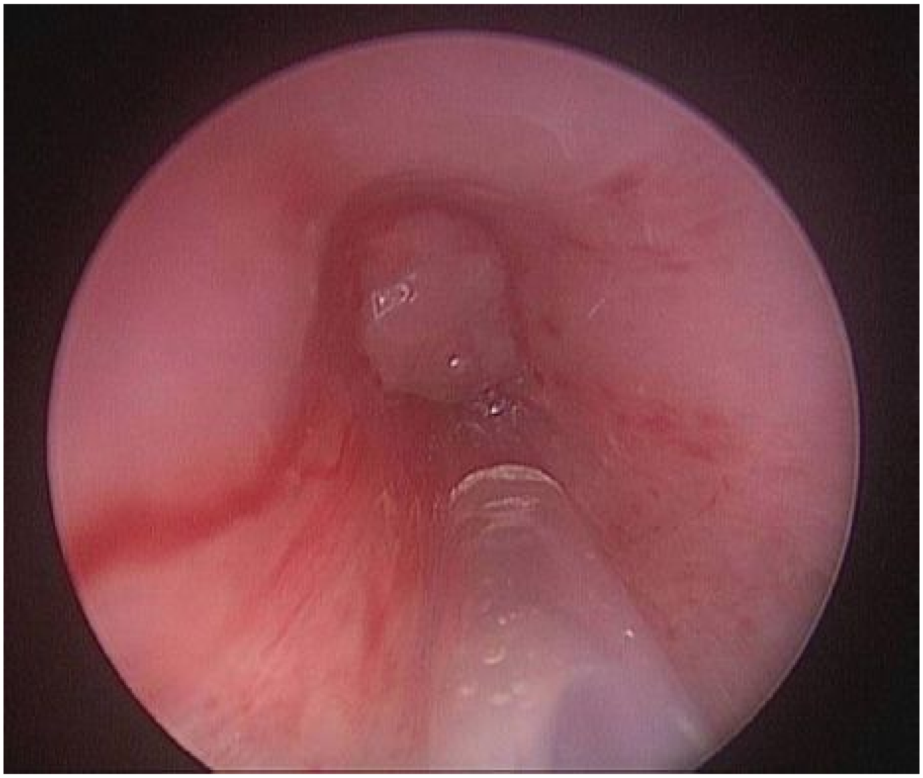

FIGURE 186-6 Bronchial obstruction caused by endobronchial disease. (*Used with permission from Nazha Abughali, MD.*)

- Diagnosis—Mainly clinical and epidemiological based on history of exposure to TB. AFB smear and culture are best obtained from early morning gastric aspirates.

Progressive primary tuberculosis

- The primary parenchymal focus may enlarge and caseate. This may drain into adjacent bronchi, resulting in local cavitation and spread into other areas of the lung (**Figure 186-7**).

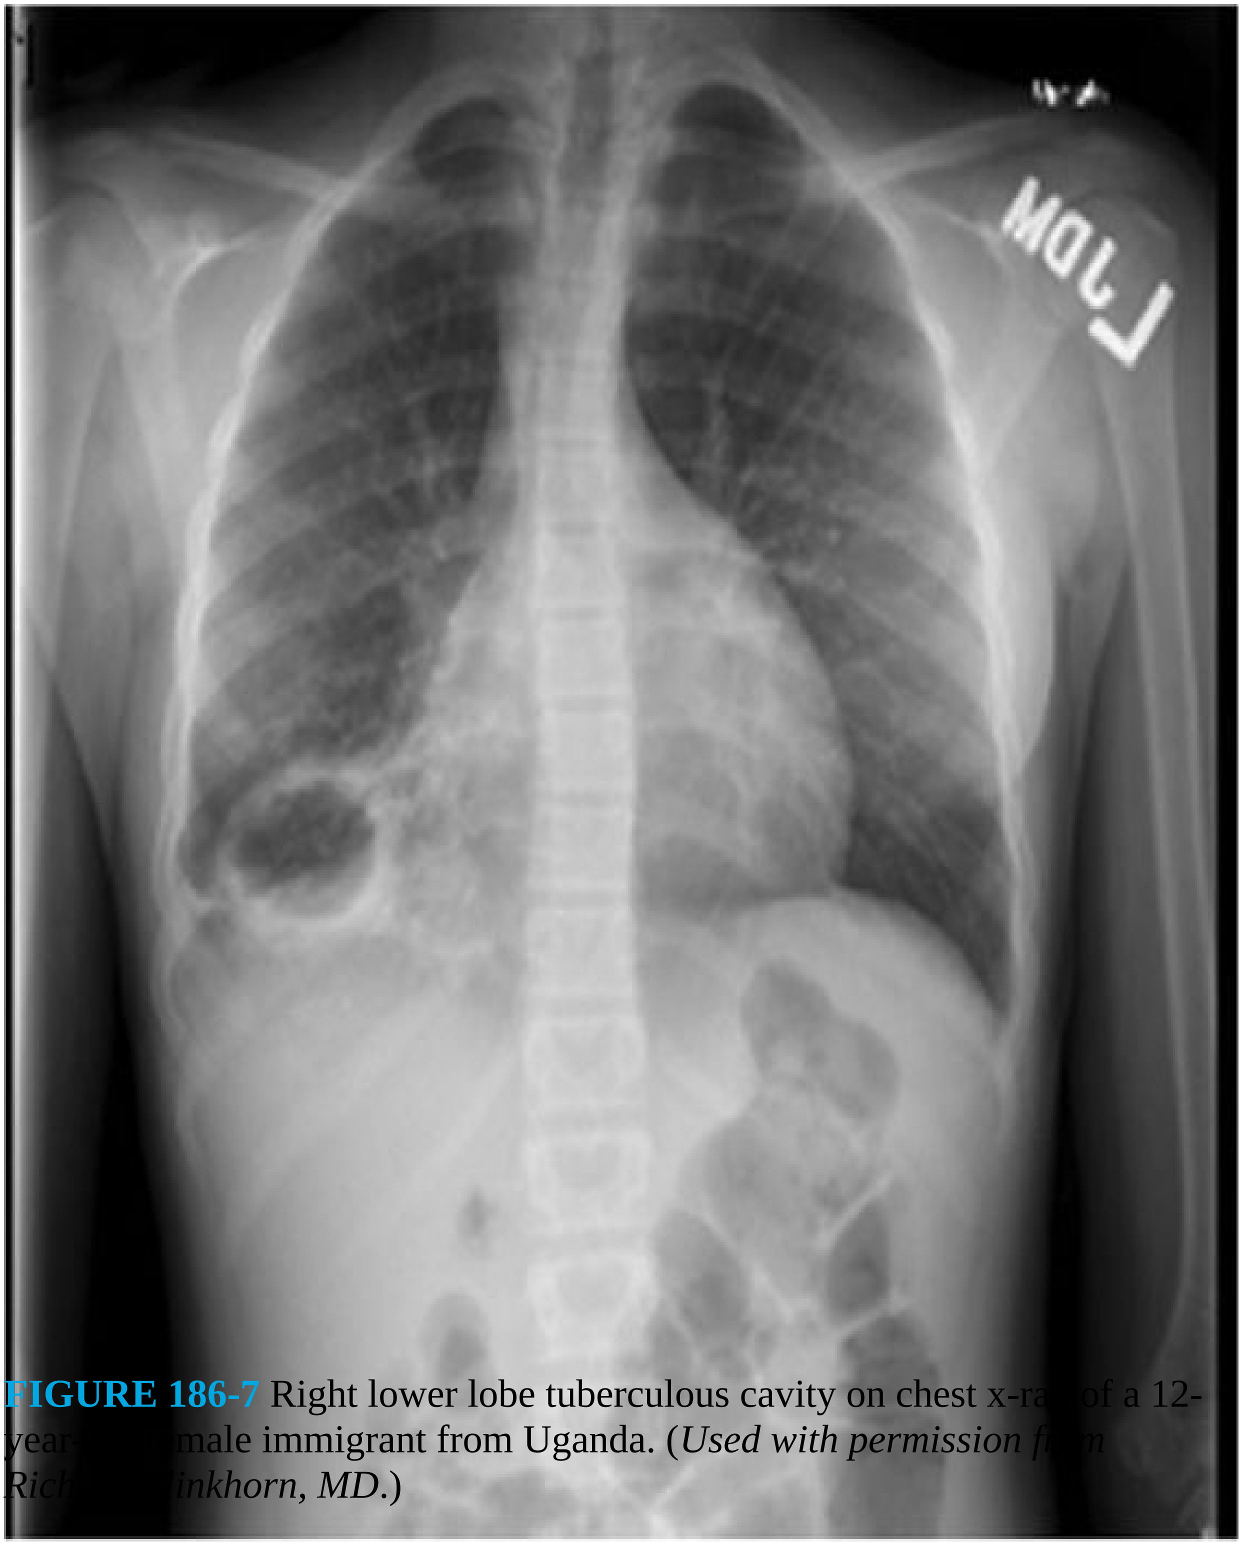

FIGURE 186-7 Right lower lobe tuberculous cavity on chest x-ray of a 12-year-old female immigrant from Uganda. (*Used with permission from Richard Blinkhorn, MD*.)

- Children are quite ill with productive cough, weight loss, fever, and malaise.

- Progressive primary TB develops more frequently in infants and immunosuppressed patients.
- AFB cultures can be obtained from sputum, gastric aspirates, or bronchoalveolar lavage.

Tuberculous pleural effusion

- Pleural effusions are more often seen in older children and appear within 6 to 9 months after the primary infection (**Figure 186-8**).

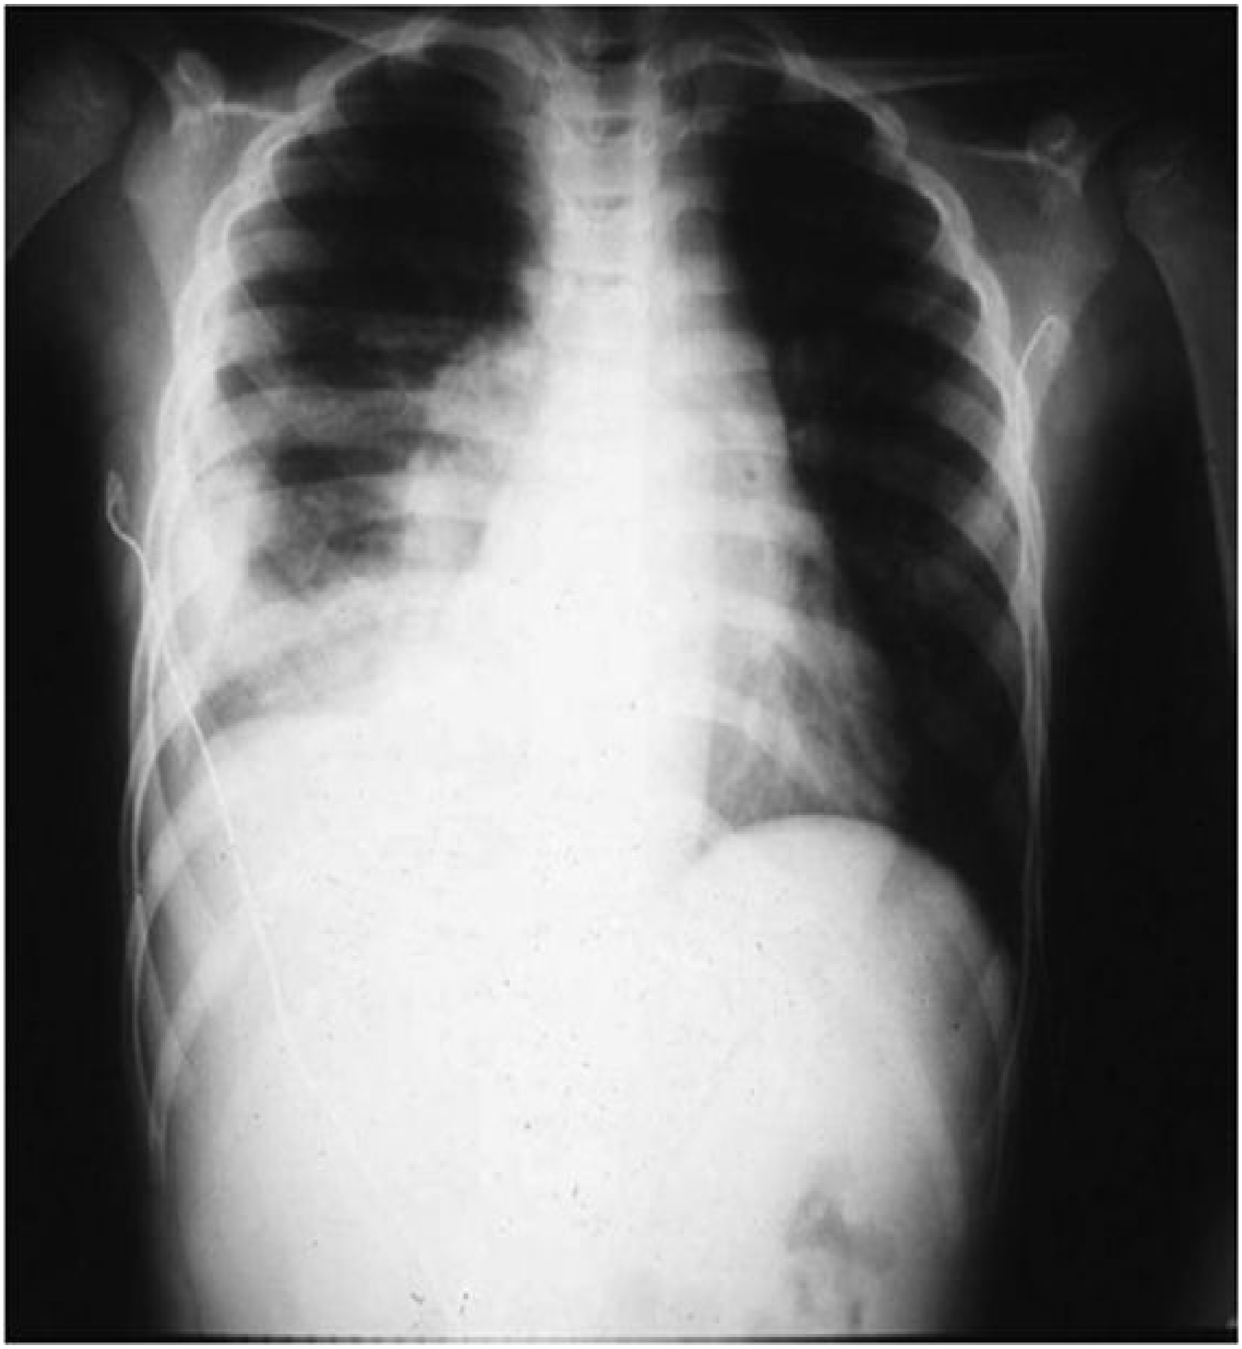

FIGURE 186-8 Right-sided pleural effusion following primary tuberculous infection. (*Used with permission from Nazha Abughali, MD.*)

- Presentation is sudden onset of fever, cough, chest pain, and shortness of breath.
- The majority of pleural effusions are believed to be secondary to hypersensitivity reaction to mycobacterial antigens in the pleural space.

- Pleurocentesis shows pleocytosis with lymphocytic predominance. AFB stain is usually negative. Pleural biopsy may show caseating granulomas with positive AFB culture.

Adult type pulmonary tuberculosis

- Similar to adult type TB disease, representing reactivation of TB in a previously healed focus. Commonly seen in adolescents (**Figures 186-9** and **186-10**).

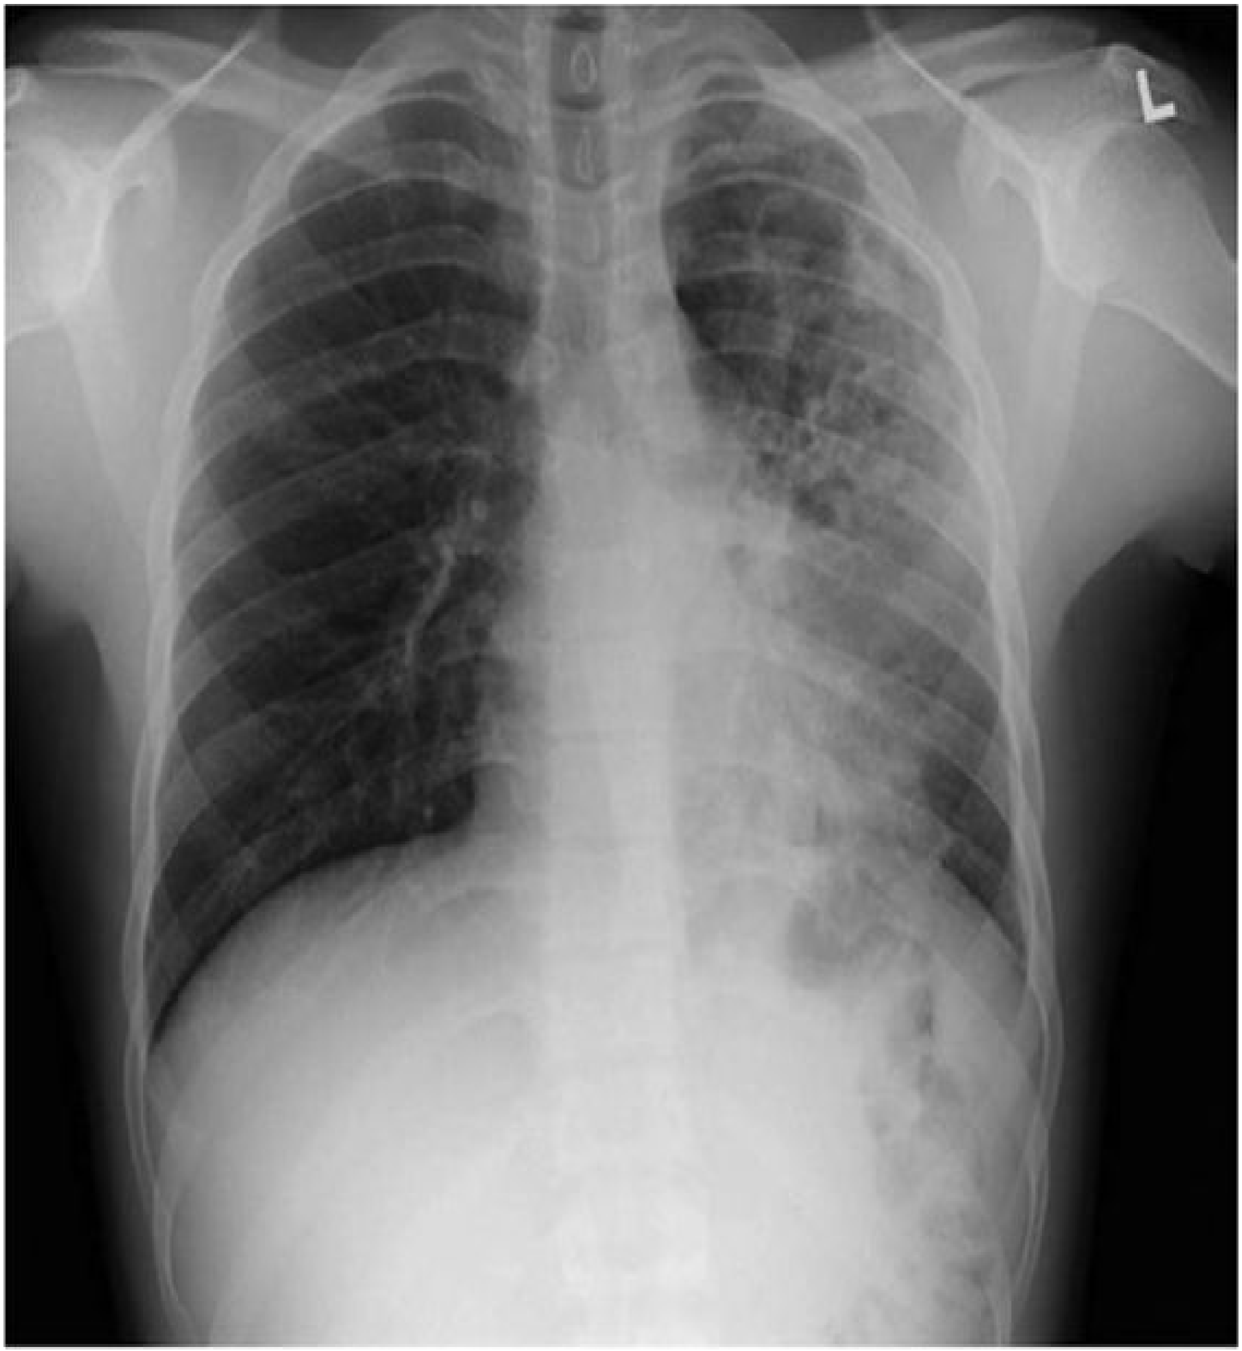

FIGURE 186-9 Significant left upper and left lower lobe infiltrates on chest x-ray of a 16-year-old male with TB pneumonia. (*Used with permission from Nazha Abughali, MD*.)

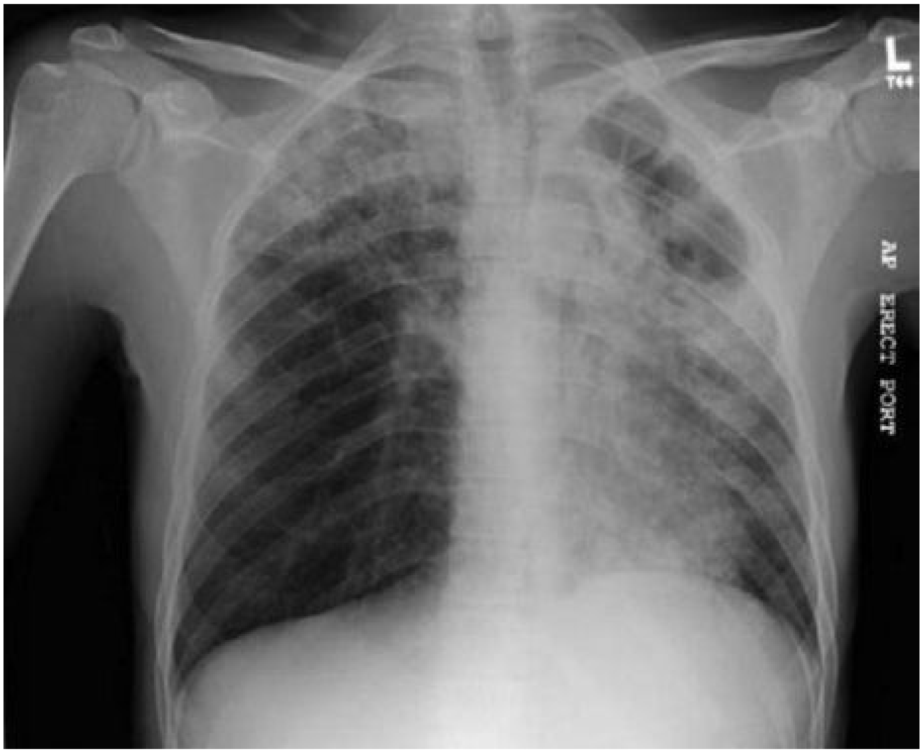

FIGURE 186-10 Nodular infiltrates predominantly in the right upper lobe and entire left lung with cavitary disease in the left upper lobe in a young adult male with tuberculosis. (*Used with permission from Nazha Abughali, MD*.)

- Presents with fever, night sweats, weight loss, cough, malaise, and occasionally hemoptysis.
- CXR shows pulmonary infiltrates with cavitary formation (**Figure 186-7**).
- Patients could be highly contagious and should be placed in respiratory isolation.
- Sputum samples should be obtained for AFB smear, culture, and sensitivity.

▸ Extrapulmonary tuberculosis

Miliary tuberculosis

- A caseous focus may erode into a blood vessel, causing widespread dissemination, usually involving multiple organs.

- More common in infants and young children.
- It occurs early, within 2 to 6 months after the initial infection.
- The patient usually presents with acute onset of high fever, weakness, anorexia, and lethargy. Close to 1/2 of children with miliary TB have evidence of meningitis at the time of diagnosis.
- Physical examination may show evidence of hepatomegaly, splenomegaly, and generalized lymphadenopathy.
- The CXR shows a typical diffuse bilateral miliary pattern throughout the lung fields (**Figure 186-11**).

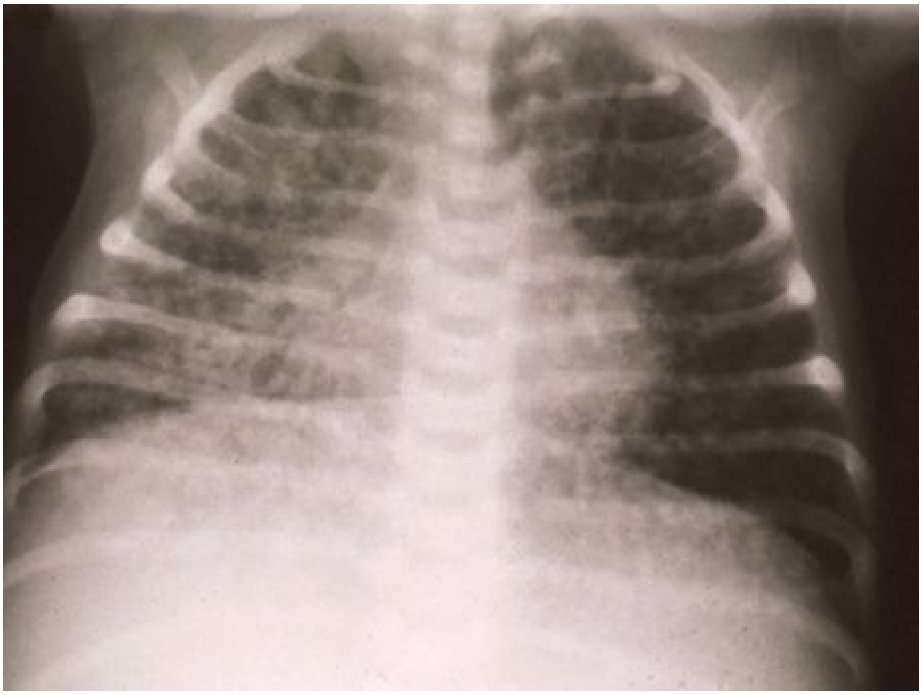

FIGURE 186-11 Miliary tuberculosis in an infant with congenital tuberculousis. (*Used with permission from Nazha Abughali, MD*.)

- AFB stains, cultures, and polymerase chain reaction (PCR) may be obtained from gastric aspirates, tracheal aspirates, and bone marrow and liver biopsies.
- Without prompt recognition and treatment, miliary TB has a very high morbidity mortality rate.

Tuberculous meningitis

- The most severe complication of tuberculous disease.
- It occurs most frequently in children less than 6 years within 3 to 6 months after the primary infection.
- The base of the brain is mostly affected with frequent involvement of the cranial nerves II, VI, and VII.
- There are clinically three stages of the disease:
  - Stage I
    - Typically lasts 1 to 2 weeks.
    - Nonspecific symptoms such as fever, headache, irritability, and drowsiness are common.
  - Stage II
    - Begins abruptly.
    - Lethargy, nuchal rigidity, seizures, vomiting, cranial nerve abnormalities, focal neurologic signs, encephalitis, disorientation, and speech impairment are manifestations.
  - Stage III
    - Symptoms include coma, hemiplegia or paraplegia, hypertension, decerebrate or decorticate posturing, and death.
- Prognosis of tuberculous meningitis correlates with the clinical stage of illness and early initiation of therapy.
- Diagnosis is challenging—Up to 40 percent have negative TST and 50 percent have negative CXR.
- Magnetic resonance imaging (MRI) and CT typically show basilar meningitis, communicating hydrocephalus or cranial nerve involvement (**Figures 186-12** and **186-13**).

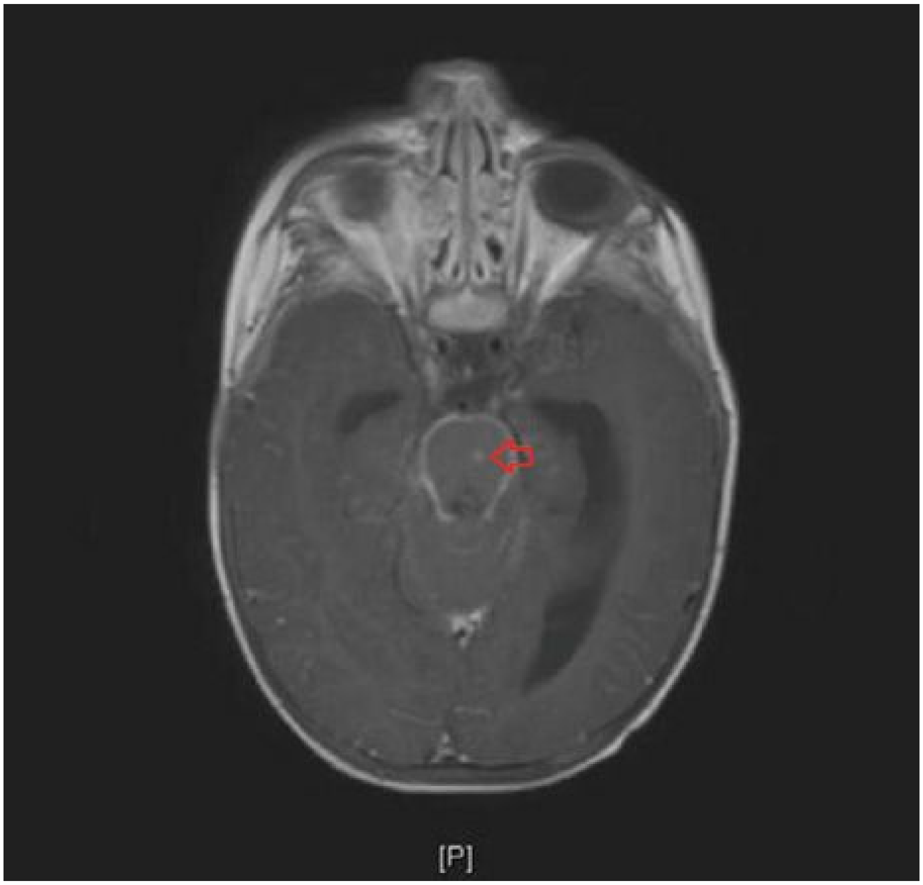

FIGURE 186-12 Tuberuculous meningitis in a 10-month-old girl. Note the leptomeningeal enhancement involving the basal pia-arachnoid and intraparenchymal enhancement (arrow) on MRI. The enlargement of the temporal horn supports the presence of hydrocephalus. (*Used with permission from Nazha Abughali, MD*.)

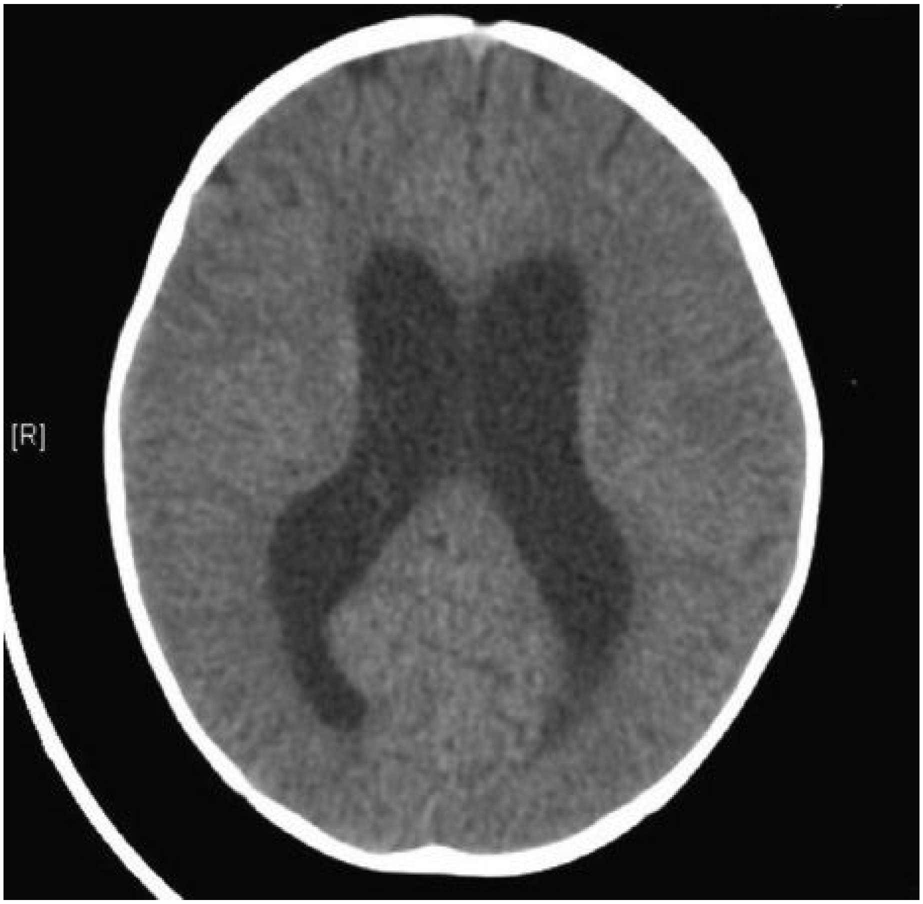

FIGURE 186-13 Communicating hydrocephalus secondary to tuberculous meningitis seen on the head CT of the infant in Figure 186-11. (*Used with permission from Nazha Abughali, MD*.)

- CSF studies typically show elevated protein, low glucose, and leukocytosis with lymphocytic predominance. CSF samples should be sent for AFB stain, cultures, and PCR.
- TB brain tuberculomas occur in 5 percent of children with central nervous system (CNS) TB. They usually appear as a ring-enhancing lesion on MRI or CT (**Figure 186-14**). They are more common in developing countries, accounting for 10 to 20 percent of pediatric brain occupying lesions.

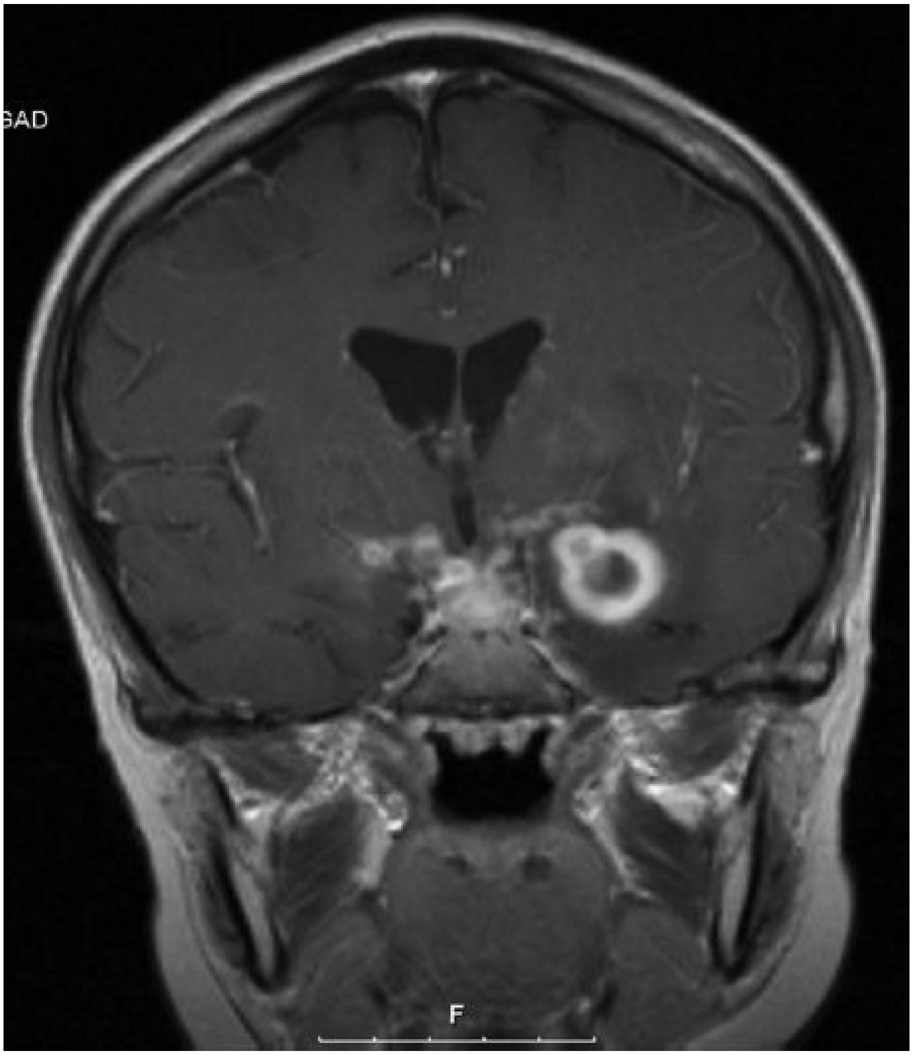

FIGURE 186-14 A tuberculoma shown with an MRI of the brain using gadolinium in an 11-year-old Hispanic child with TB meningitis. The tuberculoma is visualized as a ring enhancing lesion in the left medial and temporal lobe with surrounding edema. Leptomeningeal enhancement is also present. (*Used with permission from Nazha Abughali, MD.*)

Tuberculous lymphadenitis

- TB lymphadenitis involving superficial lymph nodes is the most frequent extrapulmonary manifestation of TB.
- It arises from either a localized extension of a primary lesion or from lymphohematogenous spread of bacilli during the primary infection.

- It occurs mostly in the neck (known as scrofula). Lymph nodes involved in terms of frequency are anterior cervical, posterior cervical, supraclavicular, submandibular, and submental. The nodes are usually firm and nontender, but may later become matted, indurated, and fluctuant (**Figure 186-15**).

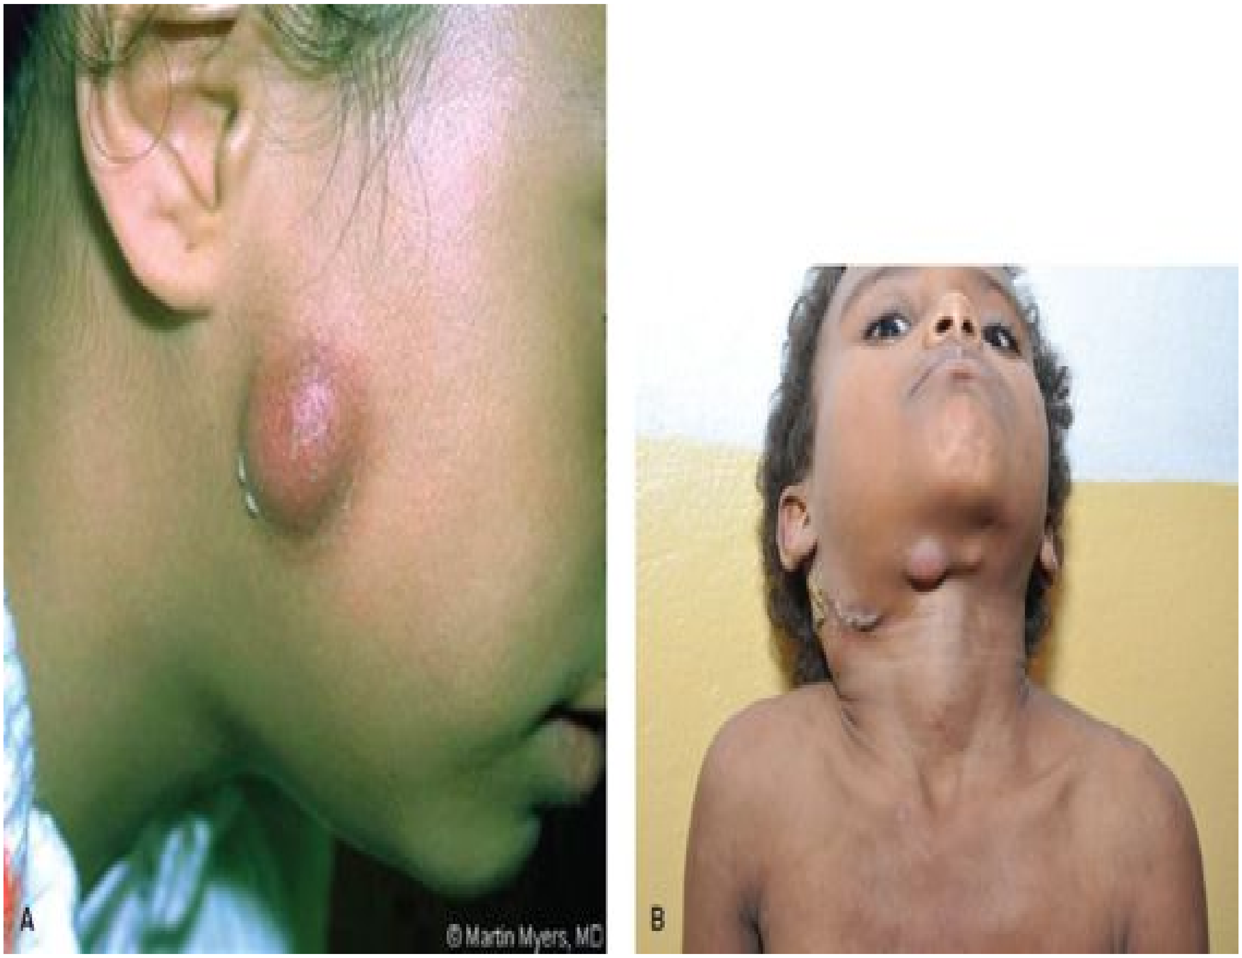

FIGURE 186-15 A. *Mycobacterium tuberculosis* scrofula in a young female. (*Used with permission from Martin G. Myers, MD.*) B. Mycobacterium tuberculosis scrofula in a young boy in Africa. Note the crusting around the areas of drainage in the lateral neck region. (*Used with permission from Richard P. Usatine, MD.*)

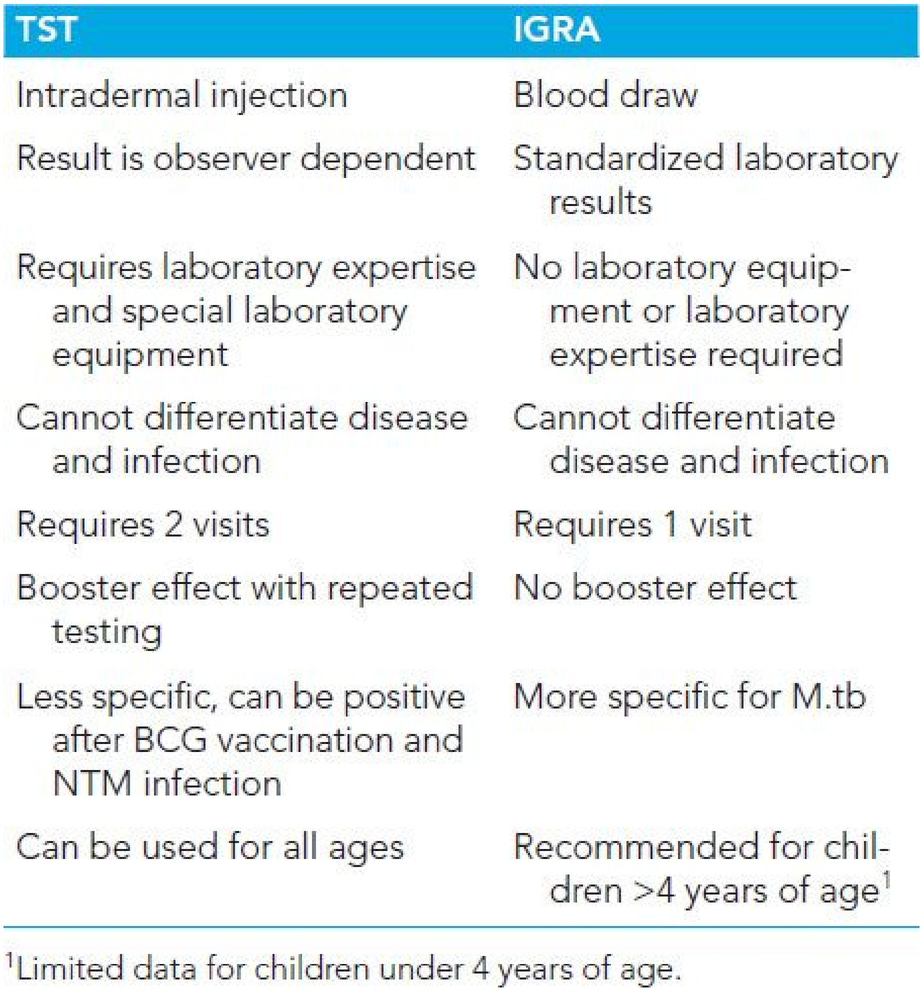
- It is important to differentiate between TB lymphadenitis (caused by M.tb) and adenitis caused by non-tuberculous mycobacteria (NTM or MOTT—Mycobacteria other than TB). The TST may be positive in both forms; positive IGRA favors M.tb (**Table 186-1**).

TABLE 186-1 Comparison of Tuberculin Skin Test (TST) with Interferon γ Release Assay (IGRA) Blood Test



TST	IGRA
Intradermal injection	Blood draw
Result is observer dependent	Standardized laboratory results
Requires laboratory expertise and special laboratory equipment	No laboratory equipment or laboratory expertise required
Cannot differentiate disease and infection	Cannot differentiate disease and infection
Requires 2 visits	Requires 1 visit
Booster effect with repeated testing	No booster effect
Less specific, can be positive after BCG vaccination and NTM infection	More specific for M.tb
Can be used for all ages	Recommended for children >4 years of age[1]

[1] Limited data for children under 4 years of age.

- Biopsy is usually not indicated. If obtained, specimens should be sent for AFB and culture and sensitivity studies.

Skeletal tuberculosis

- Approximately 1/2 of cases of skeletal TB involve the spine. Other areas are the hip, knee, shoulders, and elbow (**Figure 186-16**). Involvement of the smaller bones in the hands and feet (tuberculous dactylitis) may be seen in young children.

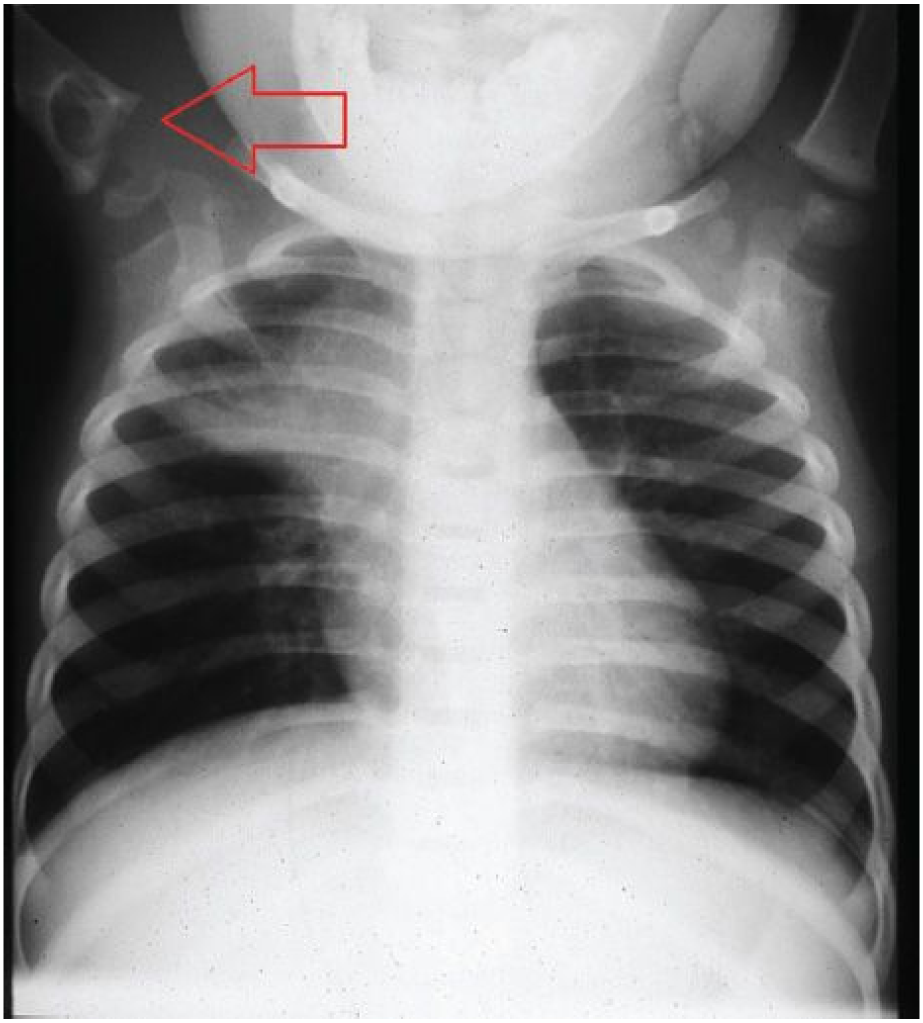


FIGURE 186-16 *Mycobacterium tuberculosis* infection in an 18-monthold with a right upper lobe infiltrate and TB osteomyelitis in the metaphysis of the right humerus (arrow). (*Used with permission from Nazha Abughali, MD*.)

- Pathogenesis is mainly secondary to lymphohematogenous dissemination to the bone or synovium at the time of the initial infection, with reactivation occurring 12 to 18 months after the initial infection in children. The presence of a primary focus on CXR strongly supports the diagnosis.
- The clinical presentation depends on the location and may consist of localized pain, swelling, and warmth of the affected joint.
- TST is usually positive.

- Diagnosis—MRI or x-ray. AFB stains and cultures from synovial aspirate and bone biopsy.

Abdominal tuberculosis

- Uncommon, this occurs secondary to ingestion or lymphohematogenous spread of TB.
- TB enteritis may present with abdominal pain, diarrhea, bloody stools, and weight loss. The ileocecal area is the most commonly involved with the formation of shallow ulcers.
- TB mesenteric lymphadenitis can present as colicky abdominal pain, especially after exercise due to adhesions.
- TB peritonitis could be either plastic or serous type. Plastic peritonitis presents with tender "doughy abdomen." Serous peritonitis might have an insidious presentation with ascites, or could present with fever as bacterial peritonitis.
- Diagnosis—CT of the abdomen could show calcification and nodules in the liver and spleen or mesenteric lymph node enlargement. In TB peritonitis, CT could also show the typical omental caking (**Figure 186-17**). Biopsies of involved organs such as liver, lymph node or omentum and peritoneal fluid could be sent for AFB culture as well as PCR.

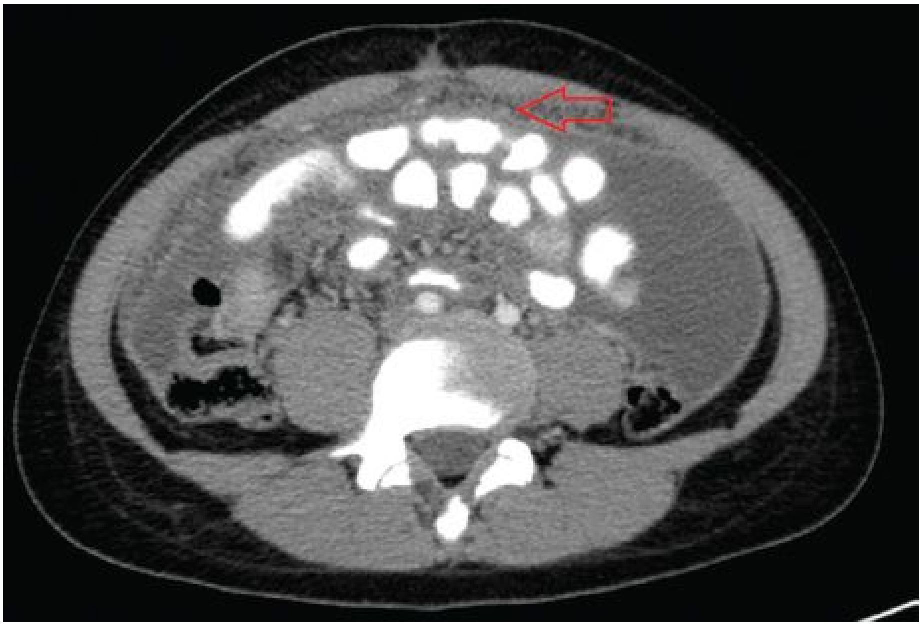

FIGURE 186-17 CT abdomen showing somewhat loculated collection of mesenteric ascites with peripheral enhancement and soft tissue thickening of the omentum. This thickening is known as “caking” (arrow). (*Used with permission from Nazha Abughali, MD.*

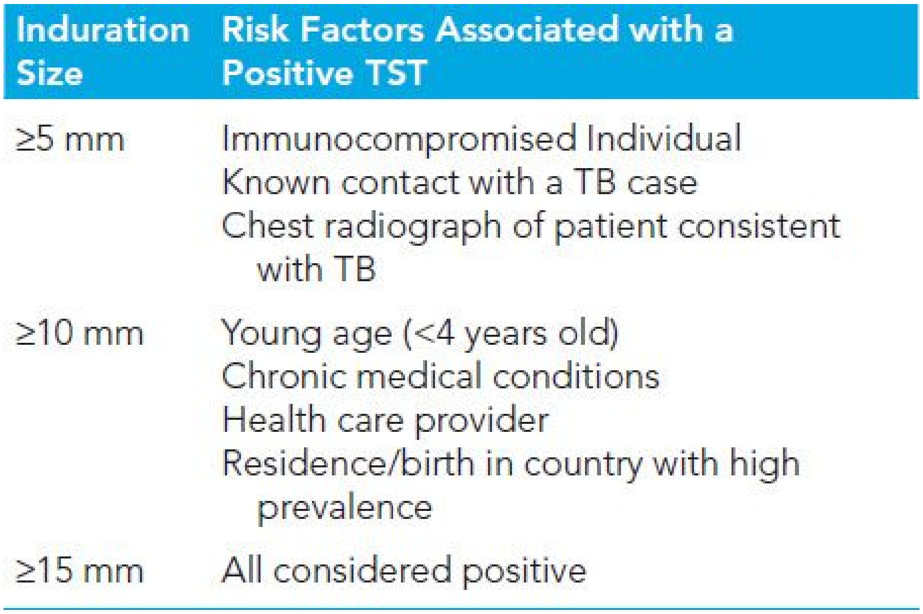
LABORATORY TESTING

Currently there are two tests available for the diagnosis of TB infection: TST and IGRA.[5]

- TST is the most common method for diagnosing LTBI. Purified protein derivative (PPD) of tuberculin is injected intradermally into the forearm; the induration is then measured to determine the presence of TB infection (**Table 186-2**).

TABLE 186-2 Risk Factors Associated with a Positive Tuberculin Skin Test (TST)

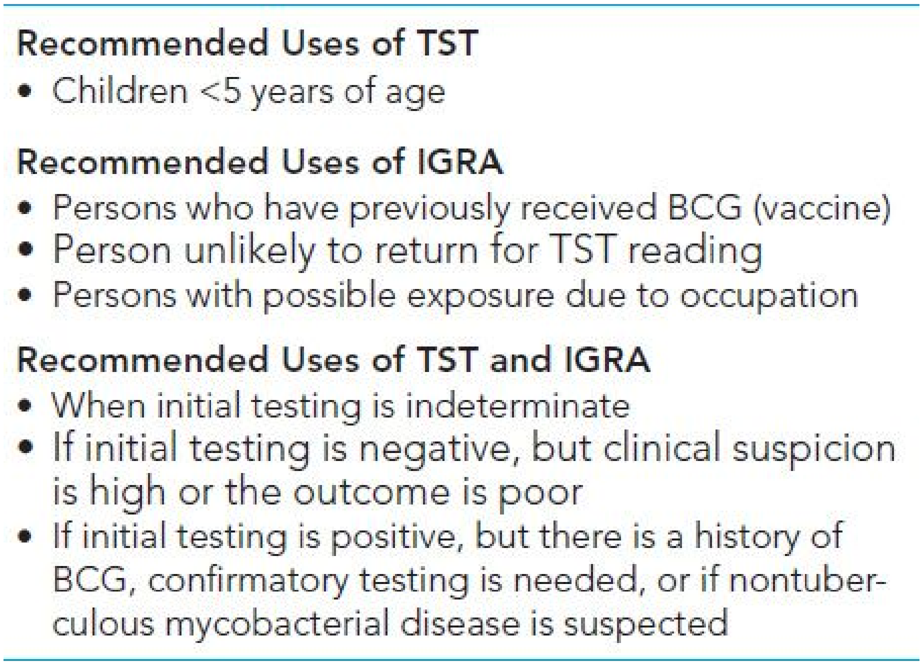


Induration Size	Risk Factors Associated with a Positive TST
≥5 mm	Immunocompromised Individual Known contact with a TB case Chest radiograph of patient consistent with TB
≥10 mm	Young age (<4 years old) Chronic medical conditions Health care provider Residence/birth in country with high prevalence
≥15 mm	All considered positive

- Interferon Gamma Release Assays (IGRA) were recently developed and approved for the diagnosis of TB infection. Two tests are currently licensed in the US. The first is the QuantiFERON-TB (Cellestix, Carnegie, Australia) that measures whole-blood interferon γ production. The second test is the enzyme-linked immunospot (ELISPOT, T-SPOT.TB, Oxford

Immunotec, Oxford, UK), which measures the number of lymphocytes that produce interferon γ (**Tables 186-1** and **186-3**). Both employ incubation of blood lymphocytes with M.tb specific antigens.

TABLE 186-3 Recommended Uses of Tuberculin Skin Test (TST) and Interferon γ Release Assay (IGRA) Blood Test



Recommended Uses of TST

- Children <5 years of age

Recommended Uses of IGRA

- Persons who have previously received BCG (vaccine)
- Person unlikely to return for TST reading
- Persons with possible exposure due to occupation

Recommended Uses of TST and IGRA

- When initial testing is indeterminate
- If initial testing is negative, but clinical suspicion is high or the outcome is poor
- If initial testing is positive, but there is a history of BCG, confirmatory testing is needed, or if nontuberculous mycobacterial disease is suspected

LABORATORY DIAGNOSIS OF TB DISEASE

- The most commonly used AFB stains are the Ziehl-Neelsen and the Fluorochrome stains. The AFB smear cannot differentiate M. tuberculosis from mycobacteria other than TB (MOTT).
- Specimens for AFB stain and culture can be obtained from gastric aspirates, sputum, bronchial washings, pleural fluid, CSF, urine, or tissue biopsies. Early morning gastric lavage in young children and induced sputum in older children have the highest yield. Drug susceptibility testing should be performed on all positive cultures.
- *M. tuberculosis* is a very slow growing organism. Cultures may take 3 to 6 weeks to grow on solid media, with drug susceptibility testing requiring an additional 4 weeks (**Figure 186-18**). Use of solid media allows examination of colony morphology and quantification of growth. Growth

can be detected in 1 to 3 weeks by utilizing a liquid media; drug susceptibilities results in an additional 3 to 5 days.

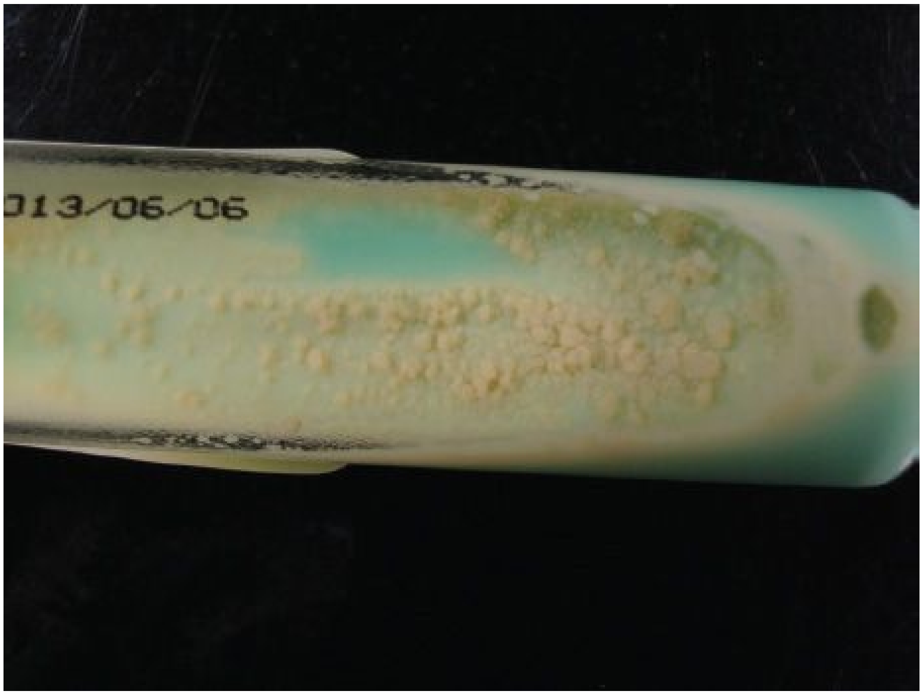


FIGURE 186-18 Tan crumb-like colonies of *M. tuberculosis* on Lowenstein-Jense agar. (*Used with permission from Joseph Tomashefksi, MD*.)

- The presence of *M. tuberculosis* in clinical specimens sometimes can be detected directly within hours using nucleic acid amplification (NAA) tests (including PCR); studies in children are limited.
- Mycobacterial TB cultures are positive in less than 50 percent of children with clinical diagnosis of pulmonary TB.
- Histological examination of all specimens from lymph nodes, liver, pleura, and peritoneal mesentery with demonstration of AFB and granulomas can be very supportive of TB diagnosis (**Figures 186-19** and **186-20**).

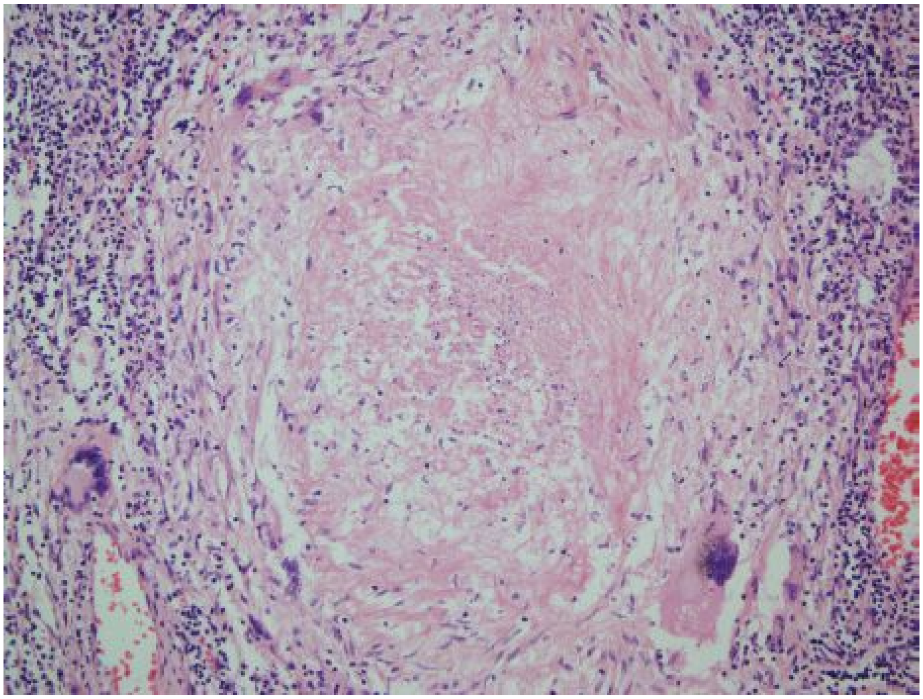

FIGURE 186-19 A caseating granuloma with central caseous necrosis, peripheral epithelioid cells, Langhans giant cells, and a lymphocyte cuff. (*Used with permission from Joseph Tomashefski, MD*.)

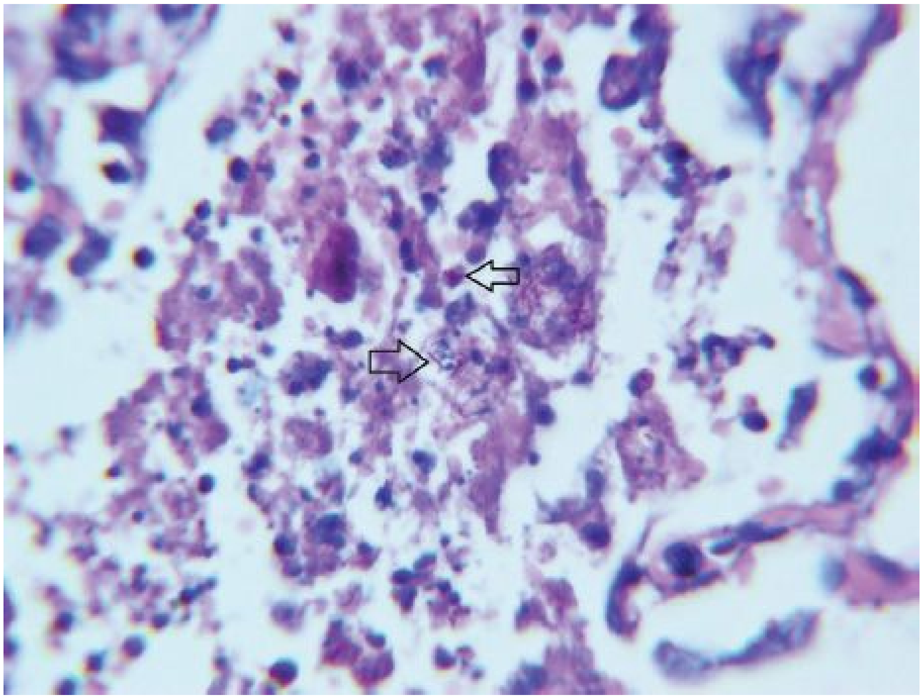

FIGURE 186-20 Acid fast bacilli (arrows) associated with caseous necrosis shown on Ziehl-Neelsen staining. (*Used with permission from Joseph*

Tomashefski, MD.)

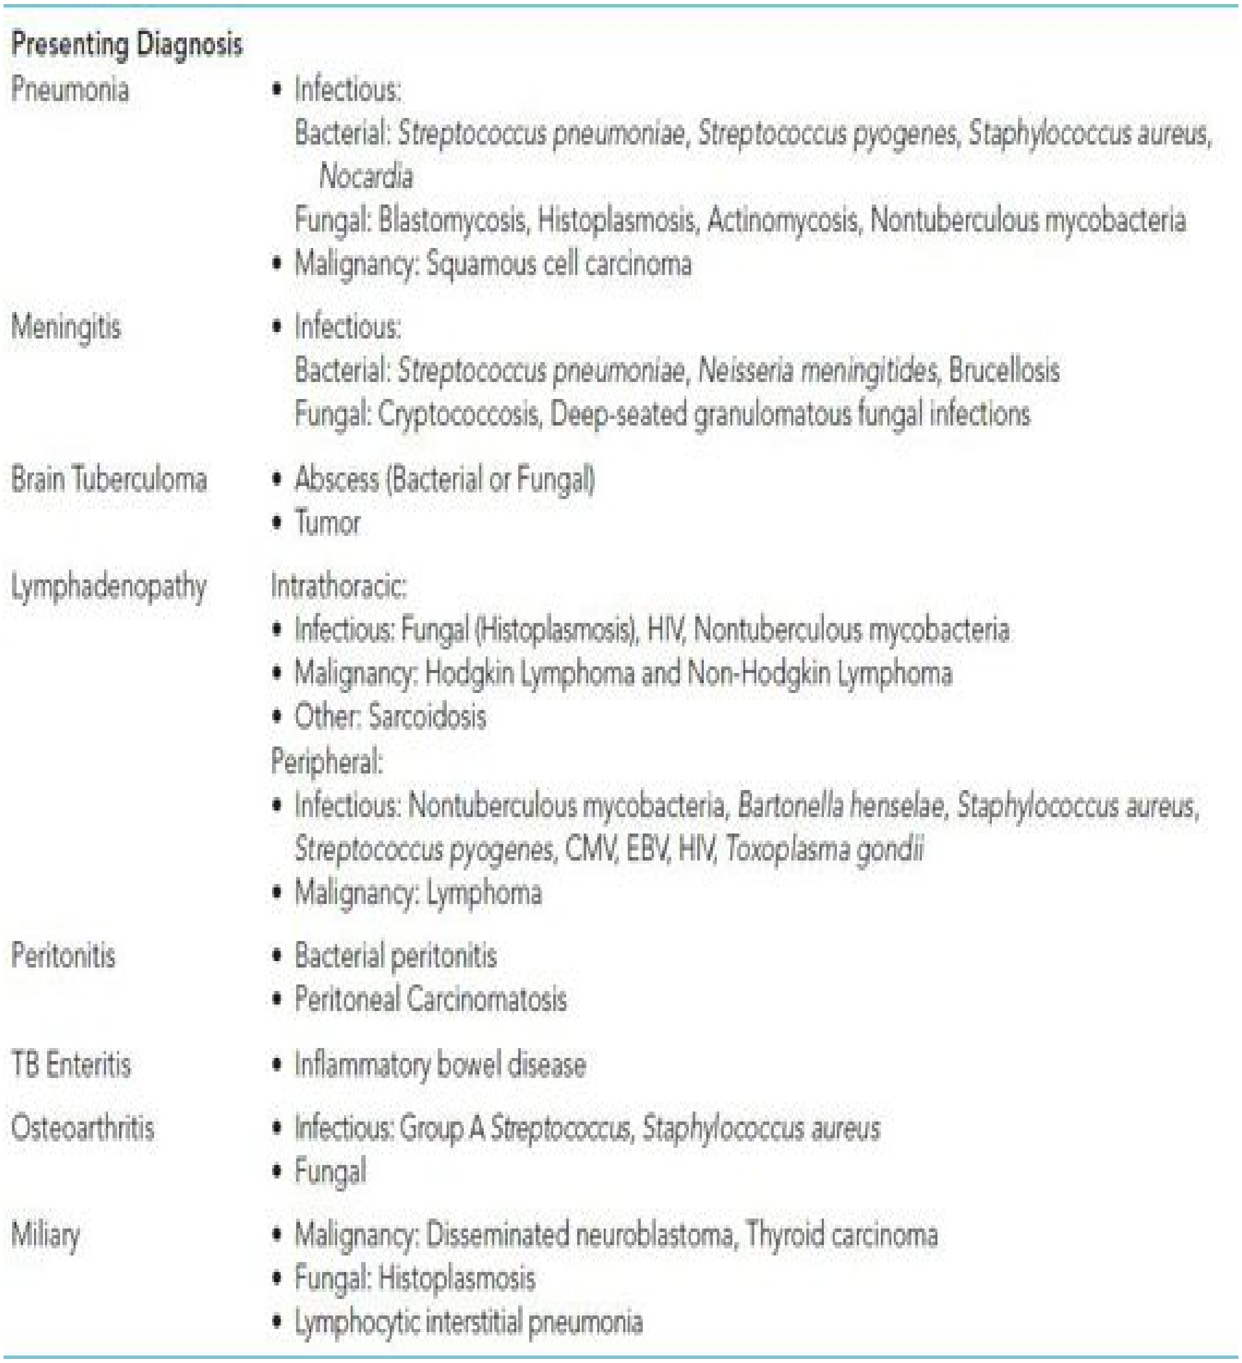
IMAGING

- CXR is recommended for all patients with a positive TST and/or IGRA.
- Depending on the extent of infection, patients may need skeletal radiograph, MRI, CT of the chest, and/or CT of the head as well as other specialized radiographic studies.

DIFFERENTIAL DIAGNOSIS

The presenting differential diagnosis of TB is elucidated in **Table 186-4**.

TABLE 186-4 Presenting Differential Diagnosis of TB



Presenting Diagnosis	
Pneumonia	• Infectious: Bacterial: *Streptococcus pneumoniae, Streptococcus pyogenes, Staphylococcus aureus, Nocardia* Fungal: Blastomycosis, Histoplasmosis, Actinomycosis, Nontuberculous mycobacteria • Malignancy: Squamous cell carcinoma
Meningitis	• Infectious: Bacterial: *Streptococcus pneumoniae, Neisseria meningitides*, Brucellosis Fungal: Cryptococcosis, Deep-seated granulomatous fungal infections
Brain Tuberculoma	• Abscess (Bacterial or Fungal) • Tumor
Lymphadenopathy	Intrathoracic: • Infectious: Fungal (Histoplasmosis), HIV, Nontuberculous mycobacteria • Malignancy: Hodgkin Lymphoma and Non-Hodgkin Lymphoma • Other: Sarcoidosis Peripheral: • Infectious: Nontuberculous mycobacteria, *Bartonella henselae, Staphylococcus aureus, Streptococcus pyogenes*, CMV, EBV, HIV, *Toxoplasma gondii* • Malignancy: Lymphoma
Peritonitis	• Bacterial peritonitis • Peritoneal Carcinomatosis
TB Enteritis	• Inflammatory bowel disease
Osteoarthritis	• Infectious: Group A *Streptococcus, Staphylococcus aureus* • Fungal
Miliary	• Malignancy: Disseminated neuroblastoma, Thyroid carcinoma • Fungal: Histoplasmosis • Lymphocytic interstitial pneumonia

MANAGEMENT[6–9]

- Young children with TB are usually not contagious and do not require respiratory isolation when hospitalized. However, pulmonary TB needs to be ruled out in the caregivers before they are allowed on the pediatric ward.

- Older children and adolescents require respiratory isolation when they have a cough.
- Whenever possible, AFB cultures and susceptibilities should be obtained in every child with suspected TB especially in the presence of:
    - Extrapulmonary TB.
    - Possible exposure to a source case with multiple drug resistant TB (MDR-TB).
    - HIV infection.
    - Child is suspected to have MDR-TB based on a history of travel or birth in areas with high TB prevalence.
- It is important to be aware of the TB resistance pattern in different areas of the world, especially in foreign-born children. All TB cases should be reported to the local TB program, and contact investigation of all family members and close contacts should be performed.
- Ideally all children with TB should have directly observed therapy to ensure compliance with treatment.

PHARMACOLOGIC

- The choice of the initial TB regimen in a child usually depends on:
    - The type of TB disease.
    - Susceptibility pattern in the child and/or the source case (if available).
    - The countries TB resistance pattern.
- See **Table 186-5** for a summary of treatment recommendations.

TABLE 186-5 Treatment Recommendations for Tuberculosis

	Primary Treatment	Recommendations for Drug Resistance
TB Exposure	• Child <4 years of age and those with HIV infection should receive isoniazid or rifampin therapy until second testing.	• Consult specialist for any additional resistance[1]
Latent Tuberculosis Infection	• Isoniazid once daily for 9 months	• Rifampin for 6 months • Consult specialist for any additional resistance[1]
Pulmonary and Extrapulmonary Disease Excluding Meningitis	• Isoniazid, rifampin, pyrazinamide, ethambutol for 2 months followed by isoniazid and rifampin for 4 months[2]	• If hilar adenopathy only is present, treat with 6 months of isoniazid and rifampin • Consult specialist for any additional resistance[1]
Meningitis	• Isoniazid, Rifampin, pyrazinamide, and an aminoglycoside or ethambutol or ethionamide for 2 months followed by 7 to 10 months of isoniazid and rifampin	• If resistance to streptomycin is present, use kanamycin, amikacin, or capreomycin • Consult specialist for any additional resistance[1]

[1] Duration of therapy is longer for HIV infected patients, and additional drugs may be indicated.
[2] In the initial CXR shows cavitary lesions, and sputum remains positive after 2 months of therapy, the duration of therapy is extended to 9 months.

- Corticosteroids are indicated as an adjunct therapy in tuberculosis meningitis and may be considered in endobronchial disease, or pleural/pericardial effusions and abdominal TB. SOR Ⓒ
- Vitamin B6 is recommended for breastfed infants, and HIV infected and/or malnourished children. SOR Ⓒ

SURGERY

- Surgical intervention includes obtaining a biopsy or aspiration sample when needed for diagnosis.
- Some patients will develop hydrocephalus and require a cerebral shunt to be placed.

REFERRAL

- Patients should be referred to the local tuberculosis program and/or infectious disease specialist.
- Ophthalmology referrals may be required for infants on ethambutol to rule out optic neuritis.
- Patients that require surgical intervention will need referred to the appropriate surgical specialist.

PREVENTION AND SCREENING

- TB prevention and control is a collaborative responsibility between health care workers and public health officials. Health care workers are required to report all suspected TB cases to their local TB program. In turn, it is the responsibility of the TB program to:
- Complete contact investigation of all TB exposed individuals.
- Prescribe TB preventive therapy to all exposed children under the age of 4 years until the second TB test results are available.
- Prescribe treatment to all LTBI cases, especially in individuals that are young, newly converted, or immunocompromised.

The American Association of Pediatrics (AAP) has recommendations for screening children who are at risk for TB (2):

Immediate Testing

- If a contact person of the child has TB disease.
- If the child was born in a high risk country.
- Any child with radiographic findings that suggest TB infection.

Non-Urgent Testing

- If a family member of the child has a positive TST.
- If the child has traveled to a high risk country and stayed for more than 1 week or immigrated from a high risk country.

Annual Testing

- Yearly TST screening should be done in all children with HIV or adolescents that are incarcerated.
- The only vaccine currently available is the BCG vaccine. It is used worldwide except in the US and the Netherlands. In general it has low efficacy, with the primary value of the vaccine being in the prevention of miliary TB and tuberculous meningitis in young infants.

PROGNOSIS

- In children, isoniazid treatment of LTBI is close to 100 percent effective in preventing future TB disease.
- Prognosis for children with drug susceptible TB who are compliant with antituberculous therapy is usually excellent, with cure rates of 95 to 100 percent.
- Without early diagnosis and prompt initiation of appropriate therapy, TB meningitis and miliary TB could be associated with high morbidity and mortality.

FOLLOW-UP

- A CXR, CT, or additional imaging should be completed as clinically indicated for patients with pulmonary tuberculosis.
- Follow-up with neurology and neurosurgery is needed in any patient with central nervous system involvement. Ophthalmology will need to follow up patients with ocular involvement.
- Liver function tests are not routinely recommended unless the child has history of hepatitis or has signs or symptoms such as jaundice, vomiting and abdominal pain.

PATIENT RESOURCES[8]

- CDC website has fact sheets available for patients—**www.cdc.gov/tb/publications/factsheets/general/tb.htm**.

PROVIDER RESOURCES[9]

- TB program information is also available at the CDC website—**www.cdc.gov/tb/programs/Evaluation/Default.htm**.
- CDC website has fact sheets available for providers—**www.cdc.gov/tb/publications/factsheets/general/tb.htm**.

187 CONGENITAL AND PERINATAL INFECTIONS

Camille Sabella, MD

PATIENT STORY

A 7-day-old infant is seen in the emergency department because of a rash that was noted on the infant's trunk and back. The rash consisted of crops of vesicular lesions on an erythematous base (**Figure 187-1**). The infant was born at term gestation to an 18-year-old mother who had poor prenatal care. The mother denied a history of herpes simplex infection or other sexually transmitted infections. A direct fluorescent antibody test for herpes simplex virus (HSV) was positive and an HSV culture from the lesion was positive. A lumbar puncture was normal, and blood and CSF tests for HSV DNA were negative. The infant was admitted and treated with intravenous acyclovir for 14 days and recovered without sequelae.

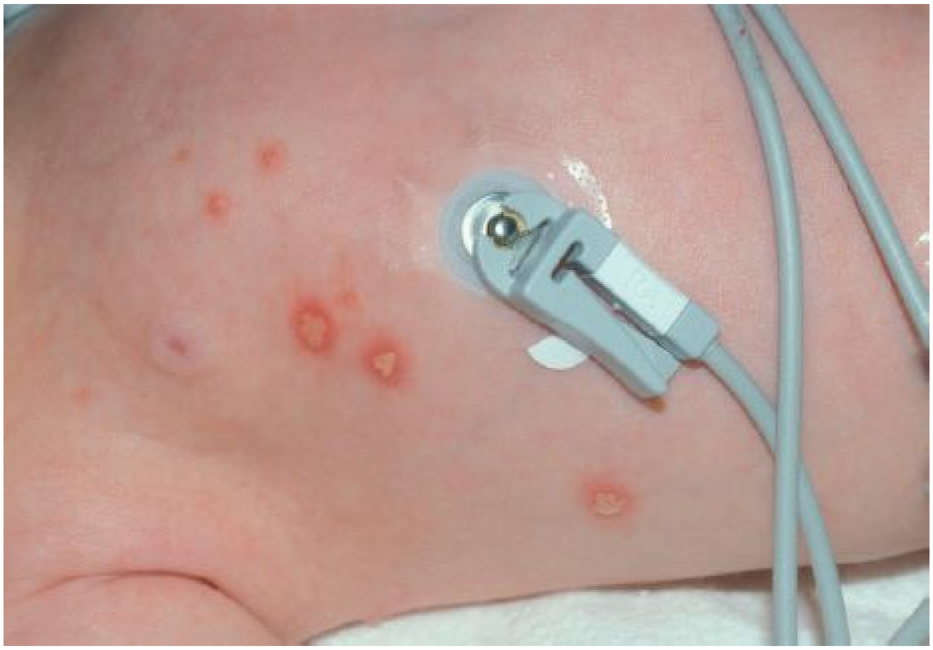

FIGURE 187-1 Vesicular lesions of HSV in an infant. (*Used with permission from Johanna Goldfarb, MD*.)

INTRODUCTION

Many microbiological agents can cause infection in the newborn infant. These infections may be acquired *in utero*, at the time of delivery, or in the immediate newborn period. Although the majority of congenital infections result in inapparent infection, it is imperative to recognize infections that manifest symptomatically. Although the clinical manifestations of these infections may be similar regardless of the pathogen, specific clinical findings and patterns may serve as important clues for specific microorganisms.

EPIDEMIOLOGY

- The epidemiology varies depending on the organism responsible for the infection:

***Streptococcus agalactiae* (Group B Streptococci)**

- Incidence of early onset disease (presentation in the first week of life) is 0.3/1000 live births.[1,2]
- Early-onset disease is related to perinatal transmission of the organism.
- Fifteen to forty percent of pregnant women are colonized with the organism in the genital and/or gastrointestinal tract.
- Fifty to seventy percent of colonized mothers transmit the organism to their infants; 1 to 2 percent of colonized infants develop early-onset sepsis (if intrapartum antimicrobial prophylaxis is not provided); risk higher if risk factors are present (see the following section “Risk Factors”).

- Incidence of early-onset GBS infection has decreased significantly since the implementation of maternal intrapartum antibiotic prophylaxis.[3]

Herpes Simplex Virus (HSV)

- Incidence is estimated to be 1 per 3200 deliveries.[4]
- Most neonates acquire the virus from an infected maternal genital tract at the time of delivery.[5]
- HSV-2 accounts for 70 percent of neonatal cases while HSV-1 accounts from 30 percent of cases.
- Because most maternal genital infections are asymptomatic, 60 to 80 percent of neonates who have HSV infection are born to mothers who have no history of current or past genital HSV infection.[5]
- The transmission rate from mother to infant during maternal primary infection is 35 to 50 percent, while the transmission rate during a recurrence of HSV is 2 to 5 percent.

Enteroviruses

- Newborns who become infected most commonly acquire these viruses at the time of delivery.
- In temperate climates, these viruses most commonly cause infections in late summer and early autumn.
- Recent maternal febrile illness and abdominal pain, lack of obstetrical complications, and summertime or autumn illness may serve as clues to the diagnosis.[6]

Cytomegalovirus (CMV)

- Most common congenital infection, affecting approximately 1 percent of all newborns in the US.[7]
- Can be acquired in utero, perinatally, or postnatally, through breastfeeding or blood transfusion.
- Can be acquired as a result of maternal primary or recurrent infection; risk considerably higher if infection is a result of a primary maternal

infection.

Toxoplasma infection

- Incidence in the US is 1 per 1,000 to 8,000 live births.[8]
- Maternal acquisition of the organism occurs via the ingestion of food containing cysts or by exposure to oocytes excreted by cats.
- Congenital infection can occur when a pregnant mother has a primary infection.
- Risk of transmission to the fetus increases with advancing gestational age; however, neonatal manifestations are more severe when the fetus is infected early in pregnancy (i.e., first trimester).[9]

Rubella

- The incidence of congenital rubella in the US today is very low because of widespread immunization against the virus.
- All congenital cases are due to maternal primary infection during pregnancy.
- Overall risk of infection of the fetus is 80 to 100 percent if maternal infection occurs during the first trimester. Risk is significantly lower if maternal infection occurs in the second or third trimester.[10]

Syphilis

- The incidence of congenital syphilis had declined to the lowest reported levels in 2000. Since that time, the rate of primary and secondary syphilis has increased among women, with a concomitant increase in cases of congenital syphilis since 2005.[11]

ETIOLOGY AND PATHOPHYSIOLOGY

- Bacterial causes of perinatal infections include *Streptococcus agalactiae* (Group B), *Escherichia coli*, and *Listeria monocytogenes*.
- Bacterial pathogens that cause early-onset infection are most commonly transmitted to the infant at the time of delivery.
- HSV is most commonly acquired by the neonate at the time of delivery; infection of the neonate may occur *in utero* (very rare) or may occur after postnatal acquisition from an oro-labial HSV infection.
- CMV infection in the neonate may follow a primary or recurrent maternal infection and may be acquired *in utero*, at the time of delivery or postnatally, through breastfeeding or blood transfusion.
- *Toxoplasma gondii* and Rubella congenital infections are a result of maternal primary infection.
- Transplacental transmission of *Treponema pallidum* may result in congenital syphilis; because the fetus acquires the infection from hematogenous spread, the clinical manifestations in the newborn are similar to those of secondary syphilis.

RISK FACTORS

- Risk factors for Group B Streptococcal sepsis include:
    - Maternal colonization at the time of delivery.
    - Prematurity (less than 37 weeks gestation).
    - Prolonged rupture of membranes (>18 hours).
    - Chorioamnionitis/maternal fever.
    - Group B Streptococcal bacteriuria.
- A risk factor for neonatal enteroviral infection is exposure of a pregnant mother to a contact who is shedding enterovirus.
- Prolonged contact with young children, especially among parents, is a risk factor for primary CMV infection during pregnancy.[12]
- Ingestion of undercooked pork, beef, and lamb during pregnancy serve as an important source of primary *Toxoplasma* maternal infection.

- Non-immunity to rubella during pregnancy—either from lack of vaccination or incomplete vaccination—is a risk factor for maternal rubella infection.
- Untreated syphilis in a pregnant mother may result in congenital syphilis.

DIAGNOSIS

CLINICAL FEATURES

▶ Perinatally acquired infections

- The clinical manifestations of infections acquired around the time of delivery usually become apparent soon after birth but may occur anytime in the neonatal period. Examples of these infections include *S. agalactiae* (Group B), *E. coli*, *L. monocytogenes*, herpes simplex virus, and enteroviruses.
- Pneumonia, septic shock, and meningitis are manifestations of perinatally acquired infections; brain abscess may complicate meningitis caused by neonatal pathogens, especially gram negative organisms (**Figure 187-2**).

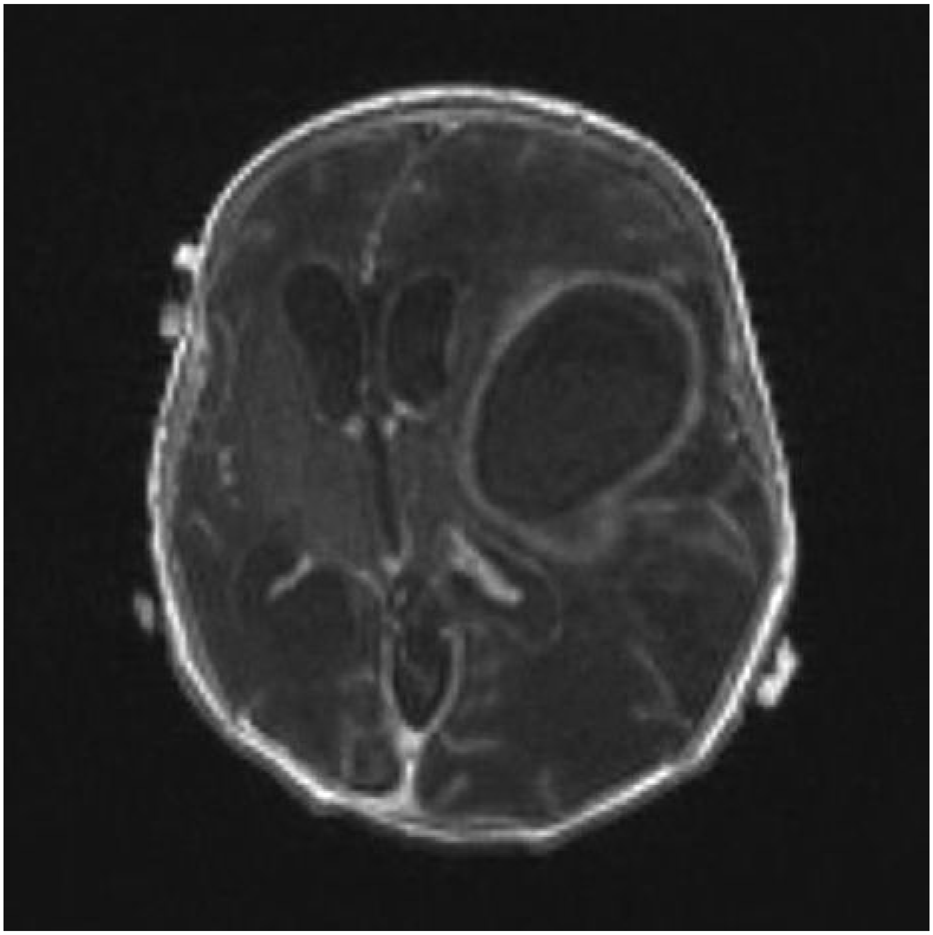

FIGURE 187-2 Multiple brain abscesses seen on MRI in a 3-week-old infant. Brain abscess is a complication of meningitis in neonates, and most commonly is caused by gram-negative organisms like *Citrobacter koseri*, *Serratia marcescens*, and *E. coli*. (*Used with permission from Camille Sabella, MD*.)

- The clinical manifestations of infection in the neonatal period may be subtle and are similar regardless of etiology; meningitis is clinically indistinguishable from sepsis in this age group.
- Common manifestations include temperature instability, respiratory distress, apnea, feeding intolerance, lethargy, and jaundice.
- Herpes simplex virus infection in the newborn may manifest with localized disease (confined to the skin, eyes, or mucous membranes), disseminated infection, or infection confined to the central nervous system.[13]

- Vesicular lesions, forming singly, or in clusters, on an erythematous base (**Figure 187-3**) are the hallmark features of localized HSV infection in the newborn.

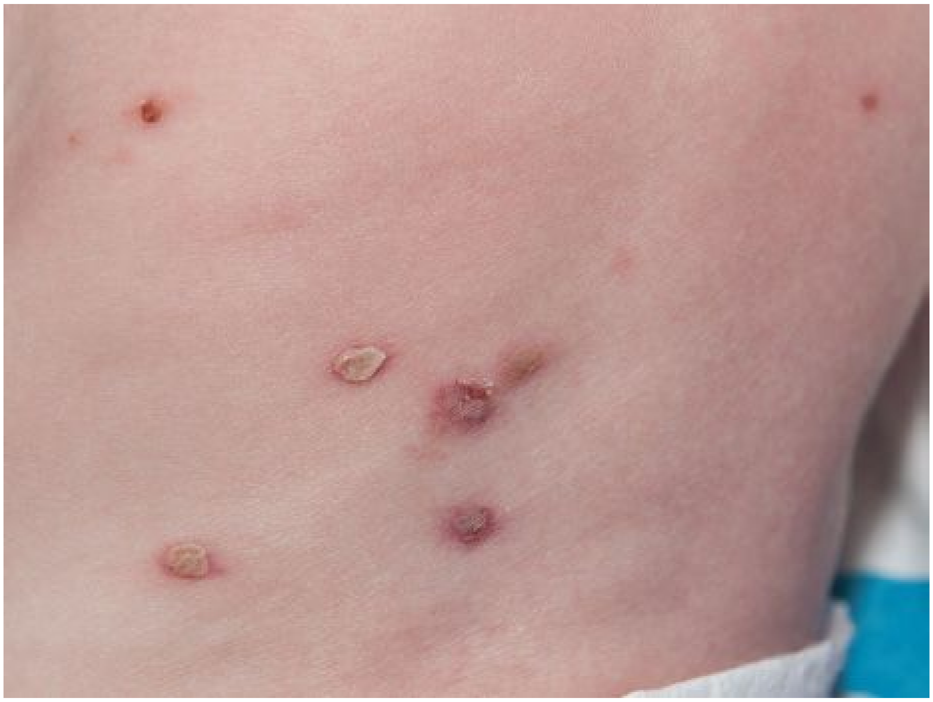

FIGURE 187-3 Crops of vesicular lesions on an erythematous base, characteristic of HSV infections in a 10-day-old infant. (*Used with permission from Blanca E. Gonzalez, MD*.)

- Enteroviral infections in the newborn may be mild and nonspecific, or may be severe and life-threatening; a macular, maculopapular, vesicular, or petechial rash may be present in these infants (**Figure 187-4**).[6]

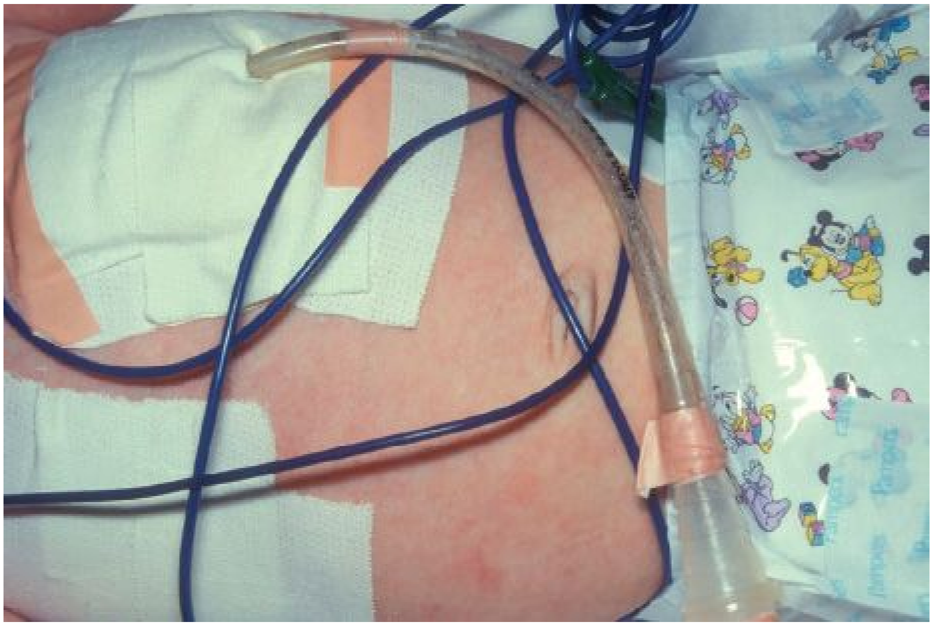

FIGURE 187-4 Enteroviral infection in a critically ill infant. Note the subtle maculopapular rash which can serve as a clue to the diagnosis. (*Used with permission from Camille Sabella, MD*.)

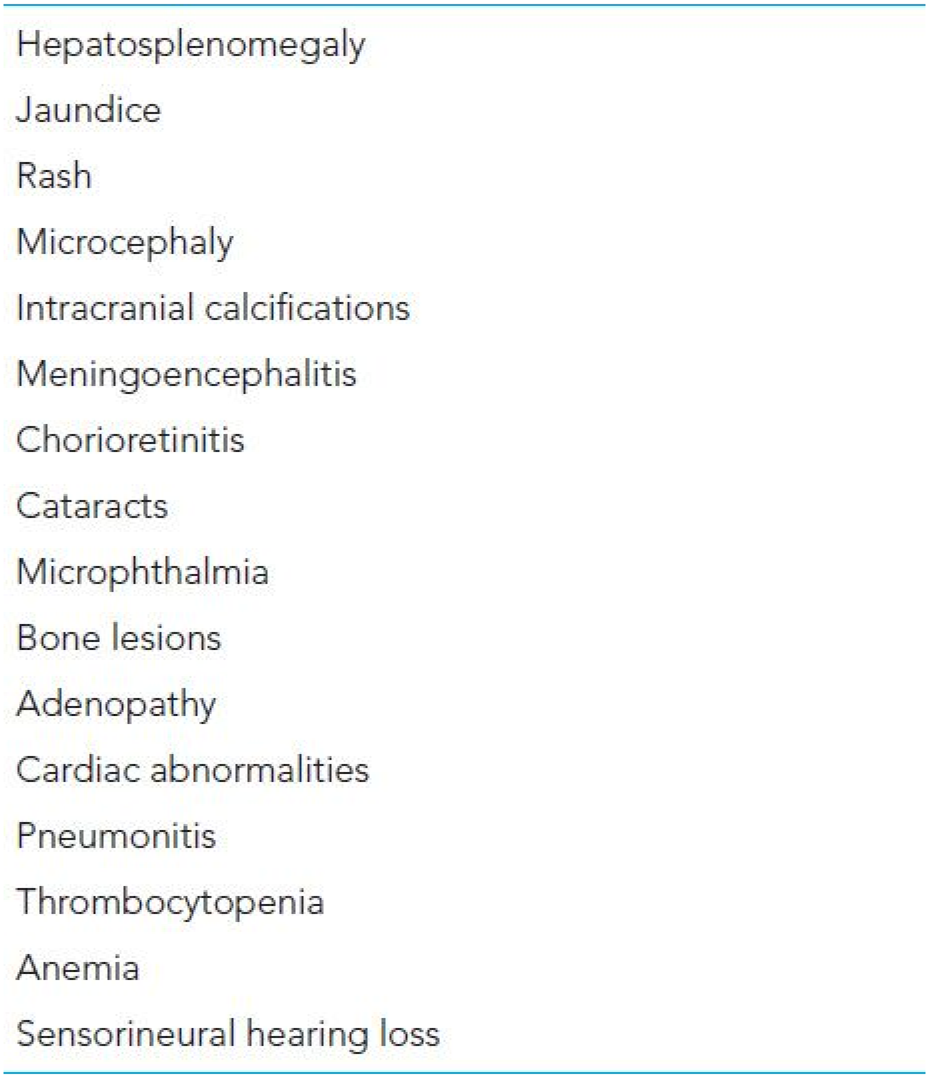
▶ Intrauterine infections

- The manifestations of intrauterine infections may be apparent at or shortly after birth, or they may become apparent months to years later.
- Clinical features of congenital infections are similar regardless of the etiology and are listed in **Table 187-1**.

TABLE 187-1 Common Clinical Manifestations of Intrauterine Infection



Hepatosplenomegaly
Jaundice
Rash
Microcephaly
Intracranial calcifications
Meningoencephalitis
Chorioretinitis
Cataracts
Microphthalmia
Bone lesions
Adenopathy
Cardiac abnormalities
Pneumonitis
Thrombocytopenia
Anemia
Sensorineural hearing loss

- Infections with certain pathogens may result in more specific congenital abnormalities:
  - Infants with CMV infection may manifest with cytomegalic inclusion disease consisting of intrauterine growth retardation, hepatosplenomegaly, jaundice, thrombocytopenia, lymphadenopathy, petechial/purpuric rash, and microcephaly (**Figure 187-5**).[14]

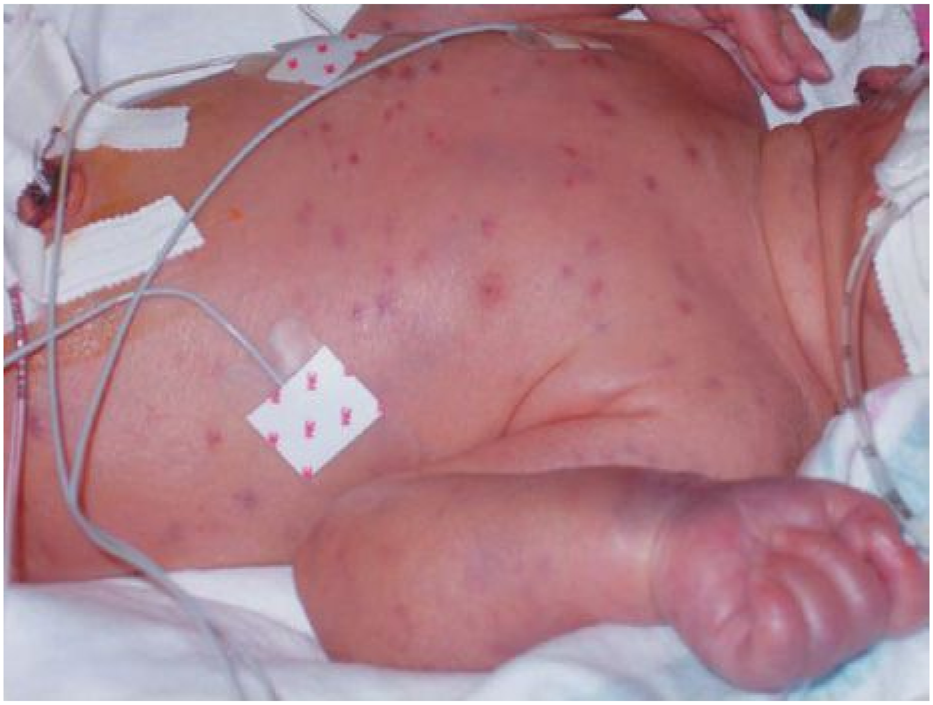


FIGURE 187-5 Infant with the "blueberry muffin" rash representing extramedullary hematopoiesis. This is classically described for congenital rubella but can be seen with congenital CMV as well. (*Used with permission from Shah SS. Pediatric Practice: Infectious Diseases. Figure 50-1. www.accesspediatrics.com.*)

- Common manifestations of rubella infection include hepatosplenomegaly, jaundice, cataracts (**Figure 187-6**), blueberry muffin lesions (dermal erythropoiesis; **Figure 187-7**), and congenital heart disease.

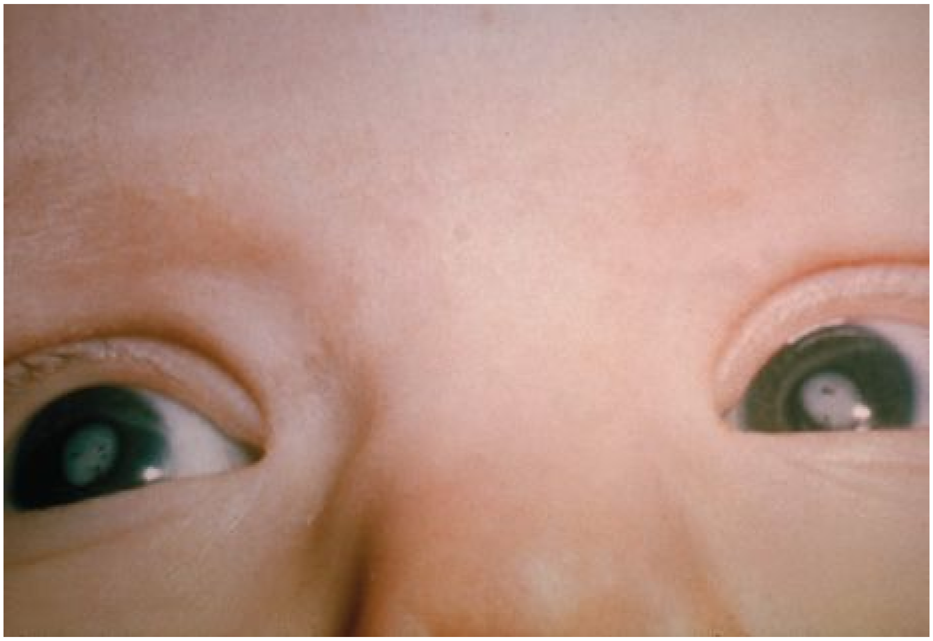

FIGURE 187-6 Bilateral cataracts in an infant with congenital rubella syndrome. (*Used with permission from CDC.*)

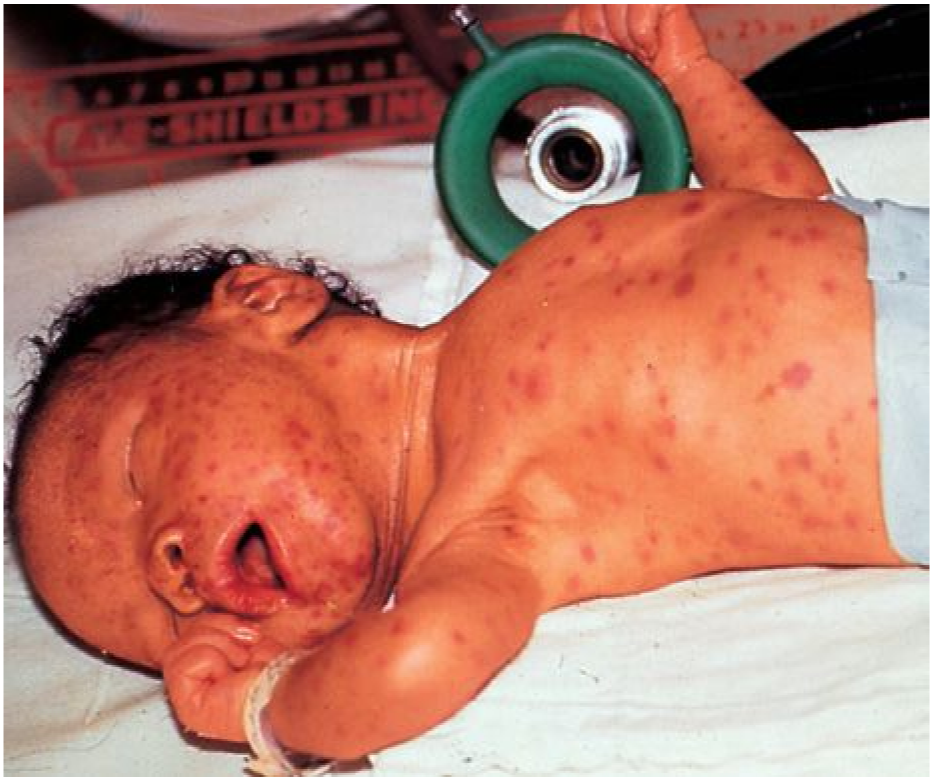

FIGURE 187-7 A neonate with congenital rubella syndrome. Note the “blueberry muffin” rash, which represents sites of extramedullary

hematopoiesis. Also note the microcephaly. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 5-51, New York, NY: McGraw-Hill, 2008*.)

- The classic triad of congenital toxoplasma infection include chorioretinitis, hydrocephalus, and cerebral calcifications.[15]
- Early features (first 3 months of age) of congenital syphilis include syphilitic rhinitis (snuffles), maculopapular, or vesicobullous rash on the palms, soles, mouth or anus, and long bone periostitis (**Figures 187-8** and **187-9**; see Chapter 181, Syphilis).[16]

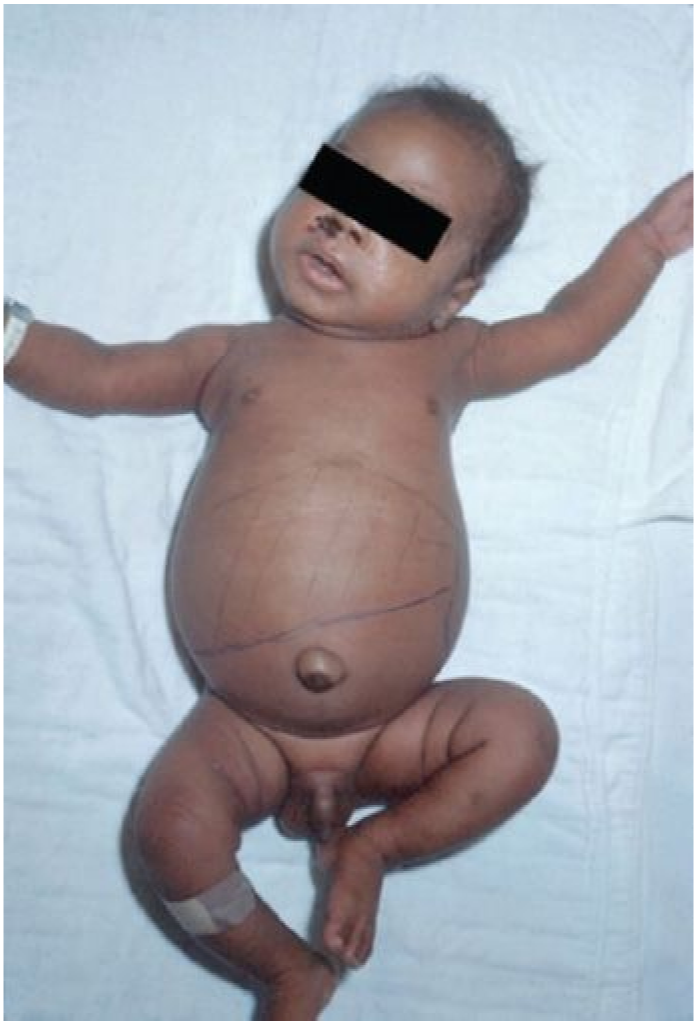

FIGURE 187-8 A newborn infant with congenital syphilis. Note the hepatosplenomegaly as outlined, right sided axillary adenopathy, and the

bloody, mucousy nasal discharge (snuffles). (*Used with permission from Camille Sabella, MD.*)

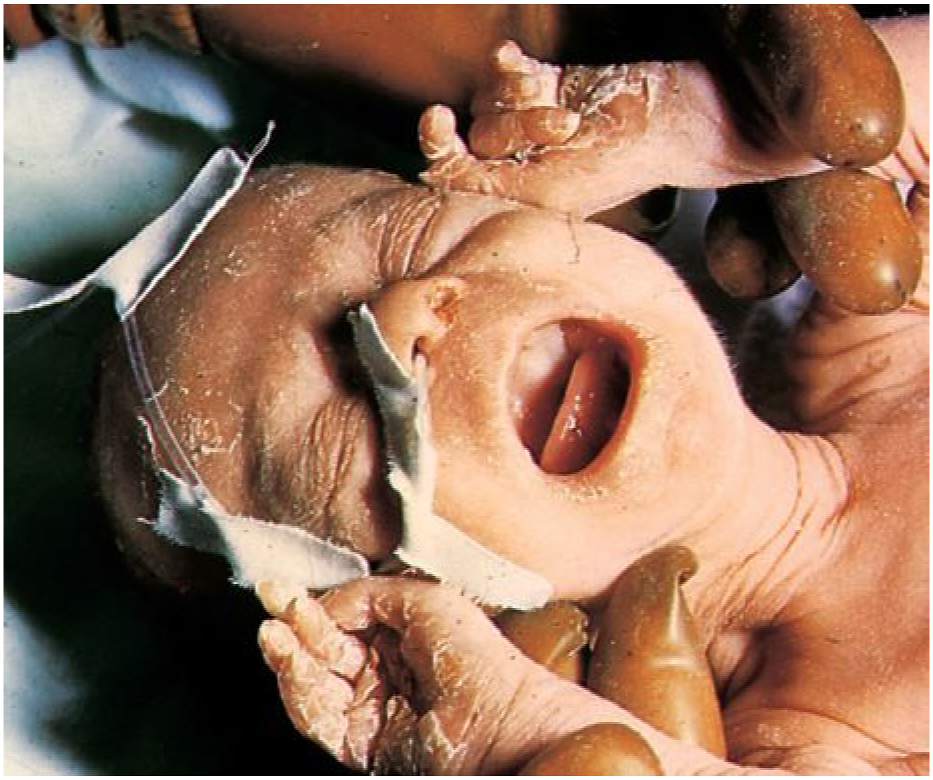

FIGURE 187-9 Infant with congenital syphilis. Note the scaly, bullous rash on the rash and extremities, including the palms in this infant. (*Used with permission from Weinberg SW, Prose NS, Kristal L. Color Atlas of Pediatric Dermatology, 4th edition, Figure 4-1, New York, NY: McGraw-Hill, 2008.*)

LABORATORY TESTING

- The diagnosis of bacterial sepsis and meningitis relies on isolating an organism from the blood or cerebrospinal fluid.
- Hematologic abnormalities and inflammatory markers are neither sensitive nor specific for the diagnosis of neonatal sepsis.
- Viral culture from a vesicular lesion is the most reliable method of diagnosing localized HSV infection in the newborn; direct fluorescent antibody testing of cells from a skin lesion can also be utilized to provide a rapid diagnosis.[17,18]

- Viral culture for HSV from sites such as the nasopharynx, conjunctivae, and rectum is used to diagnose disseminated HSV infection.
- Polymerase chain reaction testing for HSV DNA in blood mononuclear cells is recommended for diagnosing disseminated infection.[19]
- Polymerase chain reaction testing for HSV DNA in the cerebrospinal fluid is the diagnostic test of choice for diagnosing central nervous system infection.[20]
- Viral culture for enterovirus from the nasopharynx and/or rectum is helpful in diagnosing neonatal enteroviral infection; Polymerase chain reaction for enterovirus RNA from cerebrospinal fluid is more sensitive than viral culture for the diagnosis of enteroviral meningoencephalitis.[21]
- A positive urine culture for CMV in the first 2 to 3 weeks of life confirms congenital infection.
- Rubella virus can be isolated in cell culture from sites such as the urine, cerebrospinal fluid or nasopharynx in suspected cases; Rubella specific IgG and IgM titers may also be helpful in establishing the diagnosis.
- The diagnosis of congenital toxoplasmosis is difficult and usually relies on serologic assays on the infant and mother; persistent or rising IgG titers in the infant, or positive specific IgM or IgA assays help establish the diagnosis; nucleic acid assays, histopathology of the placenta or infected tissues and mouse inoculation assays on the infant’s blood or placenta may also be helpful.
- Definitive diagnosis of congenital syphilis is difficult; positive non-treponemal and treponemal antibody testing in the mother and the infant is recommended; A positive result of a nontreponemal antibody test in an infant that does not disappear by 6 months of age, a rising titer after birth, or a titer in an infant that is fourfold higher than the mother’s titer are highly suggestive of congenital infection.[22]

IMAGING

- Neonatal pneumonia, such as that caused by Group B Streptococcus, is indistinguishable from respiratory distress syndrome of the newborn

(**Figure 187-10**).

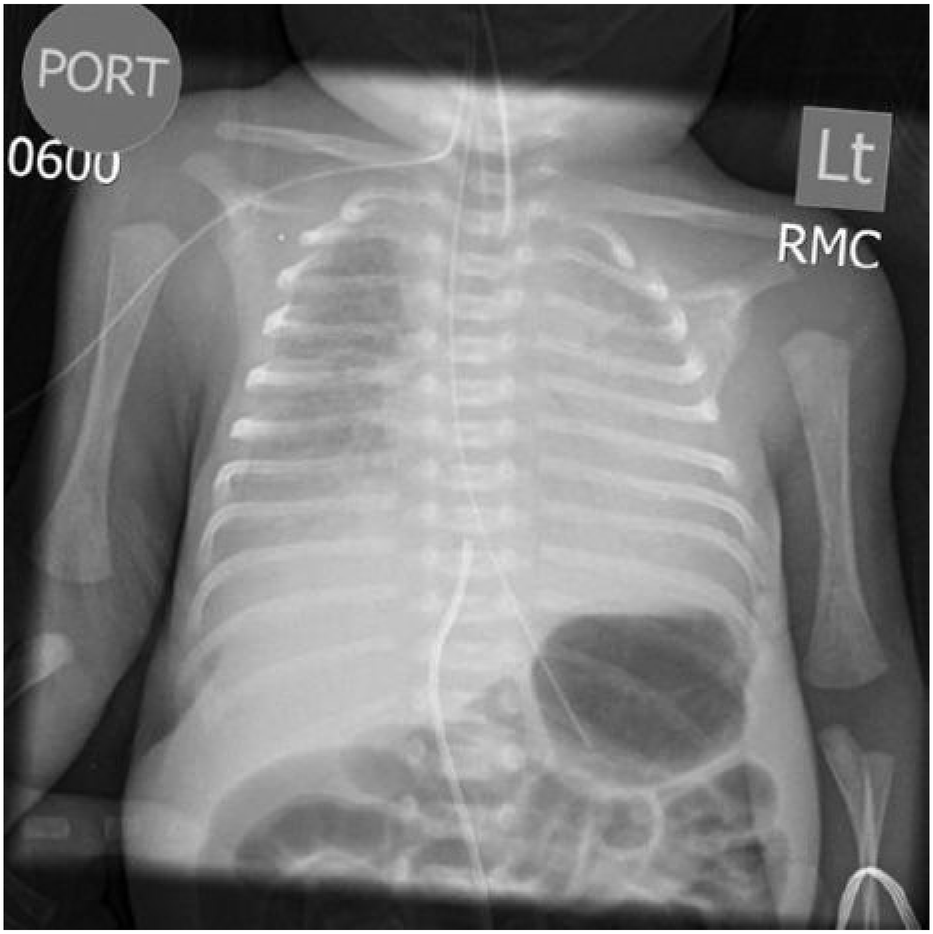

FIGURE 187-10 X-ray of neonatal pneumonia. (*Used with permission from Camille Sabella, MD*.)

- Brain abscess is a well-known complication of neonatal meningitis, and is a relatively common complication of gram negative meningitis (**Figure 187-2**).
- Periostitis or osteochondritis of long bones may be features of congenital infection, and is a common finding in infants with congenital syphilis (**Figure 187-11**).

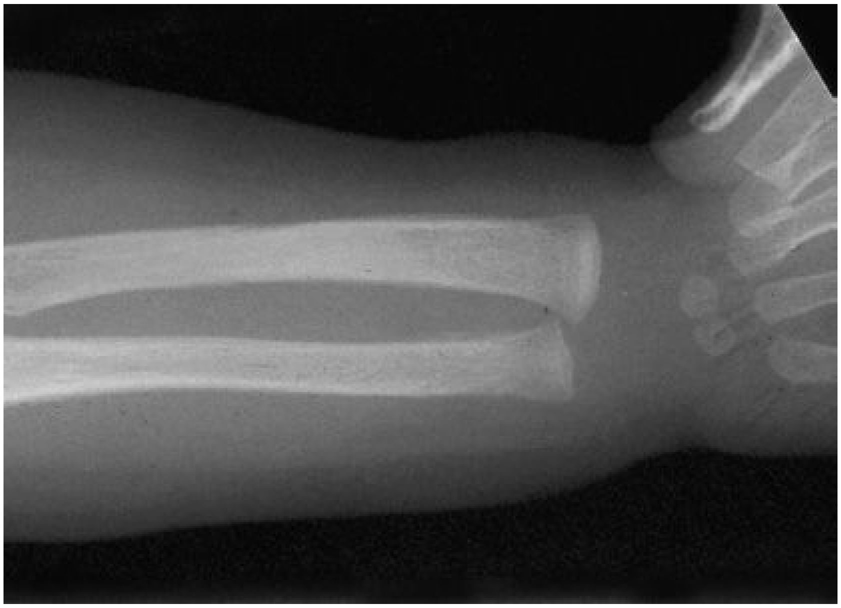

FIGURE 187-11 X-ray of the arm of an infant with congenital syphilis. There are transverse metaphyseal lucent bands seen involving the distal radius and ulna and smooth organized lamellated periosteal new bone seen involving the ulnar diaphysis and metaphysis. (*Used with permission from Camille Sabella, MD*.)

- Intracranial calcifications can occur with congenital infection caused by CMV and *Toxoplasma*; calcifications caused by CMV are often periventricular in distribution (**Figure 187-12**) while those caused by *Toxoplasma* are commonly intraparenchymal (**Figure 187-13**).

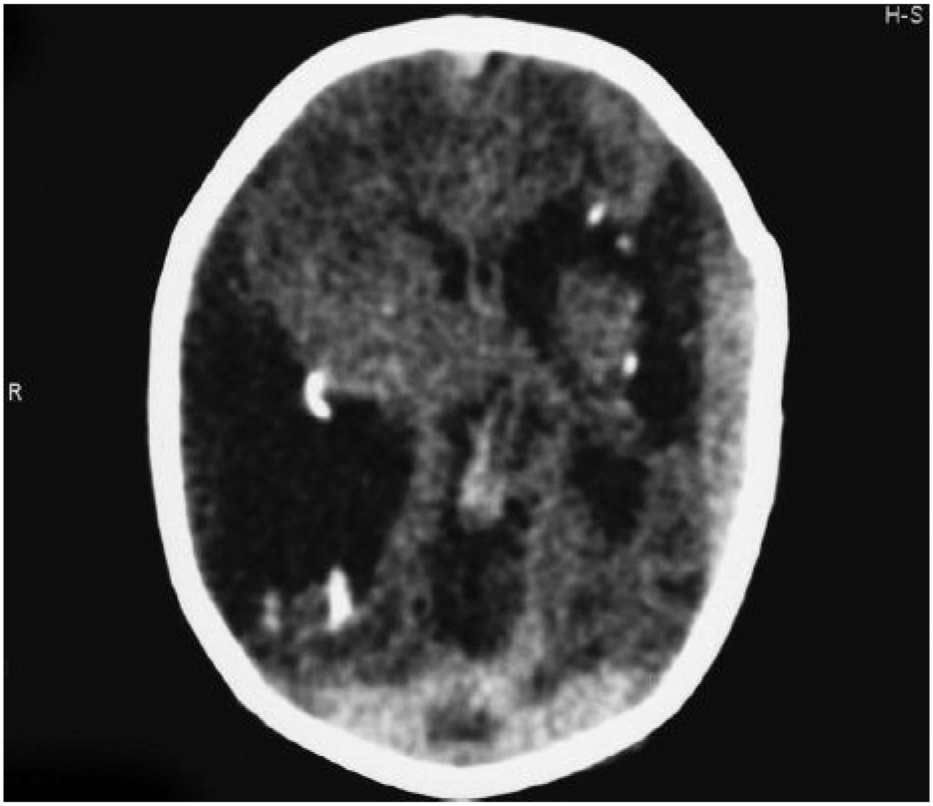

FIGURE 187-12 Periventricular calcifications in an infant with congenital CMV. (*Used with permission from Camille Sabella, MD*.)

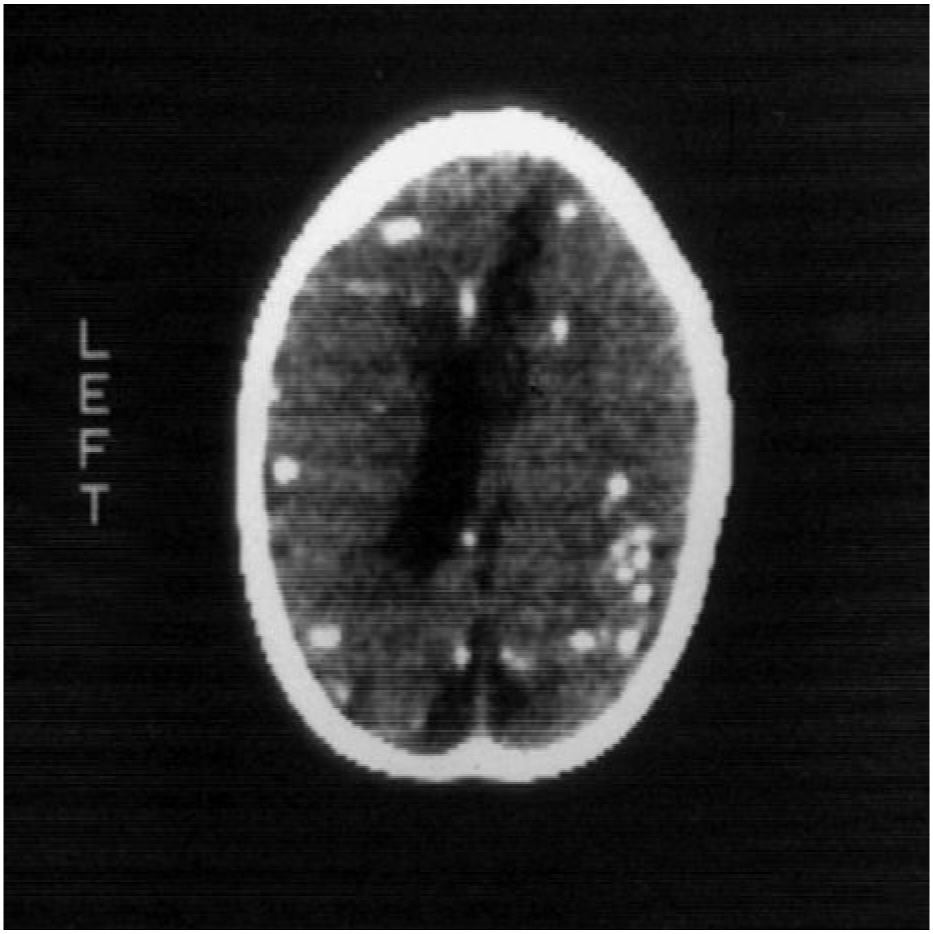

FIGURE 187-13 Parenchymal calcifications seen on CT in the brain an infant with congenital toxoplasmosis. (*Used with permission from Camille Sabella, MD.*)

DIFFERENTIAL DIAGNOSIS

- The clinical manifestation of newborn sepsis and meningitis are often indistinguishable for other newborn illnesses, such as respiratory distress syndrome, congenital heart disease, and metabolic disorders.

MANAGEMENT

NONPHARMACOLOGIC

- Appropriate respiratory and hemodynamic support should be provided for every newborn suspected of having or proven to have an infection.

MEDICATIONS

- Antimicrobial therapy for newborns suspected of having bacterial sepsis should be initiated empirically and must include coverage for Group B Streptococci, *E. coli*, and *L. monocytogenes*.
- Ampicillin and gentamicin is appropriate therapy for such infants; more specific therapy directed against a particular pathogen can be undertaken once a pathogen is identified. SOR C
- Parenteral acyclovir is the treatment of choice for infants with HSV infection.[23,24] SOR A
- The benefit of antiviral therapy for congenital CMV infection is currently under study; antiviral therapy for infants with congenital CMV infection is not routinely recommended at this time.[25] SOR C
- Early institution of pyrimethamine and sulfadiazine for infants with congenital *Toxoplasma* infection decreases the severity of disease and the frequency of sequelae.[26] SOR B
- Parenteral Penicillin γ therapy is recommended for infants with proven or suspected congenital syphilis.[27,28] SOR A

PREVENTION AND SCREENING

- Vaginal and rectal cultures for Group B Streptococcal carriage should be performed in all pregnant women at 35 to 37 weeks' gestation.[29,30]
- Intrapartum antibiotic prophylaxis (penicillin is preferred agent) is recommended for mothers who have:

  - A positive screening test for Group B streptococcus.
  - Group B streptococcal bacteriuria during current pregnancy.
  - Previous infant with group B streptococcal disease.
- If the group B streptococcal status of the mother is unknown at the time of delivery, maternal intrapartum prophylaxis is indicated if any of the following are present:
  - Delivery at less than 37 weeks gestation.
  - Membranes ruptured for 18 hours or longer.
  - Intrapartum fever (temperature ≥38°C [100.4°F]).
  - Positive intrapartum nucleic acid amplification test for group B streptococcus.
- All women should be screened serologically for syphilis early in pregnancy and preferably again at delivery; no newborn should be discharged from the hospital without determination of the mothers syphilis serologic status at least once during pregnancy.[27, 31]

PROGNOSIS

- The case fatality rate of perinatally acquired bacterial sepsis and meningitis is 10 to 25 percent.
- Long-term neurologic sequelae develop in 25 to 50 percent of survivors of neonatal bacterial meningitis.
- Despite antiviral therapy, there is a 30 percent mortality rate among neonates with disseminated HSV infection; those with localized infections that are appropriately treated with antiviral therapy all survive.[24]
- Long-term neurologic sequelae are common in survivors of disseminated and central nervous system HSV infection.[13,24]
- Ten to 15 percent of infants with localized HSV infection have long-term neurologic sequelae, despite appropriate treatment.[24]

- The prognosis of infants with congenital infection is highly variable and dependent upon the agent, the extent of involvement, and the organ systems affected.
- The mortality rate of infants with cytomegalic inclusion disease is 30 percent, whereas the overall mortality of symptomatic CMV congenital infection is 10 to 15 percent.[14]
- Long-term neurologic sequelae, especially hearing loss and intellectual deficits, occur in approximately 5 to 10 percent of infants who have asymptomatic congenital CMV infection.[32–34]

FOLLOW-UP

- Close follow-up of all infants born with perinatally acquired or congenital infection is mandatory, with particular attention to neurodevelopment, hearing, and vision.

PATIENT EDUCATION

- Pregnant women should receive good prenatal care to lower the risk of transmission of infection to their infants.

188 ZOONOSES

Lara Danziger-Isakov, MD, MPH
Camille Sabella, MD

PATIENT STORY

A 12-year-old boy developed fever to 38.9°C and felt ill. Over the next 2 days, he developed a red spots on his hands and arms, which became petechial (**Figure 188-1**) and spread to involve his entire upper extremities and trunk. He also developed abdominal pain and a headache. History was significant for a recent camping trip with his family to the Southeastern coast of the US. The parents report that he did sustain several tick bites while camping. He was treated presumptively for Rocky Mountain Spotted Fever (RMSF) with doxycycline, and his symptoms resolved over several days.

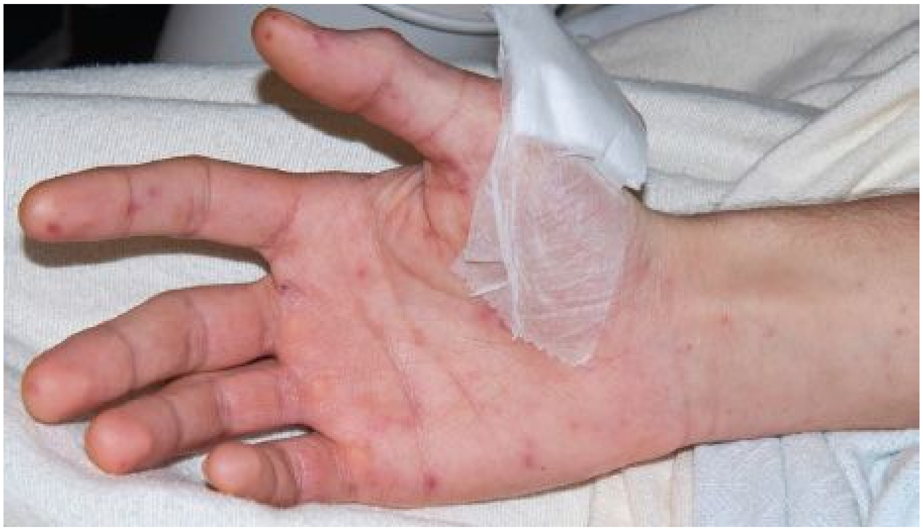

FIGURE 188-1 Petechial rash characteristic of late Rocky Mountain Spotted Fever (RMSF). (*Used with permission from Johanna Goldfarb, MD*.)

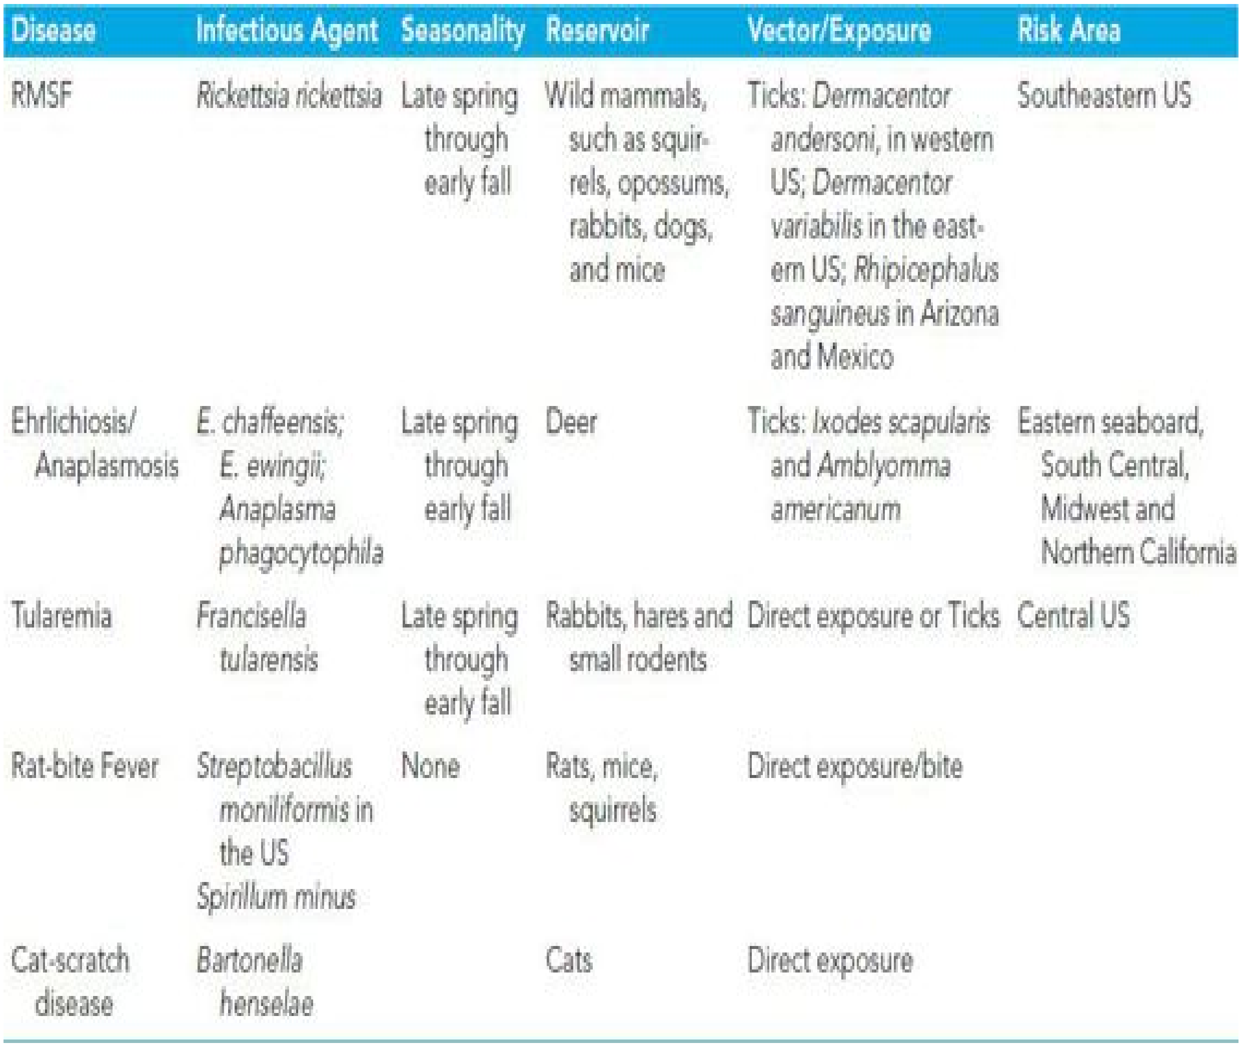
INTRODUCTION

Zoonoses are infectious agents spread to humans by animals. Infection may occur through direct contact with the animal or via vectors such as ticks (**Table 188-1**). Examples of zoonotic diseases include RMSF, Ehrlichiosis, Tularemia, Cat-scratch disease, and Rat-bite fever.

Table 188-1 Epidemiologic Characteristics of Selected Zoonoses



Disease	Infectious Agent	Seasonality	Reservoir	Vector/Exposure	Risk Area
RMSF	*Rickettsia rickettsia*	Late spring through early fall	Wild mammals, such as squirrels, opossums, rabbits, dogs, and mice	Ticks: *Dermacentor andersoni*, in western US; *Dermacentor variabilis* in the eastern US; *Rhipicephalus sanguineus* in Arizona and Mexico	Southeastern US
Ehrlichiosis/ Anaplasmosis	*E. chaffeensis; E. ewingii; Anaplasma phagocytophila*	Late spring through early fall	Deer	Ticks: *Ixodes scapularis* and *Amblyomma americanum*	Eastern seaboard, South Central, Midwest and Northern California
Tularemia	*Francisella tularensis*	Late spring through early fall	Rabbits, hares and small rodents	Direct exposure or Ticks	Central US
Rat-bite Fever	*Streptobacillus moniliformis* in the US *Spirillum minus*	None	Rats, mice, squirrels	Direct exposure/bite	
Cat-scratch disease	*Bartonella henselae*		Cats	Direct exposure	

EPIDEMIOLOGY

- RMSF
    - Incidence is highest (19 to 77 cases/1 million people in 2008) in Southeastern (Virginia, Carolinas) and Central (Tennessee, Missouri, Arkansas and Oklahoma) US (**Figure 188-2**).[1]

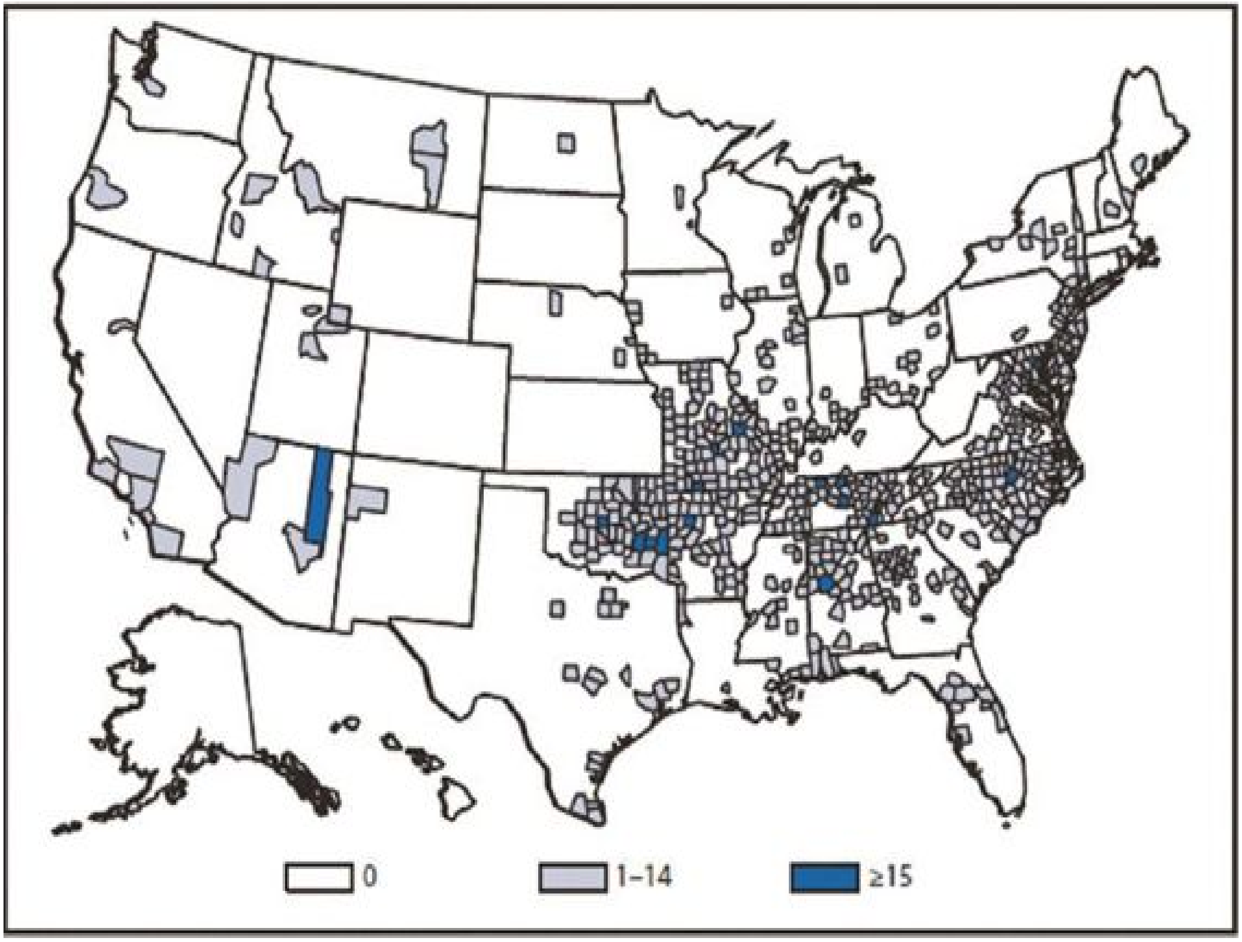


FIGURE 188-2 Rocky Mountain Spotted Fever. Number of reported cases, by county, US, 2010. (*Used with permission from the National Notifiable Disease Surveillance System, Centers for Disease Control and Prevention. MMWR Morb Mortal Wkly Rep. 2012 Jun 1;59(53):1-111.*)

-
    - Approximately 2,000 cases are reported annually in the US.
    - 1/3 of all cases are in the pediatric age group.[2,3]
- Ehrlichiosis
    - Incidence is highest (14 to 33 cases/1 million people in 2008) in Central States (Missouri, Arkansas and Oklahoma) with moderate incidence

(1.7 to 14 cases/1 million people in 2008) in Upper Midwest and Southeastern states (**Figure 188-3**).[1]

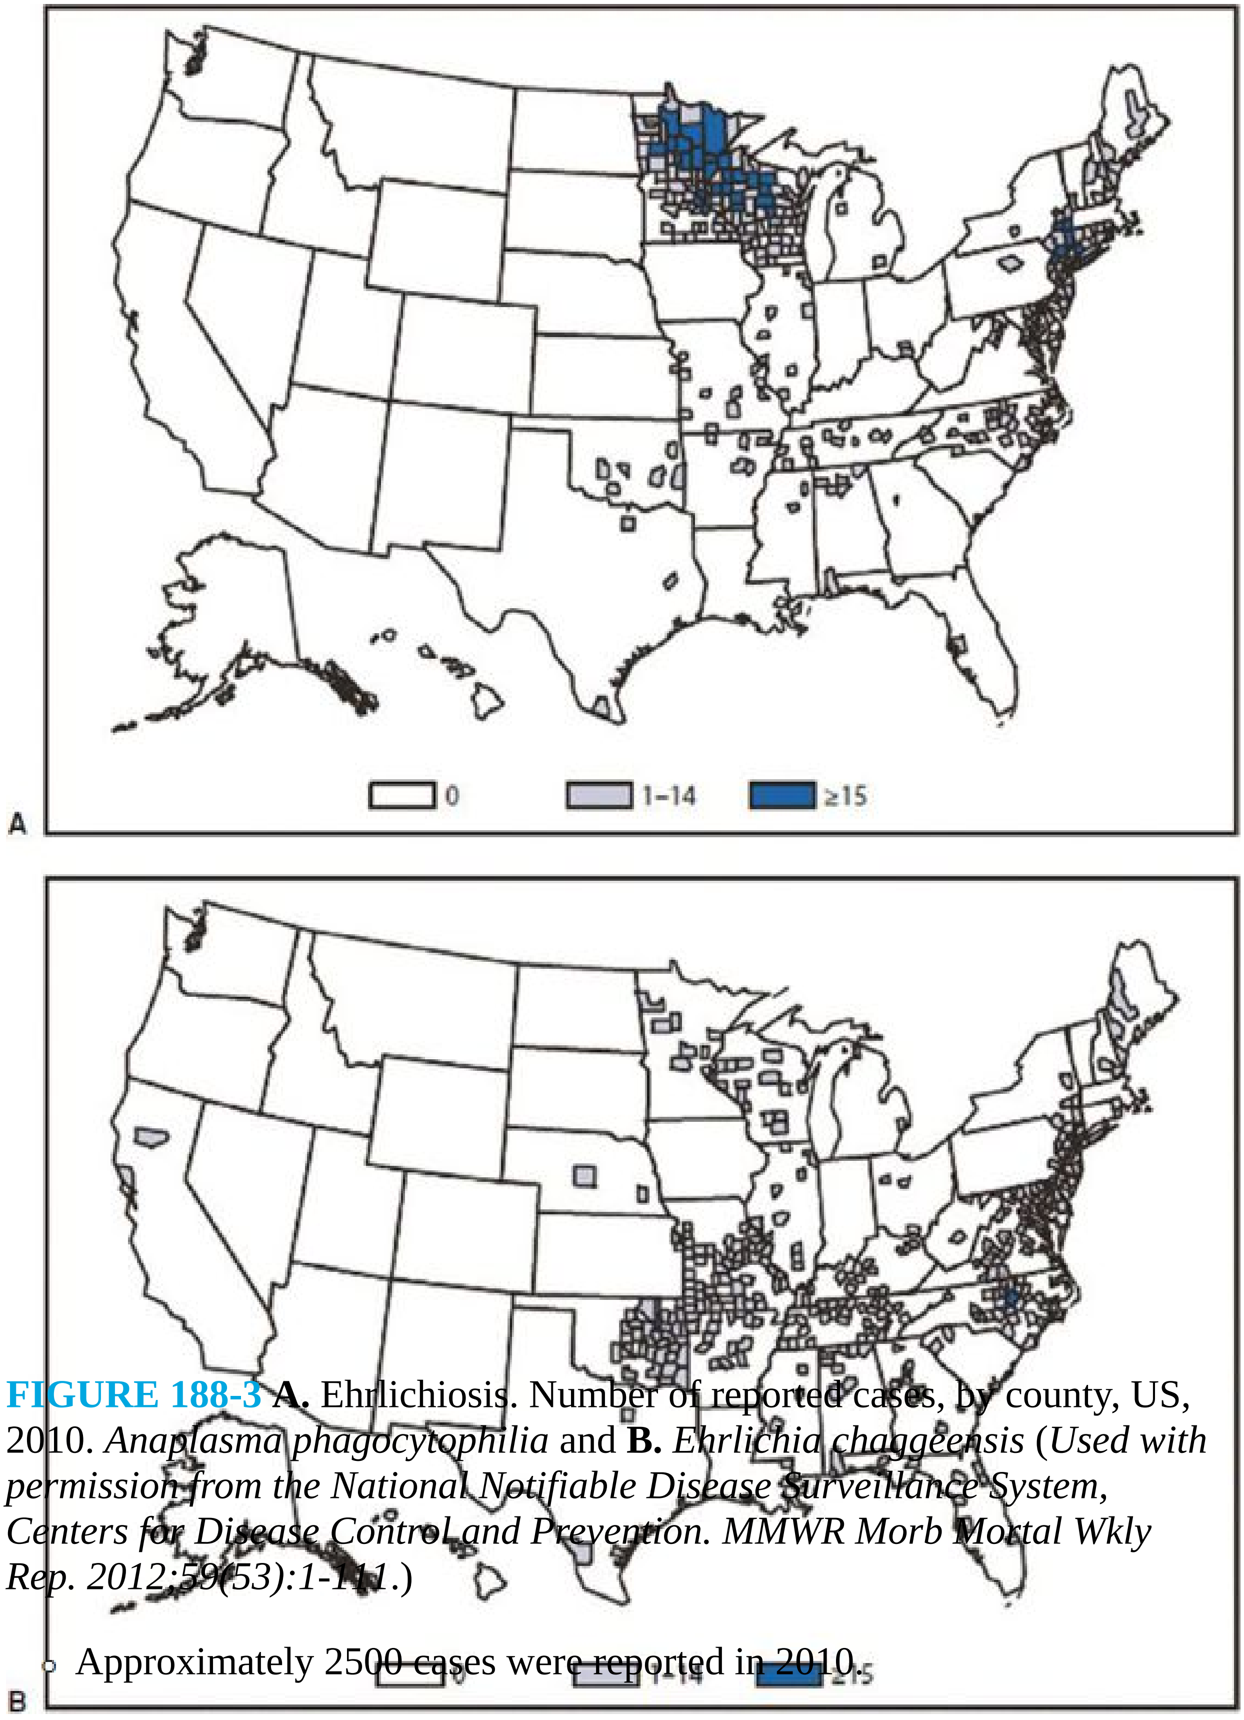

FIGURE 188-3 **A.** Ehrlichiosis. Number of reported cases, by county, US, 2010. *Anaplasma phagocytophilia* and **B.** *Ehrlichia chaggeensis* (*Used with permission from the National Notifiable Disease Surveillance System, Centers for Disease Control and Prevention. MMWR Morb Mortal Wkly Rep. 2012;59(53):1-111.*)

- Approximately 2500 cases were reported in 2010.

  - Number of reported cases as well as size of endemic regions appears to be growing with spread of tick vectors.
- Tularemia
  - Rare; only 124 cases were reported in the US in 2010.[1]
- Cat-scratch
  - Uncommon, although not routinely reported through National Notifiable Disease Surveillance System (NNDSS) at the Centers of Disease Control and Prevention (CDC).
- Rat-bite fever.
  - Rare, but not routinely reported to NNDSS.

ETIOLOGY AND PATHOPHYSIOLOGY

- RMSF.
  - Etiologic agent is *Rickettsia rickettsii*, which produces endothelial cell infection resulting in a systemic small-vessel vasculitis.
  - Ticks are the natural hosts, reservoirs and vectors. Rocky Mountain wood ticks (Dermacentor andersoni) are the most common vector for RMSF in Western North America (**Figure 188-4**). There are 3 other ticks that have been identified as vectors of *Rickettsia rickettsii* in North America.

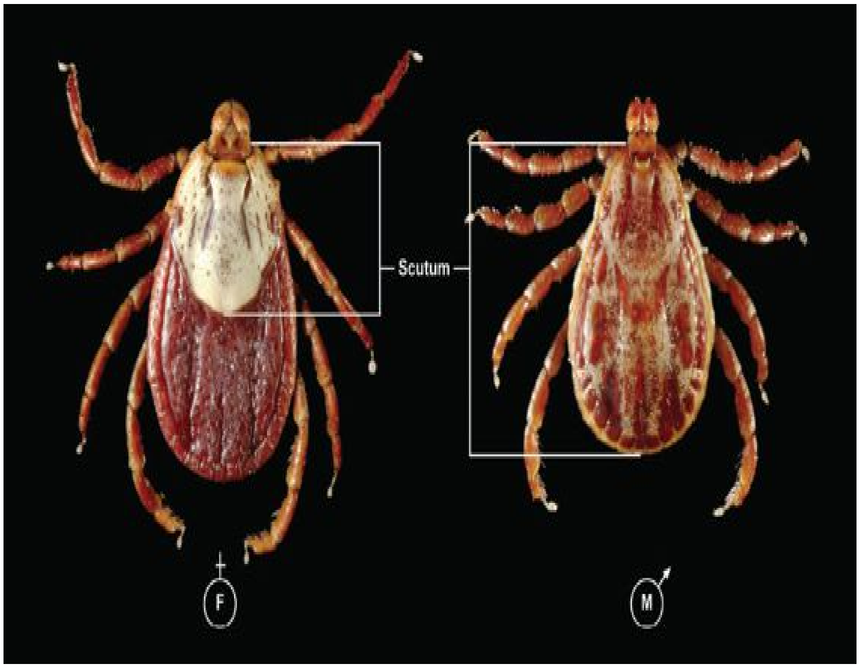

FIGURE 188-4 Rocky Mountain wood ticks (Dermacentor andersoni). A North American vector of Rickettsia rickettsii, the etiologic agent of Rocky Mountain spotted fever. Note the smaller size of the female's scutum (shield) compared to the male's larger scutum. The dorsal shield covers only a small part of the female's dorsal surface enabling her abdomen to expand and becoming engorged during feeding. (*Used with permission from CDC/Dr. Christopher Paddock*.)

- Ehrlichiosis.
  - Etiologic agents are obligate intracellular gram-negative bacteria *Ehrlichia chaffeensis*, *E. ewingii*, and *Anaplasma phagocytophilum*, which have tropisms for different white blood cells.
- Tularemia.
  - *Francisella tularensis* is the etiologic agent.
- Cat scratch disease.
  - *Bartonella henselae* is the etiologic agent.
- Rat-bite fever.
  - In the US, *Streptobacillus moniliformis* is the etiologic agent, whereas *Spirillum minus* is found in Asia.

RISK FACTORS

- RMSF/Ehrlichiosis.
  - Tick exposure in endemic areas and younger age are risk factors for infection.
- Tularemia.
  - Exposure to infected rabbits, including skinning, is a risk factor for infection.
  - Tick bite in endemic area is common mode of spread.
- Cat-scratch disease.
  - Exposure to cats, particularly kittens, is the main risk factor.
  - Can occur following a recent scratch or bite.
  - About 20 to 30 percent of patients who have cat scratch disease have no cat or kitten exposure.
- Rat-bite fever
  - Infected rodents serve as vectors.
  - May also be acquired from ingestion of unpasteurized milk, water or other food contaminated with *S. moniliformis* (Haverhill fever).

DIAGNOSIS

- RMSF.
  - Definitive diagnosis is difficult, as there are no widely available sensitive laboratory assays to confirm the diagnosis.
  - Treatment should be presumptive, pending testing results, as a delay in therapy is associated with a poor outcome.[4]
  - A confirmed case, as defined by the CDC,[4] includes the appropriate clinical symptoms and:
    - Serological evidence of a fourfold change in immunoglobulin G (IgG)-specific antibody titer reactive with *R. rickettsii* or other spotted

        fever group antigen by indirect immunofluorescence assay (IFA) between paired serum specimens (one taken in the first week of illness and a second 2 to 4 weeks later)., OR
        - Detection of *R. rickettsii* or other spotted fever group DNA in a clinical specimen (skin biopsy) via amplification of a specific target by polymerase chain reaction (PCR) assay, or demonstration of spotted fever group antigen in a biopsy or autopsy specimen by Immunohistochemical staining, OR
        - Isolation of *R. rickettsii* or other spotted fever group rickettsia from a clinical specimen in cell culture.

- Ehrlichiosis.
    - A confirmed case, as defined by the CDC,[4] includes the appropriate clinical symptoms and:
        - Serological diagnosis with a fourfold change in specific antibody titers between acute (at illness onset) and convalescent sera (4 weeks after illness), OR
        - Detection of *Ehrlichia* or *Anaplasma* DNA in a clinical specimen via PCR assay, OR
        - Demonstration of Ehrlichia antigen in a biopsy or autopsy sample by immunohistochemical methods, OR
        - Isolation of *E. chaffeensis* from a clinical specimen in cell culture.
    - A probable case, as defined by the CDC,[4] includes:
        - Presence of morulae (clusters of phagocytized ehrlichial organisms in vacuoles) in cytoplasm of peripheral blood granulocytes, monocytes, or macrophages (**Figure 188-5**), OR

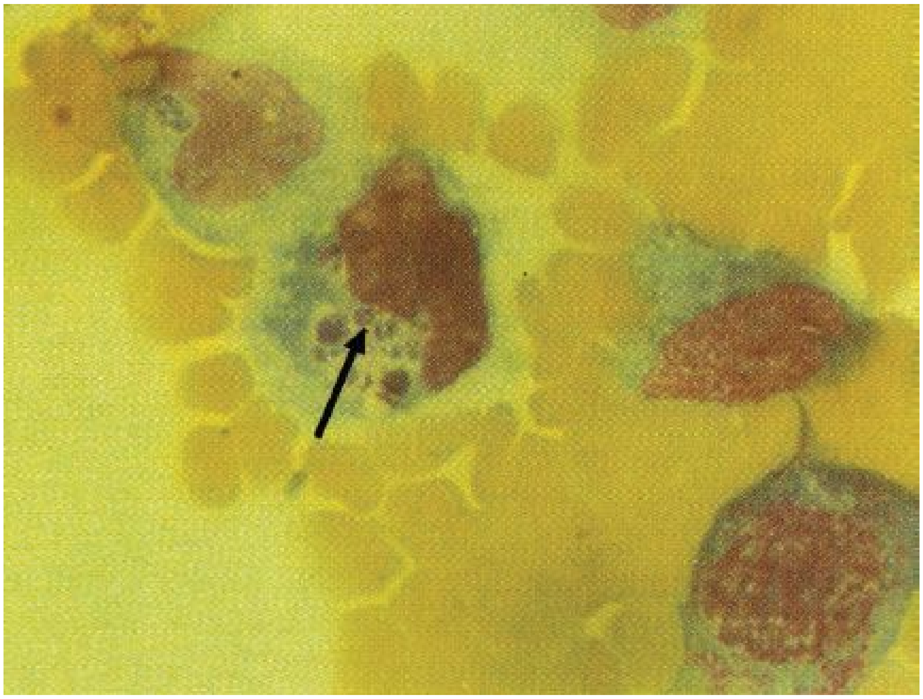

FIGURE 188-5 Peripheral blood smear showing intraleukocytic morulae in granulocytic cell. This is supportive evidence of the diagnosis of Ehrlichiosis. (*Used with permission from Camille Sabella, MD*.)

    - Serologic evidence of IgG or IgM reactive to *Ehrlichia* antigen by IFA, enzyme-linked immunosorbent assay (ELISA), dot-ELISA, or assays in other formats.

- Tularemia.
  - Growth of the organism in culture is definitive.
    - Appropriate specimens include swabs or scrapping of skin lesions, lymph node aspirates or biopsies, pharyngeal washings, sputum specimens, or gastric aspirates, depending on the form of illness.
    - Paradoxically, blood cultures are often negative.
  - Serological diagnosis with a fourfold change in specific antibody titers between acute (at illness onset) and convalescent sera (4 weeks after illness) can confirm the diagnosis. However, this is not helpful in acute clinical management because of the delay in diagnosis.
  - A presumptive diagnosis of tularemia can be made when there is:
    - Evidence of an elevated serum antibody titer to *F. tularensis* antigen without evidence of a four-fold increase,[5] OR

    - A positive result using direct fluorescent antibody, immunohistochemical staining, or PCR.

- Cat-scratch disease.
  - The diagnosis is usually confirmed by demonstrating serological evidence of antibodies to *Bartonella* antigens using an indirect immunofluorescent antibody (IFA) assay.[6]
  - PCR of body fluids is available at CDC or reference laboratories.
  - Histopathologic evidence of organisms on Warthin-Starry silver staining is not specific for *B. henselae* infection.

- Rat-bite fever.
    - The diagnosis of *S. moniliformis* infection is made via culture of blood, synovial fluid, or other body fluids using specific media; cultures should be held for 3 weeks because of the slow growth of this agent.
    - The diagnosis of *S. minus* infection is made with darkfield microscopy of blood or infected body fluids.

CLINICAL FEATURES

- RMSF.
  - Fever, headache, malaise, myalgias, nausea, and vomiting are the initial symptoms.
  - These symptoms are followed several days later by a maculopapular rash that evolves into petechial rash (late finding), spreading from the extremities (wrists/ankles) centrally (**Figure 188-1**).
  - If untreated, RMSF progresses to involve the central nervous, renal, cardiac, pulmonary, and gastrointestinal systems, and often includes disseminated intravascular coagulation and shock.
  - Delays in therapy are associated with increased risk of death.

- Ehrlichiosis.
  - Fever, headache, malaise, and myalgia are the most common features.
  - Vomiting, abdominal pain, and arthralgia are less common.
  - Rash occurs less frequently than with RMSF, but is more common in children than adults.

- Tularemia.
    - There are multiple syndrome profiles depending on the site of inoculation:
        - Ulceroglandular (ulceration at inoculation site followed by healing and localized regional lymphadenopathy; **Figure 188-6**).

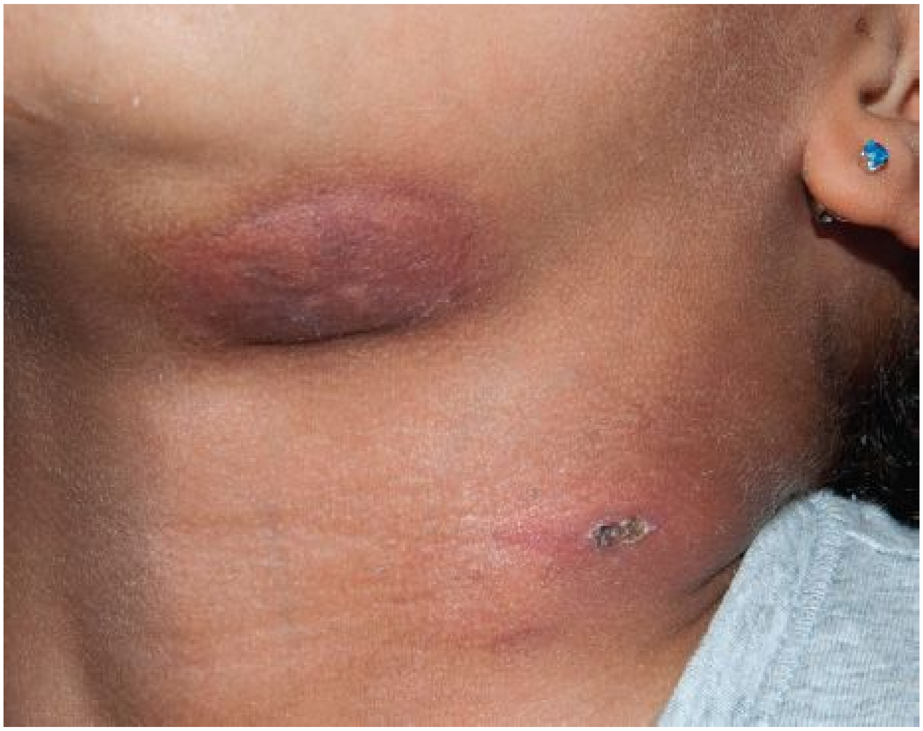

FIGURE 188-6 Ulceration with eschar at the site of inoculation with regional lymphadenopathy. This is characteristic of the ulceroglandular presentation of tularemia or cat scratch adenitis. (*Used with permission from Charles B. Foster, MD*.)

        - Glandular (without ulceration).
    - Oculoglandular.
        - Oropharyngeal.
        - Intestinal.
        - Pneumonic.
- Cat-scratch disease.
    - Regional lymphadenopathy with overlying erythema, tenderness, warmth, and induration is the most common presentation (**Figure 188-7**).

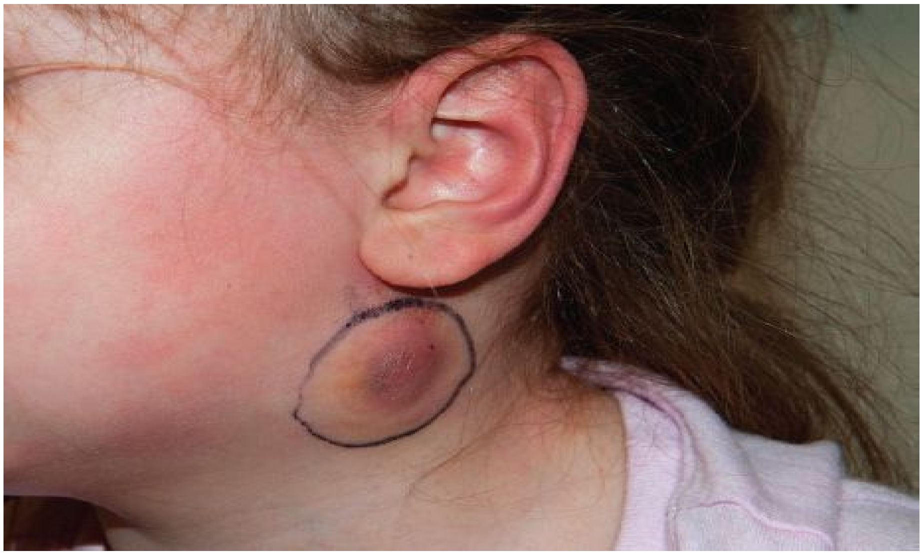

FIGURE 188-7 Cat-scratch adenitis with central fluctuance. (*Used with permission from Camille Sabella, MD*.)

- A primary papule at the inoculation site may be present at diagnosis (**Figure 188-8**).

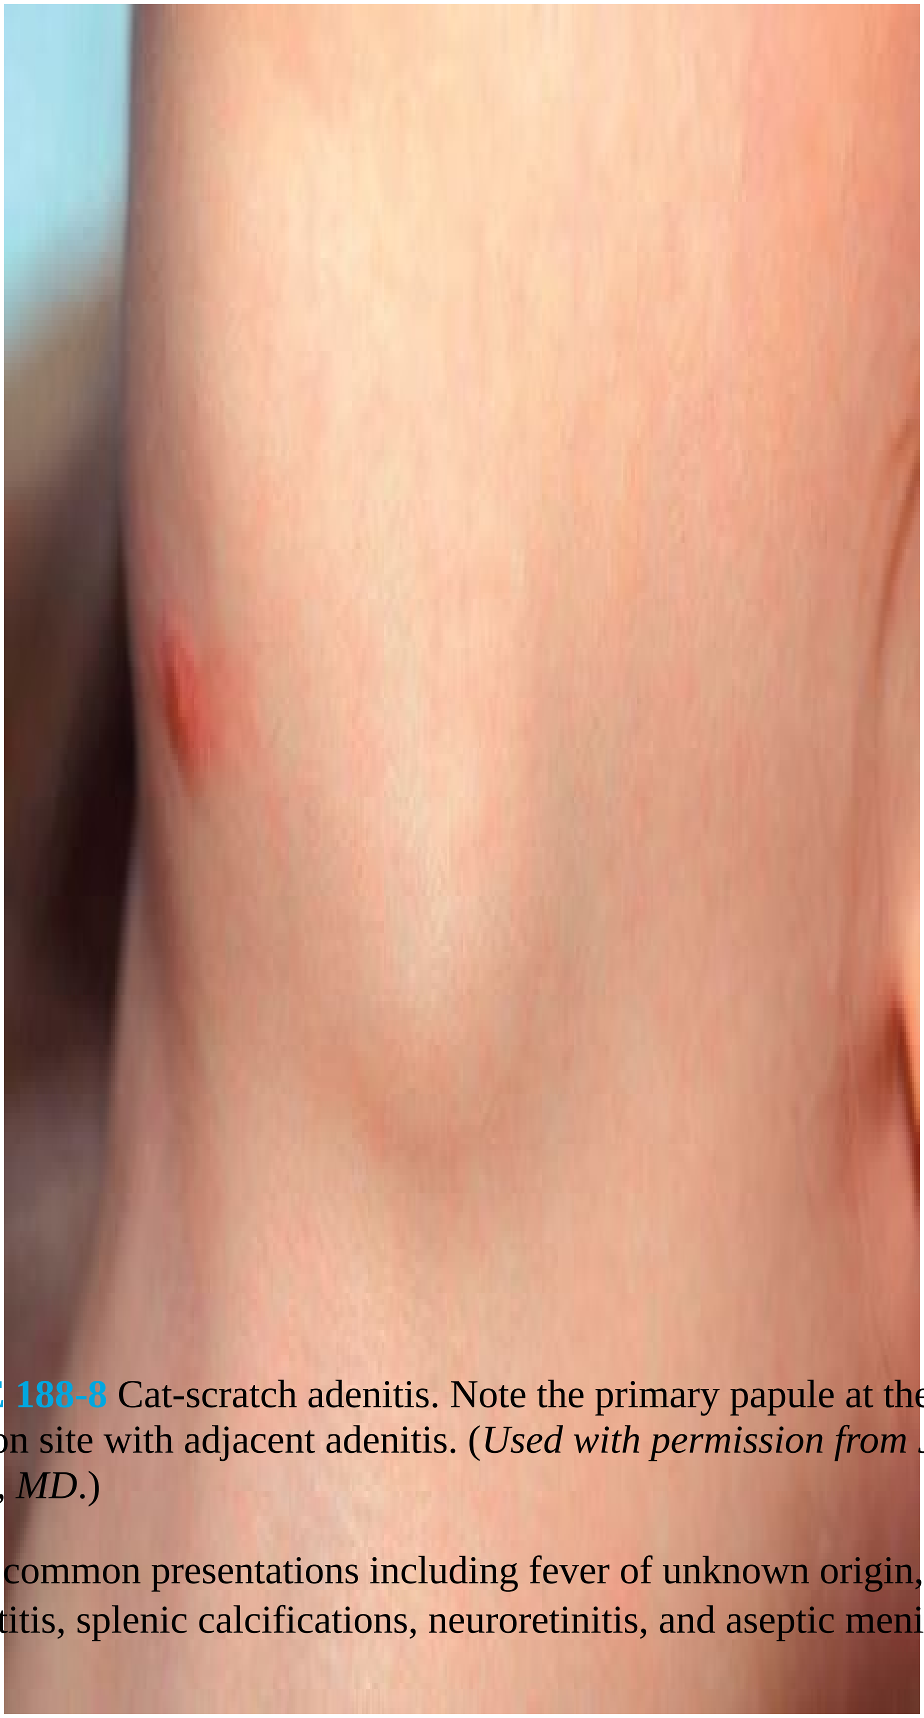

FIGURE 188-8 Cat-scratch adenitis. Note the primary papule at the inoculation site with adjacent adenitis. (*Used with permission from Johanna Goldfarb, MD*.)

- Less common presentations including fever of unknown origin, hepatitis, splenic calcifications, neuroretinitis, and aseptic meningitis.[7,8]

  - Parinaud oculoglandular syndrome with conjunctivitis and ipsilateral preauricular lymphadenopathy is a distinctive manifestation (**Figure 188-9**).

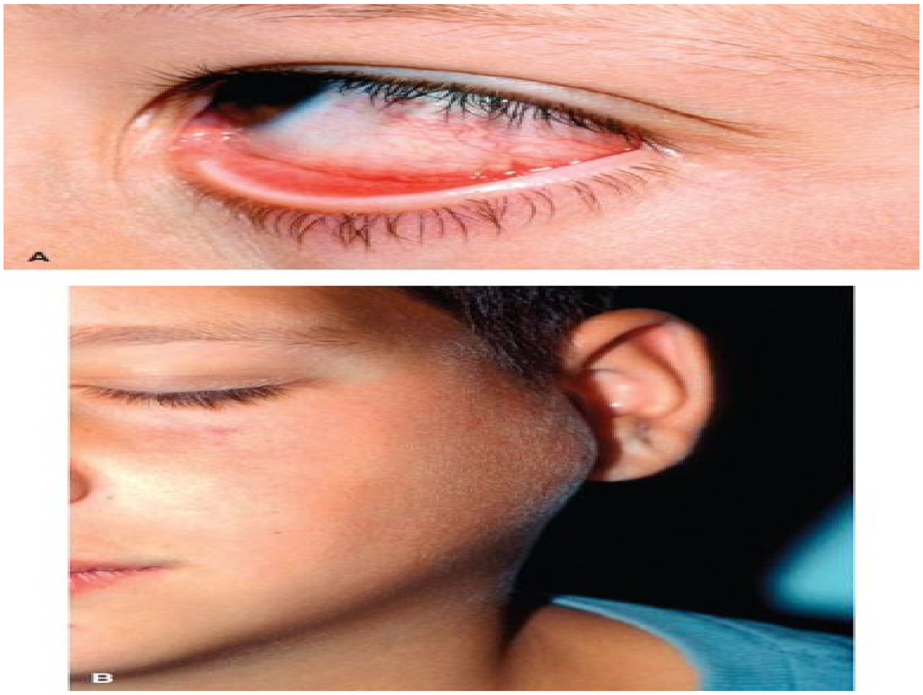

FIGURE 188-9 Parinaud oculoglandular syndrome with (**A**) conjunctivitis and (**B**) pre-auricular lymphadenitis. This child had cat scratch disease, proven by serology, but the differential diagnosis includes tularemia, adenovirus and *H influenzae* infection. (*Used with permission from Camille Sabella, MD. From Sabella C, Cunningham RJ III. Intensive Review of Pediatrics, 4th edition. Lippincott Williams Wilkins, p 448, Figure 53-2, 53-3.*)

- Rat-bite fever.
  - Abrupt onset of fever, malaise, myalgia with swelling, erythema, and purulence from the inoculation site are common manifestations.
  - A maculopapular or petechial rash spreading from extremities (palms/soles) centrally is most common (**Figure 188-10**).

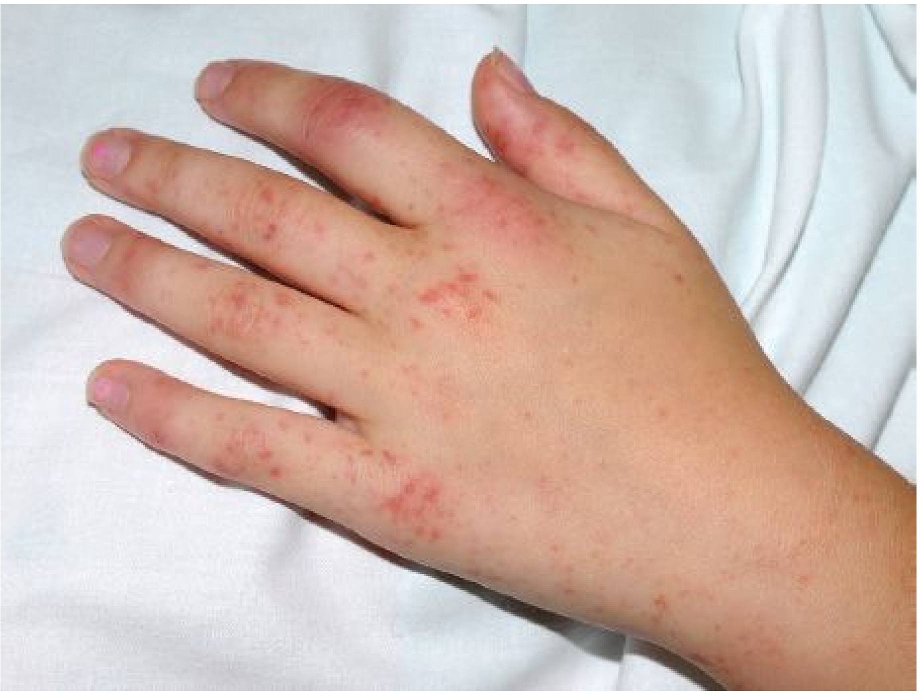

FIGURE 188-10 Maculopapular and petechial rash in 9-year old girl who developed rat-bite fever after being bitten by her pet rat. Inoculation site with swelling and erythema seen on the index finger. (*Used with permission from Camille Sabella, MD.*)

  - Fifty percent of patients develop migratory polyarthritis after the rash has appeared when due to *S. moniliformis* infection; arthritis is uncommon in *S. minus* infections.
  - A relapsing course over several weeks can occur in untreated patients.
  - Complications include septic arthritis, endocarditis, meningitis and abscesses.[9]

ADDITIONAL LABORATORY FINDINGS

- Thrombocytopenia, neutropenia, hyponatremia, and increased hepatic transaminases are common laboratory findings in RMSF, but may not be apparent until later in the course of the illness.
- Leukopenia or lymphopenia, thrombocytopenia, and increased hepatic transaminases are common findings in Ehrlichiosis.

IMAGING

- Cat-scratch disease.
  - Ultrasound is often utilized to assess for suppuration of lymph nodes in patients who are suspected of having cat scratch disease.
  - Ultrasound or Computed Tomography of the liver and spleen may demonstrate granulomatous lesions in patients with cat scratch disease. These patients may present with fever of unknown origin.[8]

DIFFERENTIAL DIAGNOSIS

- The rash that is associated with many of the infections previously discussed may mimic the rash of Meningococcemia, Kawasaki, Rubeola (measles), and Henoch Schonlein Purpura (see Chapters 177, Kawasaki Disease, Chapter 111, Measles, and Chapter 175, Henoch Schonlein Purpura). The epidemiology and route of acquisition of the zoonoses serve as important clues in differentiating these entities.
- The lymphadenitis of cat scratch disease and tularemia is sometimes difficult to differentiate from other causes of lymphadenitis, such as pyogenic (Staphylococcal and streptococcal), mycobacterial, and toxoplasma infections. A thorough history of exposures and the finding of an inoculation site can be helpful in the diagnosis of cat scratch disease and tularemia.
- The differential diagnosis of Parinaud Oculoglandular syndrome (named after Henri Parinaud) includes tularemia, cat-scratch disease, adenovirus, and *H. influenzae* infection. A thorough exposure history and appropriate diagnostic cultures for adenovirus and *H influenzae* can help to differentiate these infections.

MANAGEMENT

NONPHARMACOLOGICAL

- Supportive care for critically ill patients with any of these zoonoses is essential.
- Cat-scratch disease lymphadenopathy is usually self-limited and management is aimed at symptom relief.
- Remove ticks found on people carefully to avoid having the tick expel its contents into the patient during removal.

MEDICATIONS

- RMSF/Ehrlichiosis.
  - Doxycycline is the drug of choice for all patient with these infections, including those who are less than 8 years of age.[10] SOR Ⓐ
- Tularemia.
  - Gentamicin or streptomycin for 10 days is the recommended treatment of choice for tularemia.[11] SOR Ⓐ
  - Alternatively, doxycycline for 14 days can be given for patients 8 years of age and older who do not have severe illness.
- Cat-scratch disease.
  - Azithromycin may decrease the size of lymphadenopathy in the first month of therapy, but does not impact the overall outcome.[12] SOR Ⓑ
  - Antimicrobial therapy may hasten recovery of systemic manifestations, such as hepatic or splenic granulomas, and in immunocompromised hosts,[13] although the role of such therapy in these patients is not clear. SOR Ⓒ
  - Azithromycin, gentamicin, ciprofloxacin, trimethoprim-sulfamethoxazole, and rifampin are possible treatment options for these patients. SOR Ⓒ
- Rat-bite fever.
  - Penicillin G for 7 to 10 days is the treatment of choice.[14] SOR Ⓐ
  - Four weeks of penicillin G recommended for endocarditis.[14]
  - Doxycycline, gentamicin, or streptomycin recommended for those with severe penicillin allergy.

SURGERY

- Cat-scratch disease.
  - Needle aspiration of the involved lymph node(s) can be performed for symptom relief. SOR Ⓒ
  - Incision and drainage of the involved lymph node(s) may result in the development of a draining sinus, and is not recommended. SOR Ⓒ
  - Surgical excision is rarely necessary for enlarged lymph nodes but if performed, should be undertaken prior to the development of spontaneous drainage, if possible. SOR Ⓒ

REFERRAL

- Referral to infectious diseases may be helpful for the diagnosis and management of zoonoses, depending on the specific infection and the severity of the manifestations.
- Referral to surgery for aspiration of an infected lymph node or drainage of a pyogenic focus of infection may be required.

PREVENTION AND SCREENING

- Avoidance of direct animal contact will decrease the risk of some zoonoses such as rat bite fever, cat scratch disease, and tularemia.
- Periodic evaluation for tick-bites and prompt tick removal when in at-risk areas will help prevent tick-borne infections.
- Treatment of domestic animals for ticks as directed by veterinarian is recommended.
- Prompt and thorough cleansing of any scratches or bites from animal contacts is important in decreasing the risk of infection.

PROGNOSIS

- RMSF.
  - A delay of disease suspicion and treatment after the fifth day of illness is association with an increased risk of death.[15,16]
- Ehrlichiosis.
  - The case fatality rate is reported to be from 1 to 3 percent (*E. chaffeensis*) to <1 percent (*A. phagocytophilum*), although this may be overestimated because many individuals who are infected are asymptomatic.[17]
- Tularemia.
  - Suppuration of lymph nodes may occur despite adequate therapy.
- Cat-scratch disease.
  - Lymphadenopathy is usually self-limited and resolves over 1 to 2 months.
  - Suppuration of lymph nodes may occur in up to 25 percent of cases.
- Rat-bite fever.
  - The course of rat bite fever can be rapid and fatal.

PATIENT EDUCATION

Parents should seek medical attention if symptoms of infection develop after zoonotic exposures.

189 DIABETES OVERVIEW

Todd D. Nebesio, MD

PATIENT STORY

A 7-year-old girl presents with increased thirst and urination over the last 2 weeks. Despite previously being dry at night, she has wet the bed a few times over the past week. She has not been ill and has had a good appetite. She has had no abdominal pain or vomiting. Physical examination is remarkable for dry, tacky oral mucous membranes. Her weight is down 3 kg since her last well-child visit. A blood sugar is checked (**Figure 189-1**) on a meter and is “high” or too elevated to be read by the meter. A urinalysis shows positive glucose and ketones in his urine. A basic metabolic profile reveals sodium of 131 mEq/L, bicarbonate of 20 mEq/L, and plasma glucose of 652 mg/dL. Hemoglobin A1c is 10.8 percent. She is admitted to the hospital with the diagnosis of new onset diabetes. She is treated with intravenous fluids and insulin. While in the hospital, she is started on SQ insulin injections and she and her family receive diabetes education. With her age, the patient most likely has type 1 diabetes mellitus (T1DM).

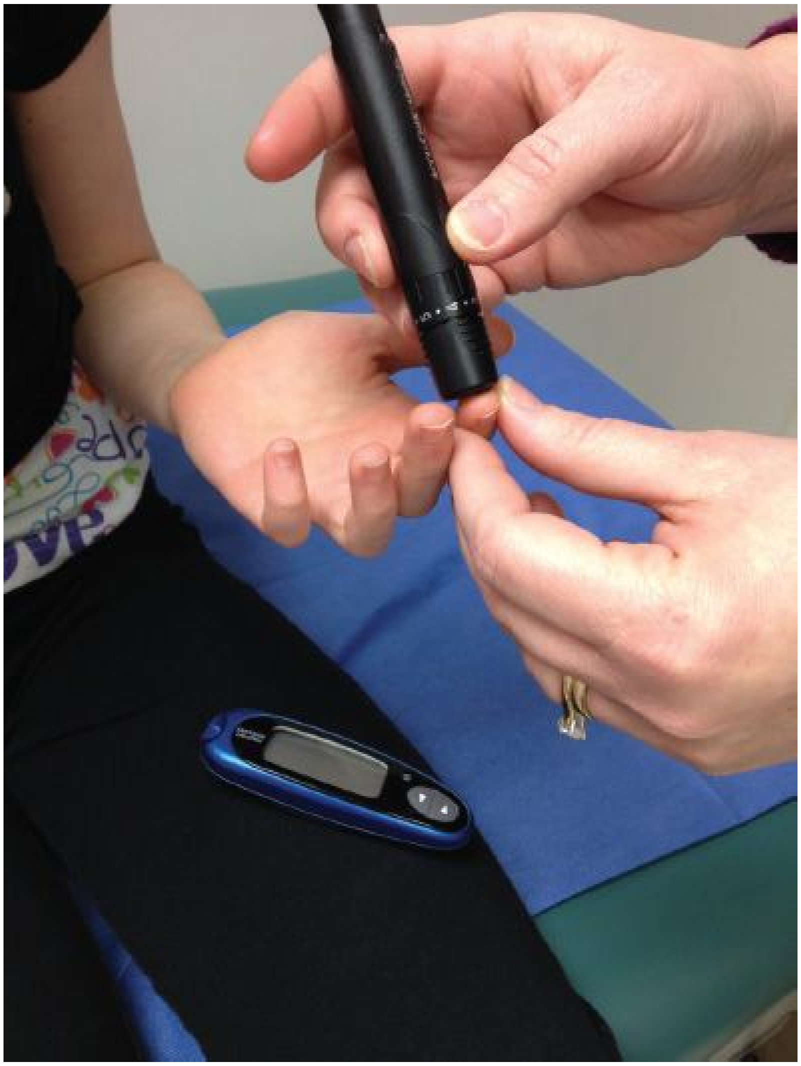

FIGURE 189-1 Blood sugar testing in a girl with suspected diabetes. (*Used with permission from Todd D. Nebesio, MD.*)

INTRODUCTION

The classic symptoms of new onset diabetes are polydipsia, polyuria, and unexpected weight loss.

SYNONYMS

T1DM has also been called insulin-dependent diabetes, juvenile-onset diabetes, and immune-mediated diabetes.

EPIDEMIOLOGY

- The incidence of T1DM is increasing by about 3 percent per year for unknown reasons.
- Less common forms of diabetes in children and adolescents include type 2 diabetes (T2DM), cystic fibrosis related diabetes (CFRD), steroid-induced diabetes, and rare genetic forms of diabetes.[11]
- The prevalence of T1DM in the US at 18 years of age is about 2 to 3 per 1,000 individuals.[2]
- Males and females are equally affected.
- There are two peaks in incidence of T1DM in children: as they start school (4 to 6 years) and early adolescence (10 to 14 years).
- The incidence of T2DM has also increased associated with the rise in childhood obesity. T2DM most often occurs in pubertal adolescents.

ETIOLOGY AND PATHOPHYSIOLOGY

- T1DM is due to autoimmune beta cell destruction in the pancreas resulting in absolute insulin deficiency.
- T2DM is due to insulin resistance and relative insulin deficiency.

RISK FACTORS

- There is an increased risk of developing T1DM if there is an already affected relative: 6 percent risk in a sibling; <50 percent chance in an identical twin; higher risk if the father has T1DM compared to a mother with T1DM.[2]
- Obesity, positive family history, ethnic minority, and evidence of insulin resistance are common risk factors for T2DM.

DIAGNOSIS

CLINICAL FEATURES

- Polyuria, polydipsia, polyphagia, and weight loss are the classic features of new onset diabetes.
- When presenting in diabetic ketoacidosis (DKA), additional features include nausea, vomiting, abdominal pain, mental status changes, and Kussmaul breathing.
- Acanthosis nigricans on the neck, axilla, or other skin folds is a sign of insulin resistance seen in T2DM and obese individuals (**Figure 189-2**; see Chapter 190, Acanthosis Nigricans). Genetic defects in insulin action can result in extreme insulin resistance (**Figure 189-3**).

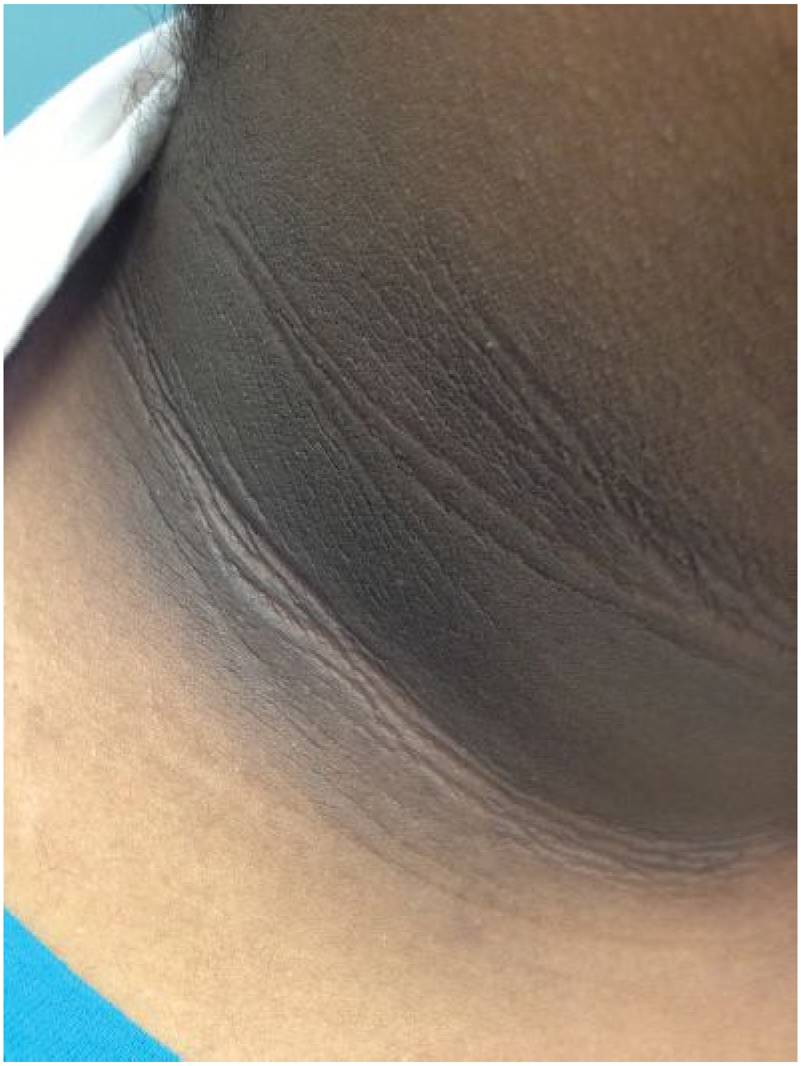

FIGURE 189-2 Acanthosis nigricans on the neck of an obese African American teenager with insulin resistance. (*Used with permission from Todd D. Nebesio, MD*.)

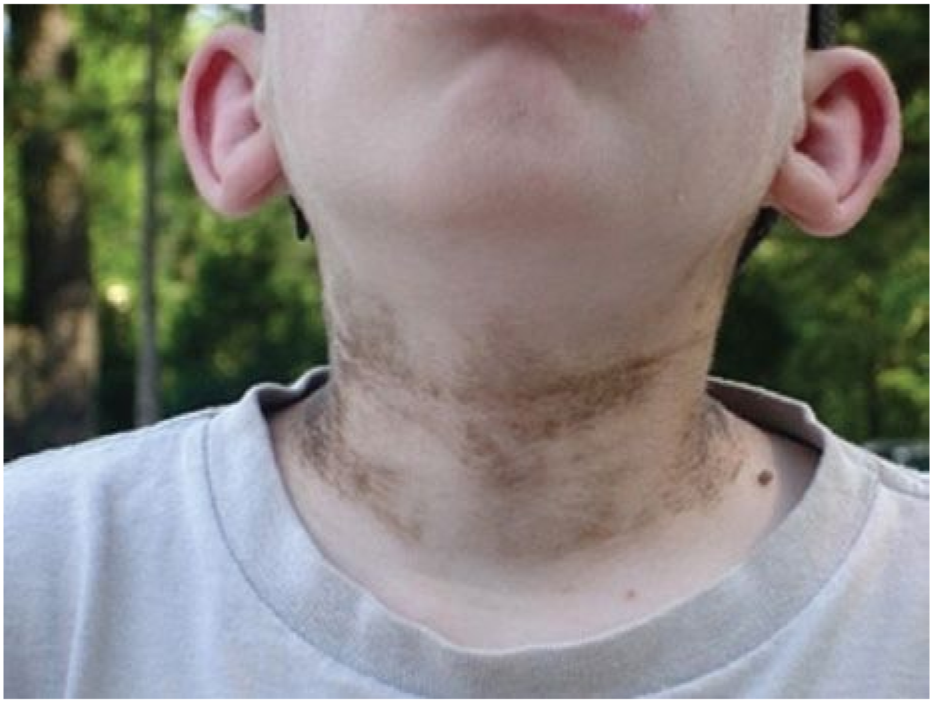

FIGURE 189-3 Severe insulin resistance and acanthosis nigricans in a child with Rabson-Mendenhall syndrome, which is due to defects in the insulin receptor gene. (*Used with permission from Todd D. Nebesio, MD*.)

- Necrobiosis lipoidica diabeticorum (NLD) is a rare skin condition occurring in <0.5 percent of diabetics and seldom seen in children (**Figure 189-4**).

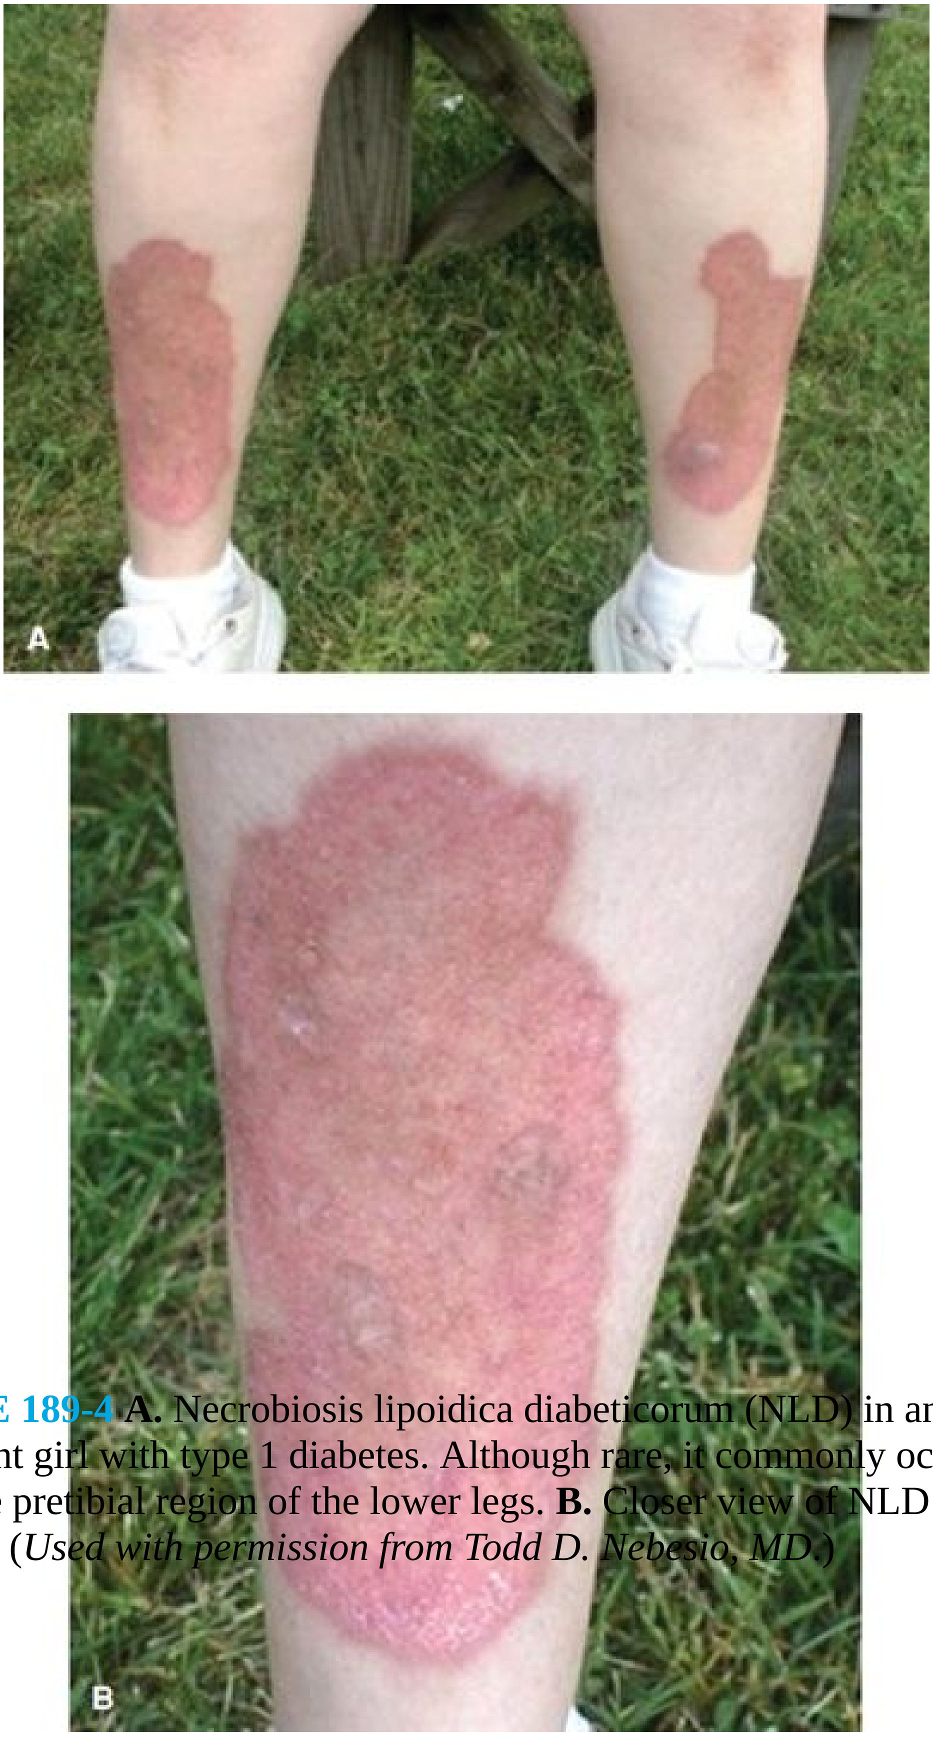

FIGURE 189-4 **A.** Necrobiosis lipoidica diabeticorum (NLD) in an adolescent girl with type 1 diabetes. Although rare, it commonly occurs along the pretibial region of the lower legs. **B.** Closer view of NLD on her right leg. (*Used with permission from Todd D. Nebesio, MD.*)

LABORATORY TESTING

- Criteria for the diagnosis of diabetes mellitus include symptoms of diabetes and a random plasma glucose ≥200 mg/dL, a fasting plasma glucose ≥126 mg/dL, a 2-hour plasma glucose ≥200 mg/dL during an oral glucose tolerance test (OGTT), or hemoglobin A1c ≥6.5 percent (3). If there are no classic symptoms of hyperglycemia, testing needs to be repeated on a second day.
- Fasting plasma glucose between 100 to 125 mg/dL indicates impaired fasting glucose (IFG) and 2-hour plasma glucose during an OGTT between 140 to 199 mg/dL indicates impaired glucose tolerance (IGT). IFG and IGT are pre-diabetic states and indicate a higher risk of developing diabetes in the future.
- Diabetes autoantibodies are commonly positive in T1DM but can also be seen in a small percentage of T2DM. Up to 25 percent of new onset patients with T1DM can be obese, which confuses the diagnosis between T1DM versus T2DM.[4,5]
- Glucosuria is present if the plasma glucose level is >180 mg/dL.
- Positive urine or blood ketones indicate insulin deficiency.
- Hyperglycemia causes pseudohyponatremia; for every 100 mg/dL increase in the plasma glucose above 100 mg/dL, a 1.6 mEq/L decrease occurs in the measured serum sodium level.
- Acidosis with a bicarbonate level <15 mEq/L indicates DKA, which is the most common cause of death in children with T1DM.

DIFFERENTIAL DIAGNOSIS

- In the setting of hyperglycemia and positive symptoms, the diagnosis is typically straightforward. However, differentiating the type of diabetes can sometimes be difficult.

- Differential for polyuria and polydipsia: diabetes mellitus, diabetes insipidus, psychogenic, hypercalcemia, hypokalemia, and hyperthyroidism.

MANAGEMENT

NONPHARMACOLOGIC

- Nutrition and meal planning is important in diabetics to maintain normal weight and growth.
- Physical fitness and regular exercise potentiates the action of insulin.
- Blood sugar testing is typically performed at least 4 times per day, specifically before meals and at bedtime (**Figure 189-5**).
- Blood or urine ketones are checked if the blood sugar is repeatedly elevated or the patient is sick, feels nauseated, or is vomiting, or has abdominal pain.

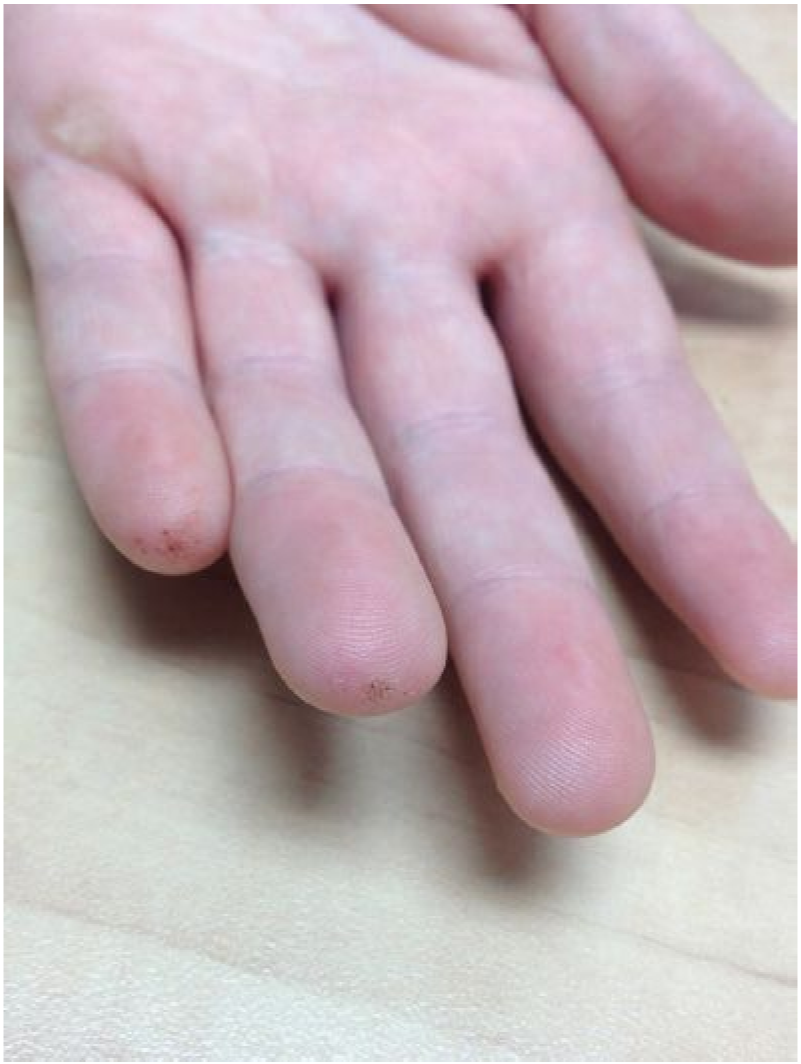

FIGURE 189-5 Evidence of blood sugar testing at the ends of the fingers in a teen with type 1 diabetes. (*Used with permission from Todd D. Nebesio, MD.*)

MEDICATIONS

- Insulin is the initial management in children with diabetes. Injection sites, including the arms, thighs, abdomen, hips, and buttocks, need to be rotated to avoid localized areas of hypertrophy (**Figure 189-6**).

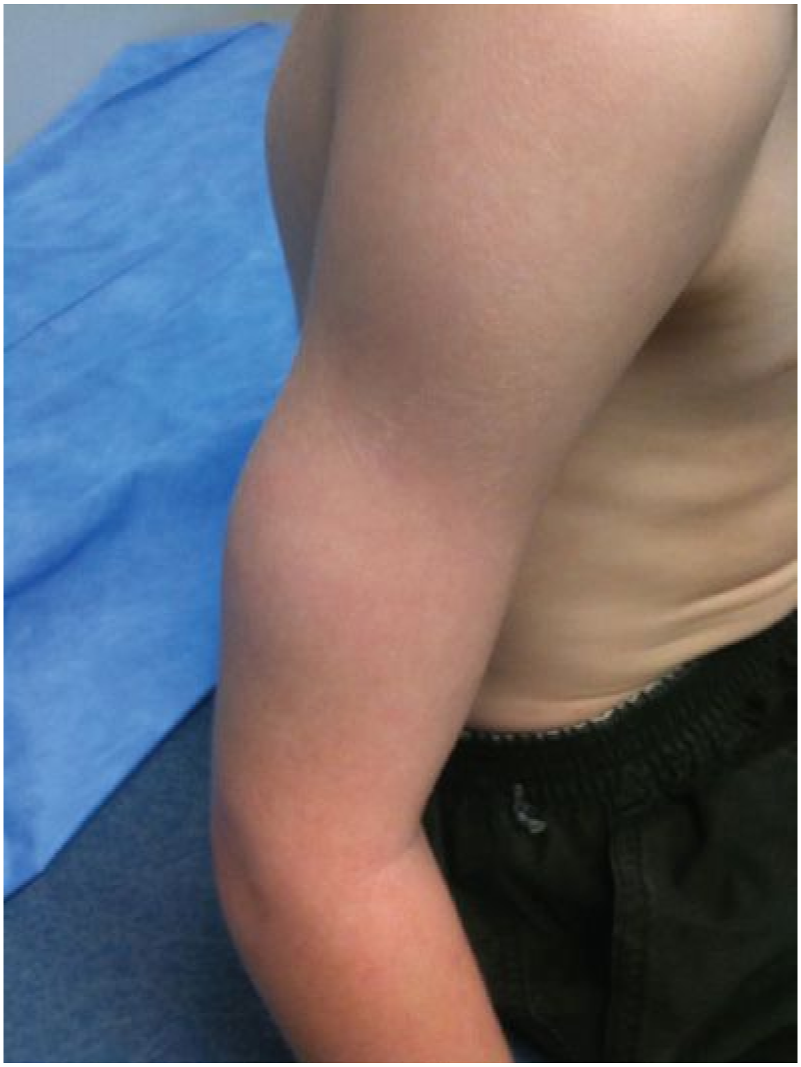

FIGURE 189-6 Repeated insulin injections in the same location on the arm can cause hypertrophy, which results in slow and erratic insulin absorption. (*Used with permission from Todd D. Nebesio, MD.*)

- Rapid-acting insulin is given at meal times for food coverage and correction of the blood sugar to a certain goal level.
- Long-acting or basal insulin is given once or twice a day and suppresses ketone body production.
- Metformin is an oral medication used in patients with T2DM.

COMPLIMENTARY THERAPY

- Insulin pumps continuously deliver rapid short-acting insulin through a pump site that is changed every 2 to 3 days (**Figure 189-7**).

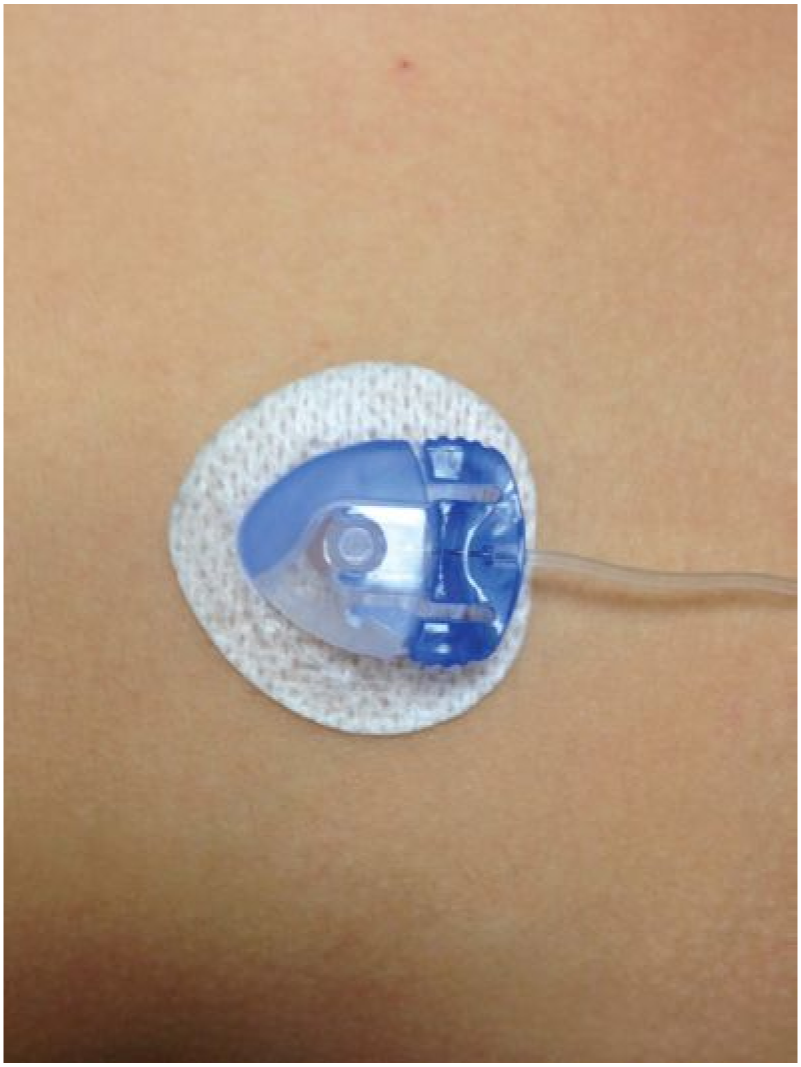

FIGURE 189-7 An insulin pump site. At the top is where a previous pump site was placed. (*Used with permission from Todd D. Nebesio, MD.*)

PREVENTION AND SCREENING

- Prevention of T1DM at this time is not possible.

- In overweight and obese children with signs of insulin resistance and a positive family history of T2DM, lifestyle intervention can prevent the development of T2DM.
- Screening in asymptomatic children with positive risk factors of developing T2DM should begin at 10 years or at the onset of puberty and then every 3 years.[6]

PROGNOSIS

- Blood sugar ranges and hemoglobin A1c targets vary with age.[6,7]
- In very young children with T1DM, significant hypoglycemia can potentially lead to neuropsychological impairment.[7]
- The most common cause of a known diabetic presenting in DKA is from not taking their insulin injections.
- Chronic complications from hyperglycemia include growth problems, nephropathy, retinopathy, and neuropathy.[2,5,7] Diabetes complications are decreased with intensive therapy and improved blood sugar control.[8]
- In T1DM, there is an increased risk of other autoimmune diseases, most commonly thyroid disease and celiac disease.

FOLLOW-UP

- Hemoglobin A1c, height, weight, and blood pressure are checked every 3 months at clinic visits.
- Dilated eye exam should be done yearly after having T1DM for 5 years or after the age of 10 years; an eye exam should be done shortly after diagnosis of T2DM.
- Periodic screening for other conditions and co-morbidities: hypertension, dyslipidemia, microalbuminuria, psychiatric disorders (e.g., depression

and eating disorders), hepatic steatosis (in T2DM), and hypothyroidism and celiac disease (in T1DM).

PATIENT EDUCATION

- Lifestyle interventions such as dietary measures and exercise can prevent and control the onset and course of T2DM.
- New onset diabetics and their families need education regarding nutrition, exercise, and blood sugar testing.

190 ACANTHOSIS NIGRICANS

Mindy A. Smith, MD, MS

PATIENT STORY

A 10-year-old girl with obesity and recently diagnosed type II diabetes mellitus (DM) presents to her pediatrician with concerns about a “dirty area” under her arms and on her neck that “couldn’t be cleaned” (**Figure 190-1**). The pediatrician makes the diagnosis of acanthosis nigricans and explains to the mother the importance of weight loss, good diet, and exercise. She uses this as a teachable moment to explain how the obesity and diabetes are adversely affecting the daughter and how this is visible on the skin. The role of genetics is discussed too but there is emphasis on the risk factors that can be altered.

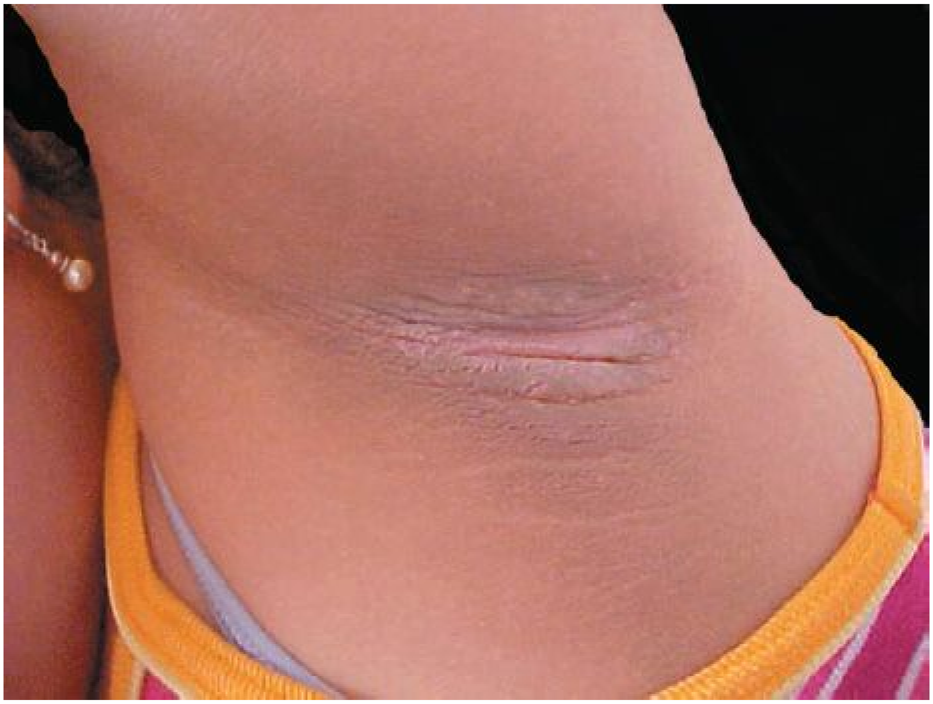

FIGURE 190-1 Acanthosis nigricans in the left axilla of an overweight Hispanic 10-year-old girl. Note areas of dark velvety discoloration and pink filiform hypertrophy. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

- Acanthosis nigricans (AN) is a localized form of hyperpigmentation that involves epidermal alteration. AN is associated with insulin resistance and usually seen in patients with endocrine disorders (e.g., type 2 DM, Cushing syndrome, acromegaly), obesity, and polycystic ovary syndrome.

EPIDEMIOLOGY

- In a cross-sectional study conducted in a southwestern practice-based research network (N = 1133), AN was found in 17 percent of children and 21 percent of adults.[1]
- In two studies, AN was present in 36 percent of patients with newly diagnosed DM and 39 percent of children with obesity.[2,3] AN prevalence rates have been reported to be as high as 60 to 92 percent of black and Hispanic children with diabetes.[4]
- AN has been reported in children with Wilms' tumor and osteogenic sarcoma.[4]
- A condition of hyperandrogenism (HA), insulin resistance (IR), and acanthosis nigricans (AN) called HAIR-AN syndrome is a subphenotype of the polycystic ovary syndrome (**Figure 190-2**).[5–7] It is one of the most common causes of menstrual problems, hyperandrogenic symptoms, and insulin resistance among adolescent patients.[6] In one series of patients with HAIR-AN in an adolescent clinic, the mean age of affected patients was 15.5, initial mean weight at diagnosis was 94.5 kg, and the mean BMI was 33 kg/2.6 m.

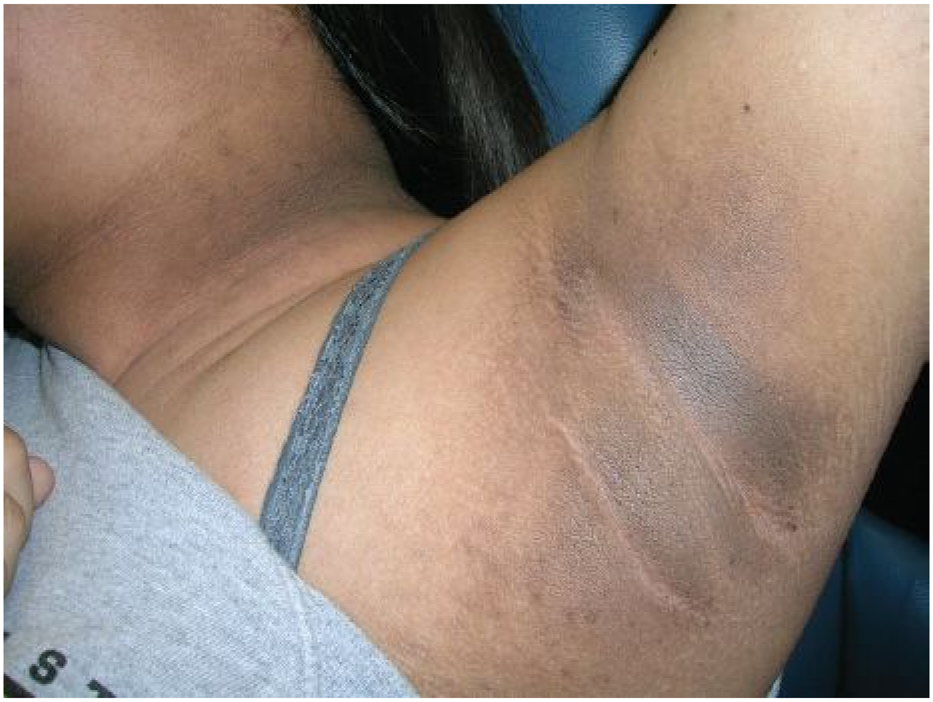

FIGURE 190-2 Acanthosis nigricans on the neck and in the axilla of an overweight 13-year-old Hispanic female with insulin resistance, hirsutism, and secondary amenorrhea. She was diagnosed with HAIR-AN syndrome and treated accordingly. (*Used with permission from Richard P. Usatine, MD*.)

- AN can be an adverse effect from hormonal therapies.[8]

ETIOLOGY AND PATHOPHYSIOLOGY

- AN results from long-term exposure of keratinocytes to insulin and is an indicator of insulin sensitivity independent of body mass index (BMI).[4]
- Type A IR appears responsible for producing AN in patients who are obese and Type B resistance, mediated by antibody formation against insulin receptors, appears to cause AN in patients with other autoimmune diseases.[4]
- Keratinocytes have insulin and insulin-like growth receptors on their surface and the pathogenesis of this condition is linked to insulin binding

to insulin-like growth receptors in the epidermis.

- Fibroblast growth factor receptor 3 (FGFR3) gene mutations should be considered in patients with coexistent AN and skeletal dysplasia (e.g., thanatophoric dysplasia, severe achondroplasia with developmental delay and AN [SADDAN syndrome], and Crouzon syndrome with AN);[9,10] in these patients, IR does not appear to be the mechanism in producing AN.[10] Insulin receptor mutations have also been described.[4]
- Malignant AN likely occurs as a result of tumor cell expression of peptides that enhance proliferation of transforming growth factor-α and epidermal growth factor.[4]

DIAGNOSIS

The diagnosis of AN is made clinically in a patient with or at risk for IR who has the characteristic lesions.

CLINICAL FEATURES

- AN ranges in appearance from diffuse streaky thickened brown velvety lesions to leathery verrucous papillomatous lesions (**Figures 190-1** to **190-6**).
- Women with HAIR-AN syndrome have evidence of virilization (e.g., increased body hair in male distribution, enlarged clitoris) in addition to AN.[6]
- There is a significant correlation between AN and obesity (**Figures 190-3** and **Figure 190-4**) and hypertension.[11]

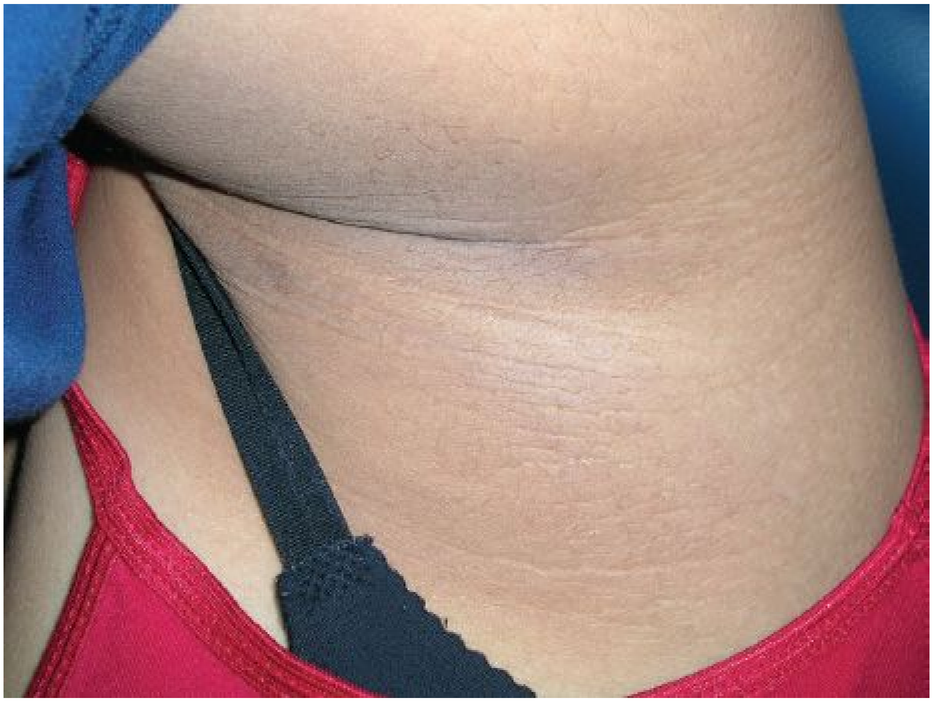

FIGURE 190-3 Acanthosis nigricans in the axilla of an 11-year-old obese Hispanic girl. (*Used with permission from Richard P. Usatine, MD.*)

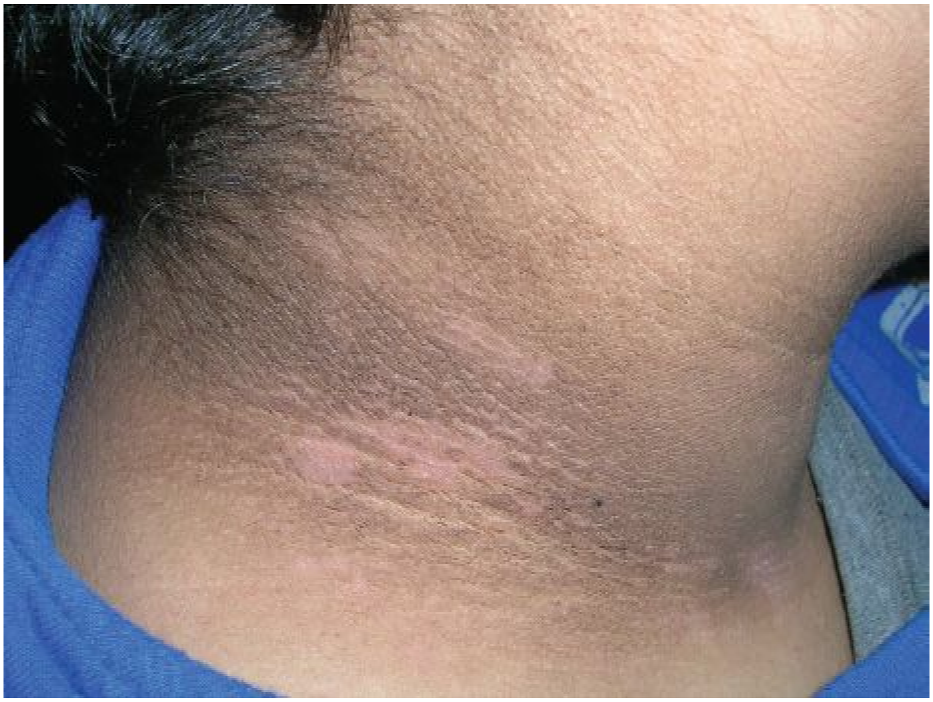

FIGURE 190-4 Acanthosis nigricans on the neck of a 15-year-old obese Hispanic male. (*Used with permission from Richard P. Usatine, MD.*)

TYPICAL DISTRIBUTION

- Commonly located on the neck (**Figures 190-4** to **190-6**) or skin folds (i.e., axillae [**Figures 190-1** to **190-3**], inframammary folds, groin, and perineum).

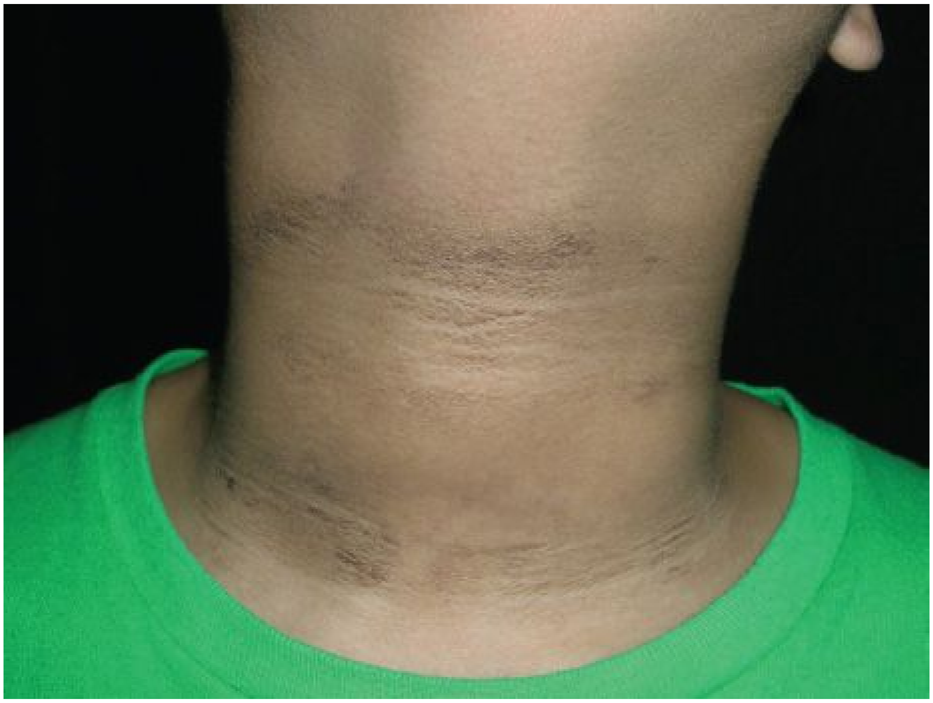

FIGURE 190-5 Acanthosis nigricans on neck of a 12-year-old African American boy with a strong family history of diabetes. Note that this child is not overweight and currently does not have diabetes. The acanthosis nigricans makes the neck appear dirty but this child has very good hygiene. (*Used with permission from Richard P. Usatine, MD.*)

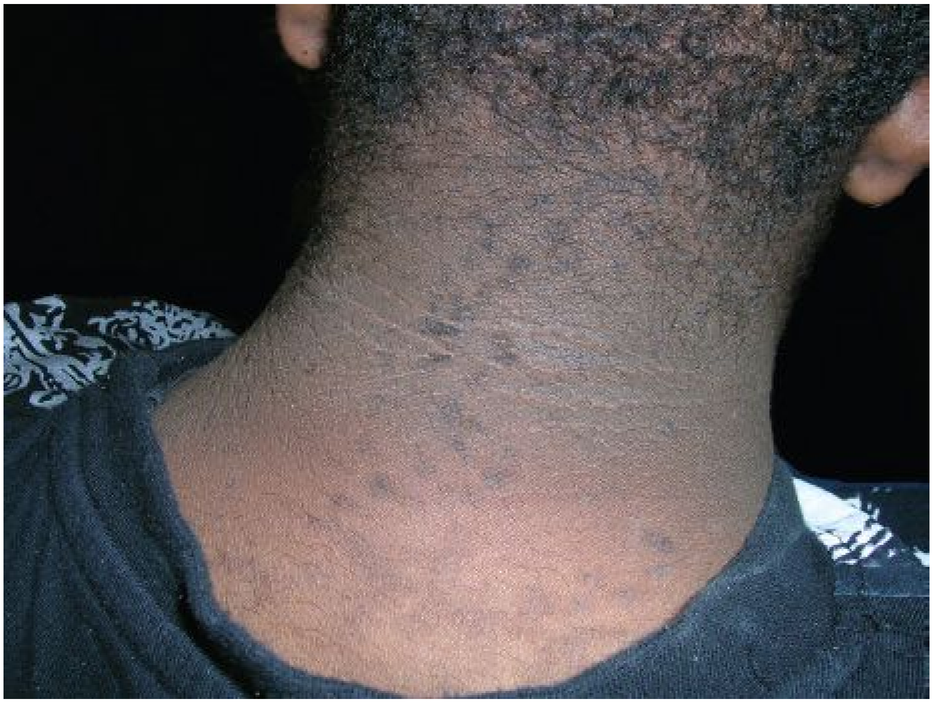

FIGURE 190-6 Acanthosis nigricans on the neck of a 15-year-old boy with no obesity or diabetes. His mother has very prominent acanthosis nigricans. (*Used with permission from Richard P. Usatine, MD.*)

- Less often AN is seen on the nipples or areolae, perineum, groin, and extensor surfaces of the legs.[6]
- Verrucous AN can affect the eyelids, lips, and buccal mucosa.[6]
- In patients with malignancy, the onset of AN can be abrupt and the distribution of lesions is more widespread and may include the periorbital skin and the palms and soles.[12]

BIOPSY

- Biopsy is rarely needed in unusual cases.
- Histologic examination reveals hyperkeratosis and papillary hypertrophy, although the epidermis is only mildly thickened.[13]

DIFFERENTIAL DIAGNOSIS

Other hyperpigmented lesions that may be confused with AN include:

- On the neck, AN can be confused with tinea corporis (see Chapter 123, Tinea Corporis) or atopic dermatitis (see Chapter 130, Atopic Dermatitis).
- Ichthyosis hystrix, a rare form of ichthyosis, can cause massive hyperkeratosis that can resemble AN; distinguishing features are greater body distribution including palmar and plantar keratoderma and resolution in the summer months.[4]
- There is also a rare AN form of epidermal nevus that shows histopathological evidence of both lesions (see Chapter 145, Epidermal Nevus and Nevus Sebaceous for additional information on epidermal nevi).[14]

MANAGEMENT

NONPHARMACOLOGIC

- Children with AN are at higher risk of metabolic syndrome, and lipid screening should be considered along with consideration of testing for DM. There is controversy about whether children should be screened for AN as marker for early detection of diabetes mellitus. In a cohort of Native American youth (N = 161), BMI was a more sensitive marker for insulin resistance although less specific than AN,[15] and the Centers for Disease Control and Prevention do not recommend screening for AN. The American Academy of Pediatrics recommends screening children with obesity for hyperlipidemia and hyperglycemia.[16]
- Treat the underlying cause, if identified. Weight loss through diet and exercise helps reverse both IR and compensatory hyperinsulinemia and

can improve the condition in obese patients.

- Resolution of AN also occurs with removal of the associated malignancy or associated drug in drug-induced AN.[4]

MEDICATIONS

- Keratolytic agents (e.g., salicylic acid) can improve the cosmetic appearance. Other topical therapies, including 0.1 percent tretinoin cream (to lighten the lesion), combination tretinoin cream with 12 percent ammonium lactate cream, or topical vitamin D ointments,[17] may be useful.[6] SOR Ⓒ
- Metformin[18] and octreotide have also been used to manage AN. SOR Ⓒ
- Adolescent girls with HAIR-AN were treated with a diet, exercise, oral contraceptive pills, and metformin (in most cases) in one large series.[6] All the girls who took their oral contraceptive pills began to have regular menstrual periods and their acne and/or hirsutism improved or remained unchanged. Only 20 percent of the adolescents had improvement in their acanthosis nigricans with treatment.[6]

COMPLEMENTARY AND ALTERNATIVE THERAPY

- The use of omega-3-fatty acid and dietary fish oil supplementation has also been reported to improve AN.[19] SOR Ⓒ

PROGNOSIS

- AN may regress when the underlying condition (e.g., diabetes, HAIR-AN syndrome, malignancy) is treated.[6] However, in one series of girls with

HAIR-AN syndrome, only 20 percent of the adolescents had improvement in their acanthosis nigricans with treatment.[6]

PATIENT EDUCATION

- Patients who are overweight should be encouraged to lose weight through diet and exercise because weight loss may help diminish this condition.

191 HYPOTHYROIDISM

Mindy A. Smith, MD, MS

PATIENT STORY

A 6-week-old girl, who was born at home and was not screened at birth for congenital hypothyroidism, presented to her pediatrician with signs of jaundice and was found to be hypothyroid with an elevated TSH (**Figure 191-1**). She was started on levothyroxine and her dose was titrated until her TSH was normal. At her 1 year old visit she was a normal healthy child with a normal developmental exam.

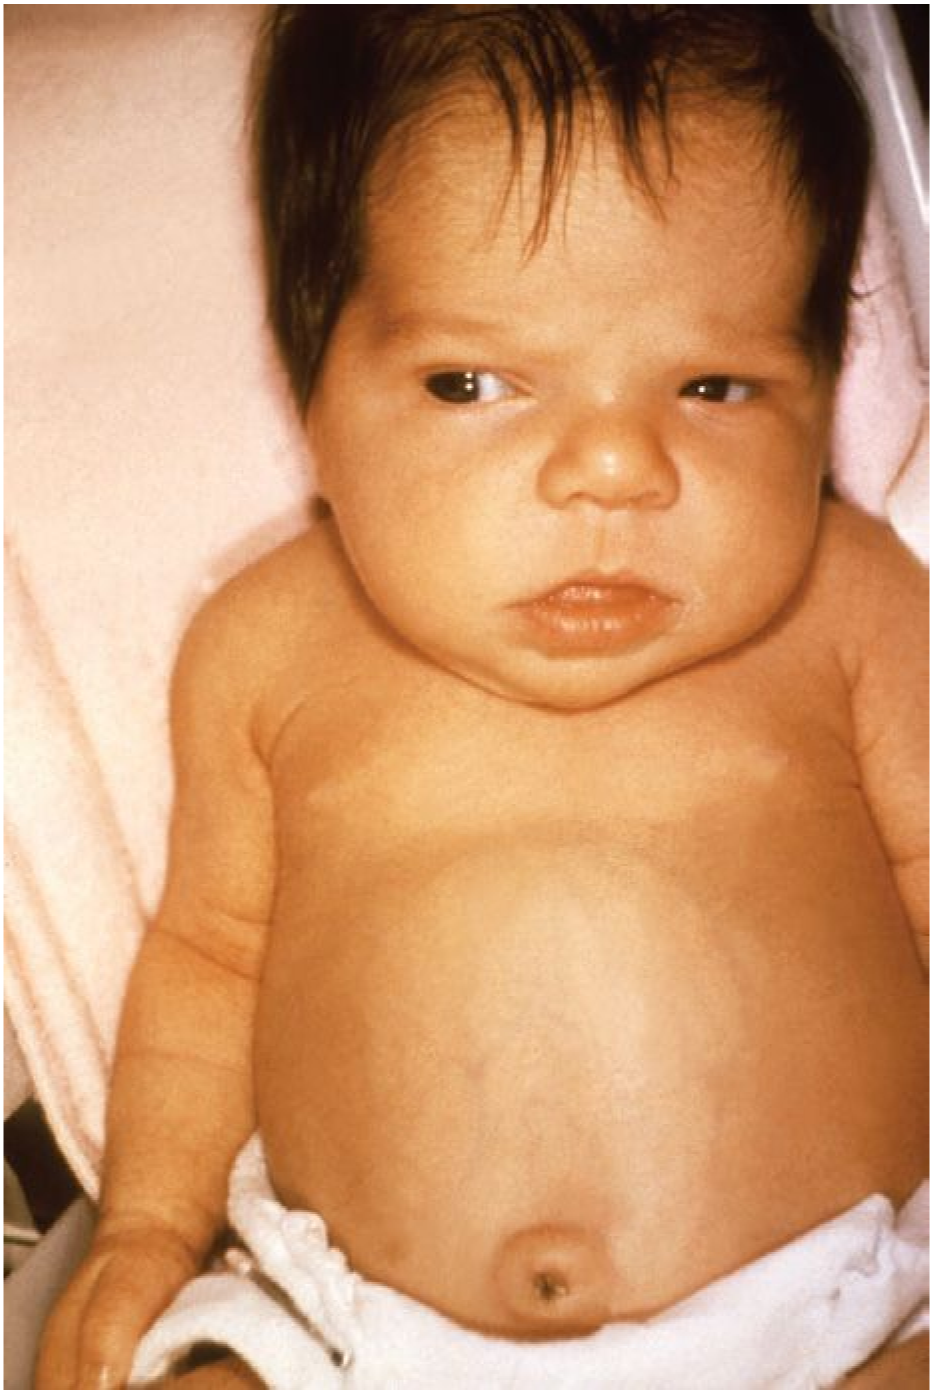

FIGURE 191-1 Congenital hypothyroidism in a 6-week-old girl with signs of jaundice and an elevated TSH. (*Used with permission from the CDC/Dr. Hudson*.)

INTRODUCTION

- Hypothyroidism is a condition caused by lack of thyroid hormone and usually develops as a result of thyroid failure from intrinsic thyroid disease. The most common cause of nonendemic goitrous hypothyroidism in both children and adults is chronic lymphocytic (Hashimoto) thyroiditis, also called autoimmune thyroiditis.[1]
- Congenital hypothyroidism (CH) is decreased or absent thyroid function and thyroid hormone production that is present at birth. Historically this was due to lack of iodine. In iodine-replete countries, most cases of CH are caused by defects in embryonic development (e.g., congenitally absent, underdeveloped, or ectopic thyroid gland). Other causes include inherited enzymatic defects in the synthesis of thyroxine (T_4), prematurity, and anti-thyroid drugs taken during pregnancy.
- Goiter is a spectrum of changes in the thyroid gland ranging from diffuse enlargement to nodular enlargement depending on the cause. In the US, the most common cause of goiter with normal thyroid function or transient dysfunction is thyroiditis.
- Subclinical thyroid disease refers to a patient with no or minimal thyroid-related symptoms but abnormal laboratory values (elevated TSH and thyroxine level within the normal range).

EPIDEMIOLOGY

- Based on a population study in Scotland, the prevalence of hypothyroidism in children (<22 years of age) is 0.135 percent; the prevalence is 0.113 percent in children aged 11 to 18 years.[2] These values are twice those of previous estimates. The most common cause of acquired hypothyroidism was autoimmune disease.
- CH occurs in about 1 per 3000 to 4000 births in the US with a female to male ratio of 2: 1. It is the most preventable cause of cognitive impairment in children.[3] There is a higher incidence of CH in some ethnic groups such as Greek Cypriots (1 per 1800) and Asians (1 per 918 in Northern England).[4,5]

- In a New Zealand population study, the overall incidence of CH rose from 2.6 to 3.6 per 10,000 live births over an 18-year period thought to be due to a shift in population with proportionately more Asian and Pacific Island births.[6]
- Worldwide, goiter is the most common endocrine disorder with rates of 4 to 15 percent in areas of adequate iodine intake and more than 90 percent where there is iodine deficiency.[7]Endemic goiter is defined as goiter that affects more than 5 percent of the population (**Figure 191-1**).
- Most goiters are not associated with thyroid dysfunction.
- The prevalence of goitrous hypothyroidism varies from 0.7 to 4 percent of the population. Among adolescents, the incidence of Hashimoto thyroiditis during adolescence is approximately 1 to 2 percent.[3]
- Subclinical hypothyroidism is present in 3 to 10 percent of population groups.[8,9]
- Prevalence rates of hypothyroidism and subclinical hypothyroidism are higher for children with certain conditions including Down syndrome (10.8% of children with Down syndrome in one 11-year population study filled a new prescription for thyroid medication),[10] Turner syndrome, type 1 diabetes mellitus (7.2% of children in one study had subclinical hypothyroidism),[11] celiac disease, and cystic fibrosis (CF) (108/129 children with CF in one study were iodine deficient and 11.6 percent had subclinical hypothyroidism).[12] Autoimmune thyroid disease is also more common in individuals with vitiligo. In a recent report of 104 Iranian children age 5 to 15 years referred with migraine headache, 24 percent had subclinical hypothyroidism.[13]

ETIOLOGY AND PATHOPHYSIOLOGY

Hypothyroidism can be caused by disease of the thyroid gland itself (e.g., Hashimoto thyroiditis or thyroid dysgenesis), treatment of hyperthyroidism (e.g., anti-thyroid medication or radioiodine thyroid ablation in the patient or mother during pregnancy, or thyroidectomy), high-dose head and neck radiation therapy, medications (e.g., lithium or alpha-interferon) or, rarely, by pituitary or hypothalamic disorders (e.g., tumors, inflammatory conditions, infiltrative diseases, infections, pituitary surgery, pituitary radiation therapy, and head trauma).[8]

Hashimoto thyroiditis is caused by thyroid peroxidase (TPO) antibodies.

- There is marked lymphocytic infiltration of the thyroid in Hashimoto thyroiditis; the infiltrate is composed of activated CD4+ and CD8+ T cells, as well as B cells.
- Thyroid destruction in Hashimoto thyroiditis is believed to be primarily mediated by CD8+ cytotoxic T cells.

CH can be either permanent or temporary.

- Permanent causes include defective embryonic development resulting in congenitally absent, underdeveloped, or ectopic thyroid gland (85%); inherited enzymatic defect in the synthesis of thyroxine (T4) caused by an autosomal recessive gene (10%); abnormal function of hypothalamus or pituitary, or thyroid hormone resistance (<5%). In the New Zealand study previously cited, of 330 new cases of CH over an 18-year period, 86 percent of cases had a scintiscan of which 67 percent showed thyroid dysgenesis (female to male ratio 5:1), and 33 percent demonstrated dyshormonogenesis (female to male ratio 0.9:1.0).[6]
- About 2 percent of thyroid dysgenesis is familial. In one case series, TSHR was found to be the main causative locus in autosomal recessively inherited thyroid dysgenesis.[14]
- Among cases of temporary hypothyroidism, causes include antithyroid drugs taken during pregnancy, prematurity, and iodine deficiency or excess.

Contributing factors for goiter are:

- Iodine deficiency or excess (**Figures 191-2** and **Figure 191-3**).

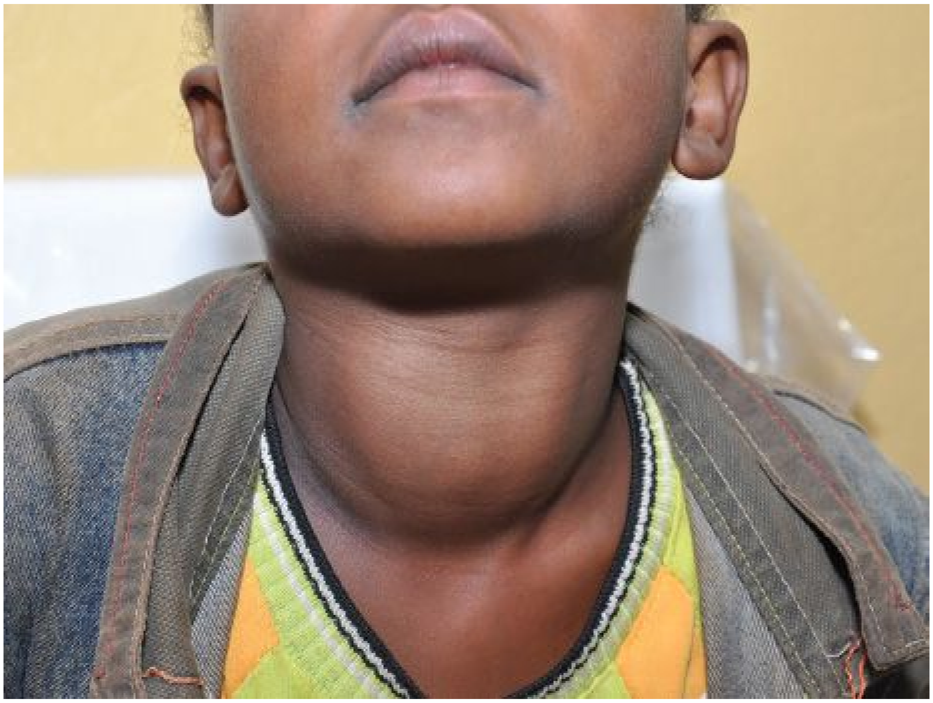

FIGURE 191-2 Goiter developing in a 12-year-old girl in an endemic area for goiters. (*Used with permission from Richard P. Usatine, MD*.)

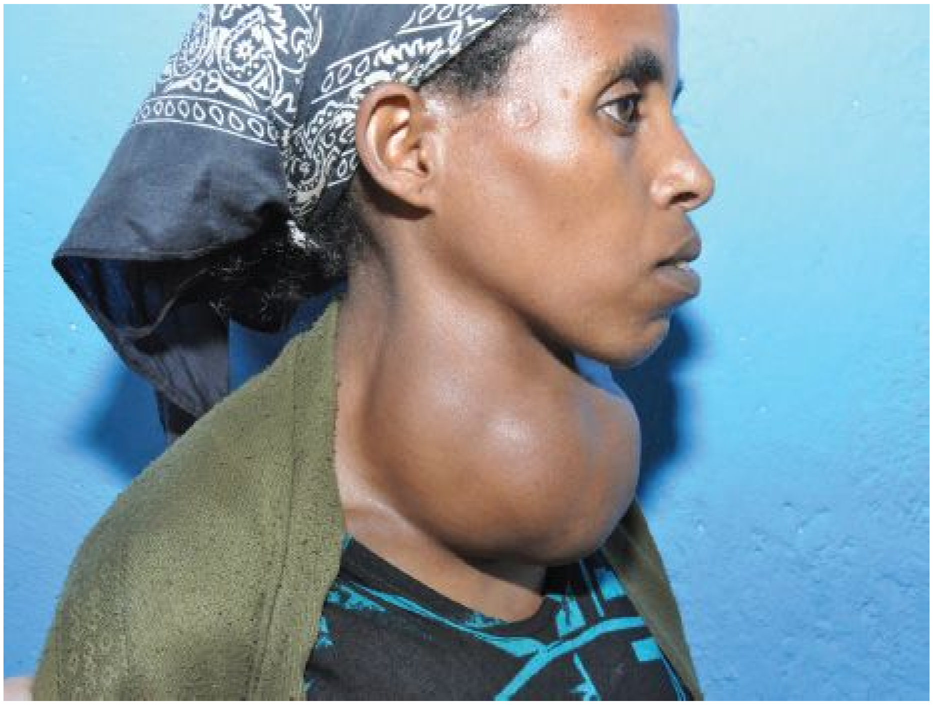

FIGURE 191-3 Massive goiter in an Ethiopian woman who lives in an endemic area for goiters. Many adults have large goiters in Ethiopia where

there is little iodine in their diets. (*Used with permission from Richard P. Usatine, MD.*)

- TSH stimulation.
- Drugs, including lithium, amiodarone, anticonvulsants, and α-interferon.
- Autoimmunity/heredity.

RISK FACTORS

Other risk factors for hypothyroidism include[2]:

- Symptoms of thyroid hormone deficiency.
- Goiter.
- Personal or family history of thyroid disease.
- Personal treatment of thyroid disease.
- History of an autoimmune disease, especially diabetes mellitus.

DIAGNOSIS

CLINICAL FEATURES

Many children with autoimmune thyroiditis are asymptomatic at diagnosis.[15] Classic signs and symptoms of hypothyroidism are[3]:

- A decrease in linear growth.
- Fatigue and/or weakness.
- Dry and cool skin (**Figure 191-4**).

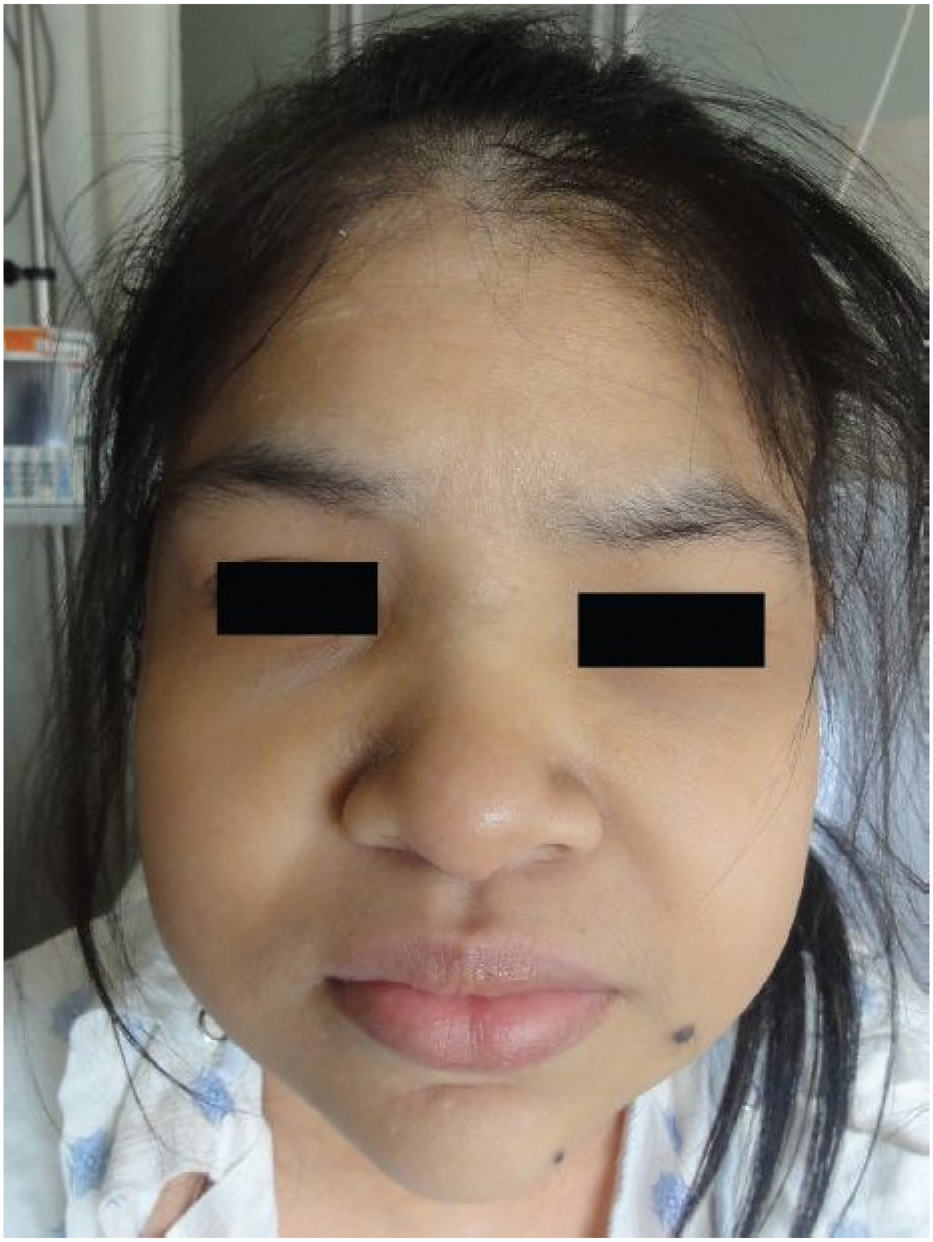

FIGURE 191-4 Myxedema with puffiness of the face, dry skin, some hair loss of the scalp, and eyebrows. (*Used with permission from the University of Texas Health Sciences Center, Division of Dermatology*.)

- Increased body hair.
- Difficulty concentrating with poor school performance.

- Bradycardia.
- Delayed deep tendon reflex relaxation.
- Weight gain despite poor appetite.
- Constipation.
- The most useful signs in adults for diagnosing hypothyroidism in one study were puffiness (likelihood ratio positive [LR+] 16.2) and delayed ankle reflex (LR+ 11.8).[16]
- Clues to a central cause of hypothyroidism include a history of pituitary/hypothalamic surgery or radiation, headache, visual field defects, or ophthalmoplegia.[8]

Among infants with CH, the vast majority (95%) has few clinical manifestations.[3] Features suggestive of CH include:[3]

- An open posterior fontanelle in a term baby.
- Lethargy or hypotonia.
- Hoarse cry.
- Feeding problems or macroglossia.
- Constipation.
- Umbilical hernia (**Figure 191-5**).

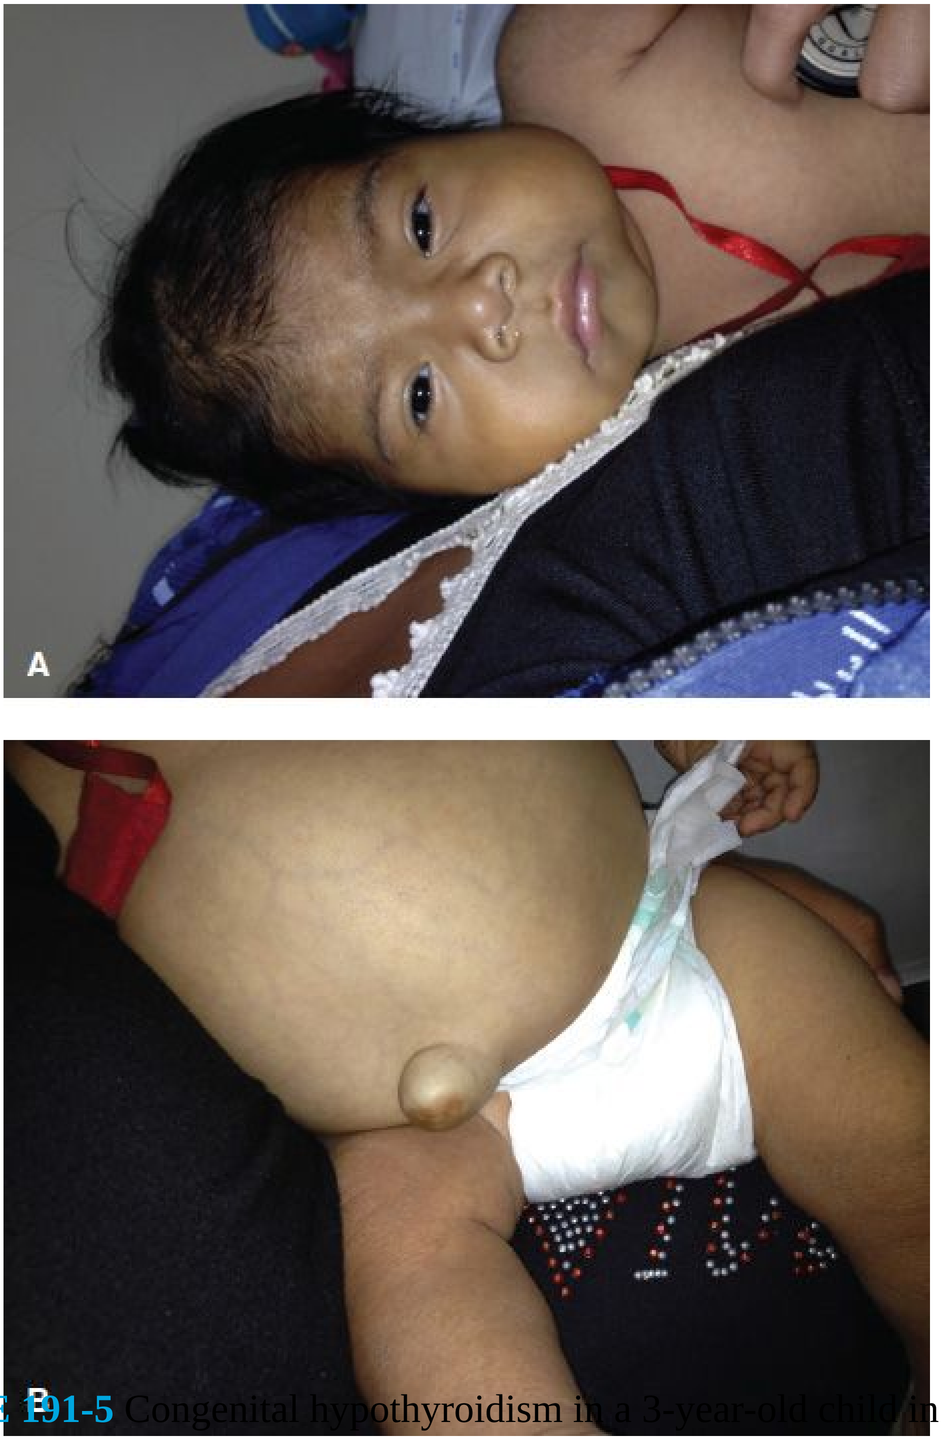

FIGURE 191-5 Congenital hypothyroidism in a 3-year-old child in Peru. The child was developmentally delayed and was not diagnosed until a medical mission team provided access to health care for this child. **A.** Note the puffiness of the cheeks and the increased facial hair on the forehead. **B.** Note the persistent umbilical hernia and the fact that the child is still in diapers. (*Used with permission from Sangeeta Krishna, MD*.)

- Dry skin.
- Hypothermia.
- Prolonged jaundice.

Features of goiter are:

- A painful neck mass is usually a form of thyroiditis.
- Large goiters are easily visible before palpating the neck (**Figures 191-2** and **191-3**). In a case series of children with autoimmune thyroiditis (N = 61), the vast majority of patients had a goiter; approximately half were euthyroid (N = 29), nine had hypothyroidism and seven had hyperthyroidism.[17]
- Physical examination maneuvers that help detect goiter are neck extension (**Figure 191-6**), observation from the side, palpation by locating the isthmus first, and having the patient swallow.[18]

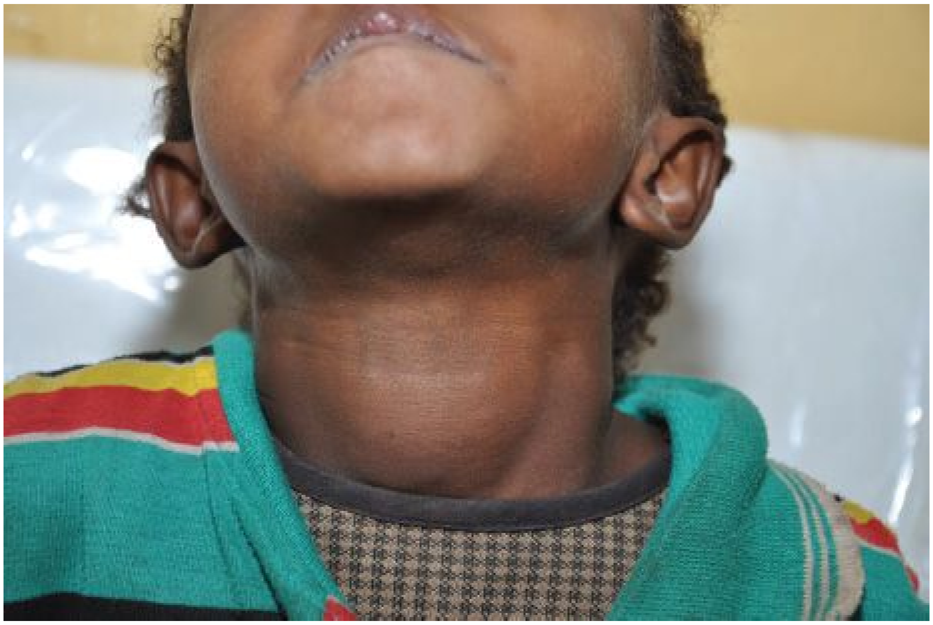

FIGURE 191-6 Child with goiter and kwashiorkor (protein malnutrition) in Africa. Note how the goiter is easily visible when she extends her neck. (*Used with permission from Richard P. Usatine, MD.*)

- Asymmetric goiters can shift the trachea away from the midline.

LABORATORY AND IMAGING STUDIES

Laboratory tests include an erythrocyte sedimentation rate (ESR) if thyroiditis is suspected, and TSH (elevated in hypothyroidism and subclinical disease) and FT_4 levels (low in hypothyroidism).

- In acute granulomatous thyroiditis, ESR is >50 (LR+ 95) and the TSH and FT_4 are usually normal.
- In primary hypothyroidism, the TSH is >10 mU/L (LR+ 16) and FT_4 is <8 (LR+ 11).
- Based on several case series, about half of children with autoimmune thyroiditis are euthyroid at diagnosis.[15,17]
- The presence of antibodies to TPO and thyroglobulin help establish the diagnosis of Hashimoto thyroiditis but is unnecessary for treatment. TPO antibodies will be positive in 90 to 95 percent of adult patients and the majority of children.[3,15]
- Confirming a positive neonatal screening result with formal thyroid function testing is a matter of urgency.[19] SOR Ⓐ
- Thyroid imaging with radionuclide scan for children with CH along with ultrasound will identify thyroid dysgenesis (accounts for 85% of cases). Radionuclide scintigraphy is considered the ‘gold standard’ for visualizing ectopic thyroid tissue. In one study (N = 174 screening-referred infants),151 had normally located thyroid on scintigraphy, ultrasound was found to be 95.8 percent sensitive (95% CI, 76.8 to 99.7), and 99.3 percent specific (95.8 to 100) for absence of normal thyroid.[20]
- In pituitary causes of hypothyroidism (central hypothyroidism), the TSH may be normal or elevated but FT_4 will be low.[8]
- In the future, reference limits may need to change as TSH distribution and reference limits have been shown to shift to higher concentrations with age and are unique for different racial/ethnic groups.[21]

DIFFERENTIAL DIAGNOSIS

Goiter presenting as a painful neck mass is most commonly caused by subacute granulomatous (de Quervain) thyroiditis (likely viral) or hemorrhage into a thyroid cyst or adenoma. Other causes include the following:

- Painful Hashimoto thyroiditis—Hypothyroidism with the presence of antibodies helps to confirm this diagnosis.
- Infected thyroglossal duct or branchial cleft cyst—Mass palpates as cystic and may be fluctuant; focal (e.g., erythema and warmth) and systemic symptoms of infection (e.g., fever) may be present. Even a noninfected thyroglossal duct cyst can be confused for an enlarged thyroid.
- Acute suppurative thyroiditis (microbial)—Focal (e.g., erythema and warmth) and systemic symptoms of infection (e.g., fever) are usually present.

Painless goiter and hypothyroidism are most often caused by Hashimoto thyroiditis, but may also be caused by the following:

- Environmental goitrogens (e.g., excess iodine, foods such as cassava, cabbage, and soybeans).
- Iodine deficiency.
- Pharmacologic inhibition (rare)—Drugs include lithium, amiodarone, and interferon-a.

Painless goiter and hyperthyroidism may be caused by the following:

- Graves disease—Symptoms of nervousness, fatigue, weight loss, heat intolerance, palpitations, and exophthalmus (Chapter 192, Hyperthyroidism).
- Postpartum thyroiditis (2% to 16% within 3 to 6 months of delivery)—Recent delivery.

MANAGEMENT

NONPHARMACOLOGIC

- For nonendemic goiter, identify and remove goitrogens.

MEDICATIONS

- Patients with endemic goiter should be provided with iodine. SOR Ⓒ
- The goal for children with acquired hypothyroidism treatment is euthyroidism by treating with levothyroxine.[3] SOR Ⓐ Dose ranges for children are 5 to 8 mcg/kg for children aged 6 to 12 months, 4 to 6 mcg/kg for children aged 1 to 3 years, 3 to 5 mcg/kg for children aged 3 to 10 years, and 2 to 4 mcg/kg for children aged 10 to 18 years.[3] Dosing should be titrated to achieve the treatment goal of a normal TSH.
- The goal of treatment for children with CH is to rapidly achieve euthyroidism. SOR Ⓐ In the first year of life, target serum T_4 level should be 10 to 16 mcg/dL (128.7 to 205.9 nmol/L), serum free T_4 should be 1.4 to 2.3 ng/dL (18.0 to 29.6 pmol/L), and TSH concentration <5 mU/L.[3] Oral levothyroxine is administered daily at 10 to 15 mcg/kg (usually 37.5 to 50 mcg/day); one author suggests a dose of 50 mcg/day in term infants for optimal preservation of cognitive abilities.[3] Authors of a Cochrane review, however, found only a single randomized clinical trial and therefor insufficient evidence to support high versus low dose initial thyroid replacement.[22] Parents can crush and mix tables with a small volume of human milk, formula, or water; soy formulas or preparations containing concentrated iron or calcium should be avoided as they can reduce thyroxine absorption.
- There is controversy over whether brand-name levothyroxine (Synthroid) performs better than generic medication in normalizing TSH in children with severe CH.[23,24]

- There is also controversy over whether children with subclinical hypothyroidism should be treated with levothyroxine. Based on a systematic literature review, overt hypothyroidism is more likely to develop in children with goiter and elevated thyroglobulin antibodies, children with celiac disease, and children demonstrating a progressive increase in thyroperoxidase antibodies and TSH value (see Prognosis);[25] in adults, a TSH >10 mIU/L is also likely to predict subsequent hypothyroidism.
    - It is reasonable to treat children at high likelihood of progression or if they have symptoms of thyroid deficiency or are pregnant.[8,26] SOR Ⓒ
    - In children with subclinical hypothyroidism, an increased growth velocity with treatment was observed in two studies and reduced thyroid volume was seen in 25 to 100 percent of children with subclinical hypothyroidism and autoimmune thyroiditis in two studies.[25] There were no observed effects on neuropsychological functions (one study) or posttreatment evolution of hypothyroidism (one study).[25]
    - Authors of a Cochrane review of 12 small randomized controlled trials (RCTs) determined that treatment of subclinical hypothyroidism did not improve survival or decrease cardiovascular morbidity.[27]
- Levothyroxine treatment is effective in reducing thyroid volume in children and can be considered for the treatment of goiter caused by autoimmune thyroiditis, even in children who are euthyroid.[28]
- Patients with acute microbial thyroiditis are treated with antibiotics (e.g., amoxicillin/clavulanate, first- or second-generation cephalosporin) for 7 to 10 days against the most common pathogens (i.e., *Staphylococcus aureus*, *Streptococcus pyogenes*, and *Streptococcus pneumoniae*). In patients with subacute thyroiditis, oral corticosteroids can reduce pain and swelling. SOR Ⓒ Symptoms of hyperthyroidism can be treated with β-blockers. SOR Ⓑ

COMPLICATIONS AND REFERRAL

- Large goiters that impinge upon the trachea or do not respond to medications can be treated with surgery.
- Children with hypothyroidism should be referred to a pediatric endocrinologist.
- Patients with myxedema coma should be hospitalized in an intensive care unit; without treatment, mortality approaches 100 percent.
- Hashimoto’s encephalopathy (HE) is a rare complication. In a case series of patients (all girls) with HE (N = 8), all had high levels of antithyroid peroxidase (TPO) antibodies at onset (4043.3 ± 2969.8 IU/mL) despite normal T4 and TSH levels in six of them. Relapses were observed in five children despite steroid therapy and four subsequently developed hypothyroidism.[29]
- Severe hypothyroidism is associated with pseudoprecocious puberty (24% of 33 children in one case series).[30]

PREVENTION AND SCREENING

- The US Preventive Services Task Force recommends screening for CH in newborns. SOR A Screening is done with TSH with backup serum T_4, primary T_4 with backup TSH, or both tests in initial screening, optimally at 2 to 4 days of age.
- Periodic screening may also be justified in high-risk populations; in an observational study of children with Down syndrome, early administration of levothyroxine for hypothyroidism appeared to improve growth.[31]
- There is insufficient evidence to support screening for hypothyroidism in pregnant and nonpregnant patients;[32] however, pregnant patients with subclinical hypothyroidism are more likely to have placental abruption (three-fold increase) and preterm delivery (two-fold increase) and their infants are at higher risk for intraventricular hemorrhage and respiratory distress syndrome.[33] Authors of a literature review found a single

intervention trial demonstrating a decrease in preterm delivery among thyroid antibody-positive women treated with levothyroxine.[34]

PROGNOSIS

- Suppression of TSH with levothyroxine effectively reduces the goiter of Hashimoto thyroiditis and should be continued indefinitely. In one study of adults, withdrawal of medication after 1 year resulted in only 11.4 percent remaining euthyroid.[35]
- Children with CH, especially severe CH, are at risk for motor and cognitive problems.[36] In a survey of 10-year-old patients with CH, reported health-related quality of life and self-worth were lower than general population ratings, independent of disease factors, IQ and motor skills.[37]
- In the most extensive community survey on goiter (Whickham, England), goiter was present in 15.5 percent of the population.[38] At the 20-year follow-up, 20 percent of women and 5 percent of men no longer had goiter and 4 percent of women and no men had acquired a goiter.
- In patients with subclinical hypothyroidism, progression to clinically overt hypothyroidism is 2.6 percent each year if TPO antibodies are absent and 4.3 percent if they are present.[39] In a review of pediatric patients with subclinical hypothyroidism, most children reverted to euthyroidism or remained with subclinical hypothyroidism; overt hypothyroidism occurred in between 0 and 28.8 percent.[25] In a 2-year follow-up study of 92 children with subclinical hypothyroidism, TSH normalized or remained unchanged in 88 percent and increased above 10 mU/L in 11 children; none developed overt hypothyroidism.[40]

FOLLOW-UP

- Children with CH should be followed with serum T_4 or free T_4 and TSH concentrations at 2 and 4 weeks after the initiation of treatment, every 1 to 2 months during the first 6 postnatal months, and every 3 to 4 months between 6 months and 3 years of age.[3] If hypothyroidism is permanent (expected in about 80%), serum tests should continue every 6 to 12 months until growth is complete or more frequently if adherence is questioned or abnormal results are obtained. If the medication dose is altered, test in 2 weeks.
- Serum free T[4] and TSH should be rechecked in children approximately 6 to 8 weeks after initiation of levothyroxine therapy and again in 4 to 6 months, with dosing adjustments made as needed. If normal, testing should continue every 3 to 6 months thereafter until growth is complete unless otherwise clinically indicated, then annually.[3,20] SOR Ⓒ
- Although the need for thyroid replacement is lifelong, dose requirements can change over time. For example, the thyroxine dose may need to be increased during pregnancy (20% to 40%), with use of estrogens, or in situations of weight gain, malabsorption, *Helicobacter pylori*-related gastritis and atrophic gastritis and with use of some medications. Requirements may decrease with increased age, androgen use, reactivation of Graves' disease, or the development of autonomous thyroid nodules.[8]
- The frequency of other autoimmune disease is increased in patients with Hashimoto thyroiditis (14.3% in one study), including rheumatoid arthritis, pernicious anemia, systemic lupus erythematosus, Addison disease, celiac disease, and vitiligo, and increased monitoring should be considered.[41]

192 HYPERTHYROIDISM

Mindy A. Smith, MD, MS

PATIENT STORY

A 12-year-old girl presents with fatigue, palpitations, and inability to sleep. She has been an excellent student in school but has had increasing difficulty concentrating in class and difficulty focusing her eyes. Family history was significant for thyroid disease in her mother (hypothyroid) and maternal aunt (Graves' disease [GD]). On examination, her pulse is 105 beats per minute, blood pressure 112/60 mm Hg, and she is mildly underweight with a BMI of 15. She has a mild resting tremor, proptosis (R >L), and her thyroid exam reveals a slightly enlarged but symmetric gland (**Figure 192-1**). You obtain blood work that reveals a low thyroid-stimulating hormone (TSH) and an elevated free thyroxin level (T_4). A thyroid scan and uptake shows a diffusely increased intake of 54 percent with no nodules (**Figure 192-2**). The patient was diagnosed with GD and the therapeutic options are presented to the family.

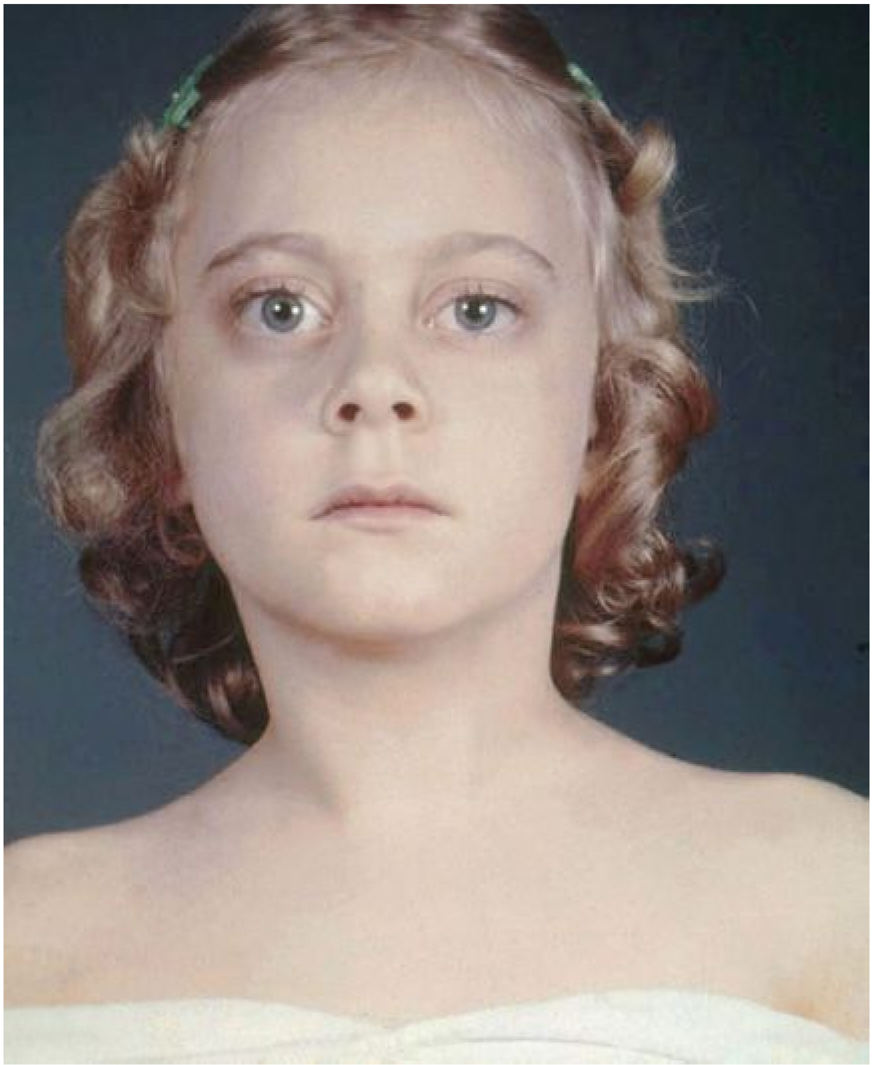

FIGURE 192-1 Graves disease presenting in a 12-year-old girl. Note the lid retraction and proptosis (exophthalmos), particularly evident on the right eye. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

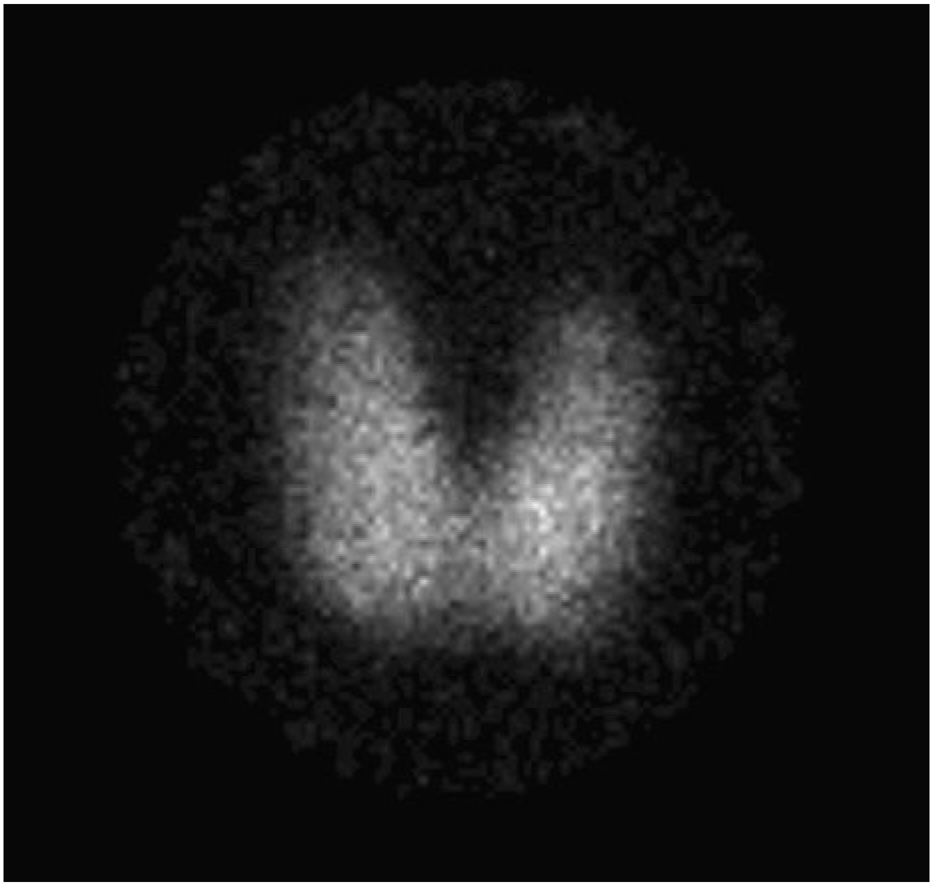

FIGURE 192-2 Nuclear scan of the thyroid in Graves disease showing increased uptake (54%) in a diffusely enlarged thyroid gland (with a homogeneous pattern). (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

GD is an autoimmune thyroid disorder characterized by circulating antibodies that stimulate the thyroid-stimulating hormone (TSH) receptor and resulting in hyperthyroidism.[1]

SYNONYMS

Thyrotoxicosis (clinical state resulting from inappropriately high thyroid hormone levels); hyperthyroidism (thyrotoxicosis caused by elevated synthesis and secretion of thyroid hormone), autoimmune hyperthyroidism, von Basedow's disease (in Europe).

EPIDEMIOLOGY

- GD is the most common cause of thyrotoxicosis in children (up to 95 percent of cases), with a prevalence in children and adolescents of between 1:2000 and 1:10,000 and an incidence between 0.1 and 3 per 100,000.[2,3] The incidence peaks in adolescence; only 1 to 5 percent of cases of childhood hyperthyroidism begin before the age of 16 years.[4]
- Similar to adults, there is a female predominance of between 3:1 to 5:1.[4]
- Autoimmune hyperthyroidism can occurs in about 2 percent of infants born to mothers with GD, but is usually transient (resolving in 3 to 12 weeks).[4,5] Cases of persistent congenital hyperthyroidism and non-autoimmune familial hyperthyroidism due to mutations in the TSH-receptor gene have been reported.[4]
- Rare forms of hyperthyroidism in children include pituitary adenomas, functioning thyroid nodules, pituitary resistance to thyroid hormones, and ingestion thyroid hormone or iodine.[4] Thyrotoxicosis of variable duration can also occur as part of Hashimoto thyroiditis (see Chapter 191, Hypothyroidism). Authors of one small case series (N = 14) reported resolution of hyperthyroidism by 8.3 ± 6.3 months after diagnosis (range 3 to 23 months); duration was positively correlated with thyroid peroxidase autoantibody level at presentation.[6]
- Graves' ophthalmopathy (see the following section "Clinical Features") occurs in more than 80 percent of patients within 18 months of diagnosis of GD. The ophthalmopathy is clinically apparent in 30 to 50 percent of patients, including children.[4,7]
- Untreated hyperthyroidism can lead to osteoporosis, atrial fibrillation, cardiomyopathy, and congestive heart failure; thyrotoxicosis (thyroid

storm) has an associated mortality rate of 20 to 50 percent.[8] In newborns, untreated hyperthyroidism can cause irreversible nervous system damage and developmental delay.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- The hyperthyroidism of GD results from circulating immunoglobulin (Ig) G antibodies that stimulate the TSH receptor.[7] These antibodies are synthesized in the thyroid gland, bone marrow, and lymph nodes. Activation of the TSH receptor stimulates follicular hypertrophy and hyperplasia causing thyroid enlargement (goiter) and an increase in thyroid hormone production with an increased fraction of triiodothyronine (T_3) relative to T_4 (from approximately 20 to up to 30 percent).[7]
- The etiology is seen as a combination of genetic (polygenetic, including human leukocyte antigen-D related [HLA-DR] and cytotoxic (T-lymphocyte antigen 4 [CTLA-4] polymorphisms) and environmental factors, including physical and emotional stress (e.g., infection, childbirth, life events).[4,7] In addition, insulin-like growth factor-1 receptor (IGF-1R)-bearing fibroblasts and B-cells exhibiting the IGF-1R(+) phenotype may be involved in the connective tissue manifestations.[9] Siblings have a higher incidence of both GD and Hashimoto thyroiditis (Chapter 191, Hypothyroidism).
- The ophthalmopathy is believed to result from an autoimmune response directed toward an antigen shared by the thyroid and the eye’s orbit. There is infiltration of the extraocular muscles by activated T cells, which release cytokines, activating fibroblasts (fibrosis can lead to diplopia) and increasing the synthesis of glycosaminoglycans (water trapping causes swelling).[7]

RISK FACTORS

- Family history of thyroid disease, especially in maternal relatives.
- Smoking (a strong risk factor for Graves ophthalmopathy).
- Children with McCune-Albright syndrome are at higher risk of hyperthyroidism and nodular goiter.[10]
- Type 1 diabetes mellitus does not appear to confer an increased risk of GD.[3]

DIAGNOSIS

CLINICAL FEATURES

Symptoms depend on the severity of thyrotoxicosis, duration of disease (initial symptoms can be nonspecific), and age. Children with congenital hyperthyroidism may be born prematurely and postnatally can display restlessness, irritability, failure to thrive, and tachycardia; premature craniosynostosis can occur if diagnosis is delayed.[4] Common symptoms of Graves' disease are:[4,7]

- Nervousness.
- Fatigue.
- Weight loss.
- Increased appetite.
- Diarrhea.
- Behavioral changes including poor school performance, insomnia, restlessness and irritability, and nocturia.

Signs of disease include:

- Tachycardia.
- Goiter—Listening over the goiter with a stethoscope may reveal a thyroid bruit (**Figures 192-3 to 192-5**).

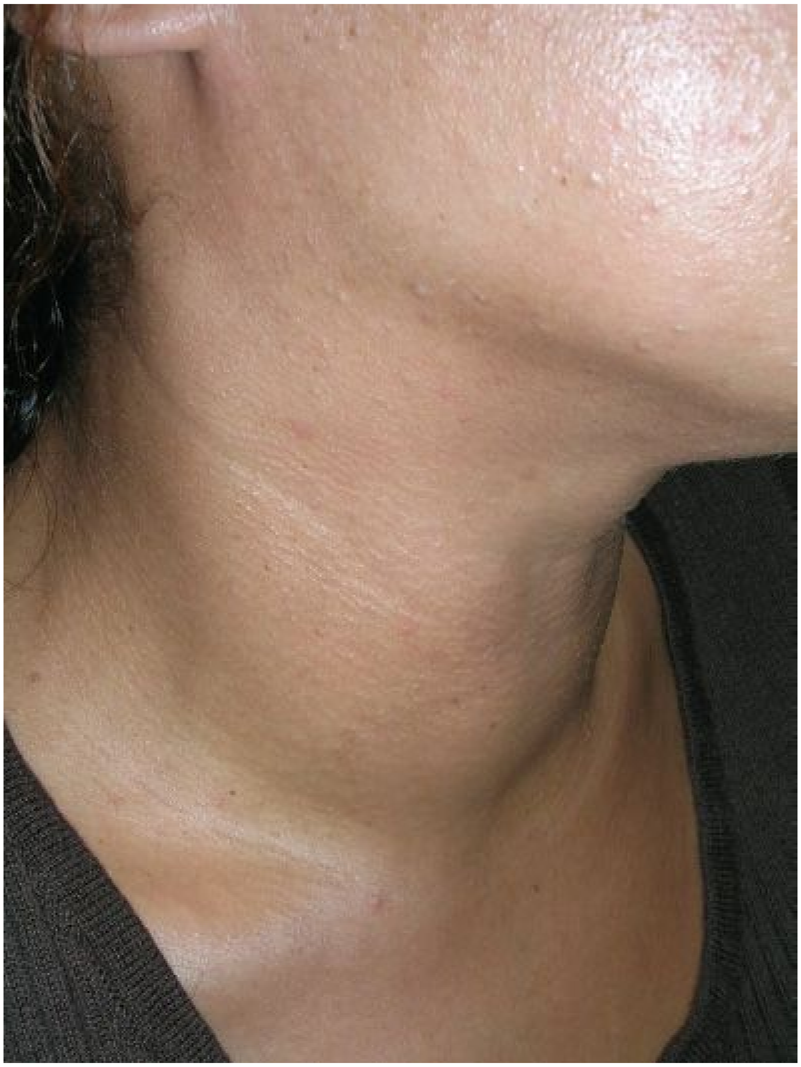

FIGURE 192-3 This young woman has Graves disease and a loud bruit over her enlarged hyperactive thyroid gland. She was thyrotoxic at this time. (*Used with permission from Richard P. Usatine, MD*.)

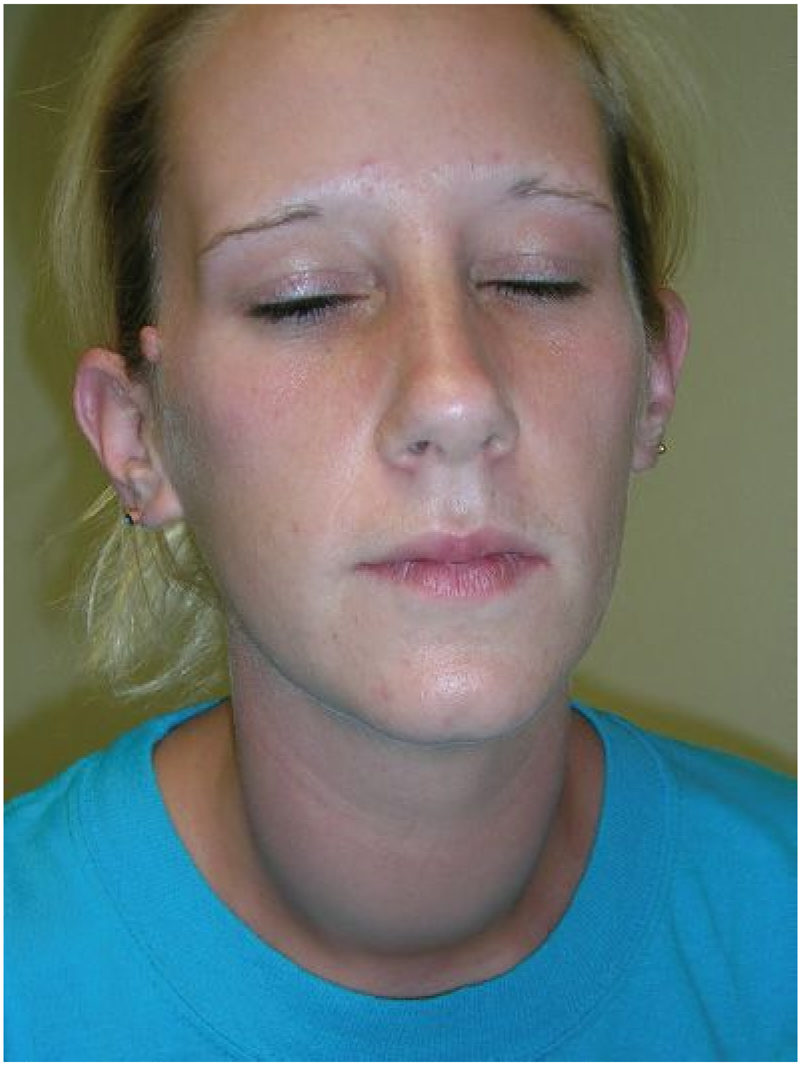

FIGURE 192-4 Flushed skin and temporal wasting in this thyrotoxic young woman with new-onset Graves disease. Her thyroid gland was diffusely enlarged. (*Used with permission from Richard P. Usatine, MD*.)

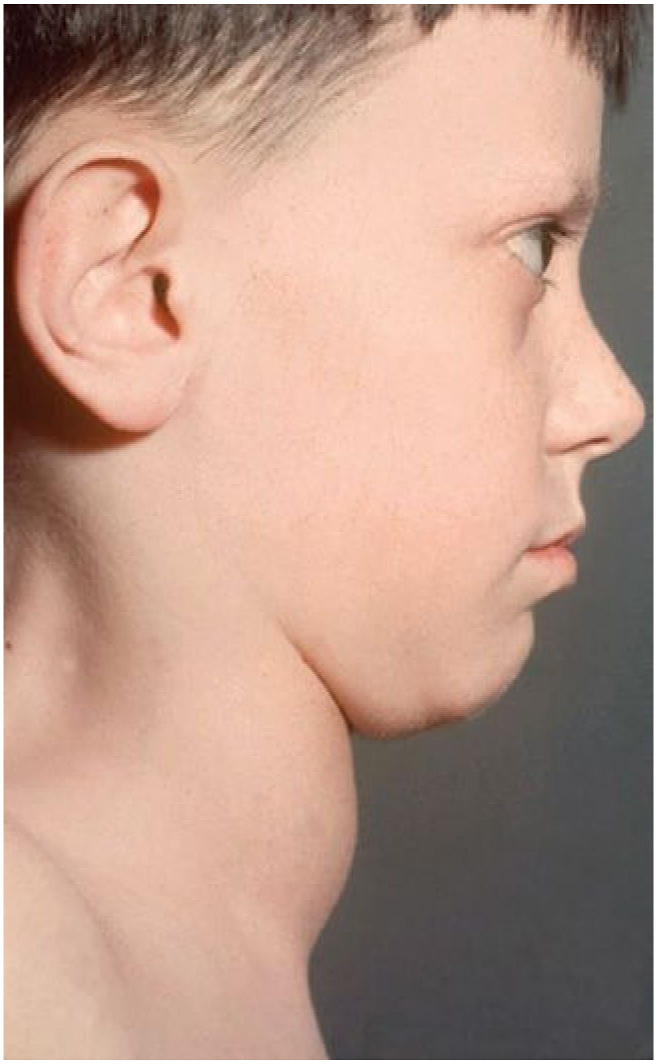

FIGURE 192-5 Graves disease presenting in a young boy with a diffusely enlarged thyroid gland and proptosis (exophthalmos). (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Resting tremor.
- Hyperreflexia
- Skin changes include:
  - Warm, erythematous, moist skin (from increased peripheral circulation).
  - Palmer erythema.
- Eye involvement can occur before hyperthyroidism (in 20% of patients) and gradually progresses with only mild discomfort (a gritty sensation

with increased tearing is the earliest manifestation). The eye findings in GD are less severe in children and include:[4,7,11]

- Lid retraction (drawing back of the eyelid allowing more sclera to be visible; **Figure 192-1** and **Figure 192-5**).
- Frank proptosis (displacement of the eye in the anterior direction; **Figure 192-1** and **Figure 192-5**).
- It is possible to have unilateral or asymmetric eye involvement with Graves ophthalmopathy (**Figure 192-1**).
- Extraocular muscle dysfunction (e.g., diplopia), severe strabismus, and optic neuropathy are rare in children.

LABORATORY TESTING AND IMAGING

- With typical symptoms, you can confirm the diagnosis of GD with a low or undetectable sensitive assay for TSH and an elevated free T_4 level or T_3 level (T3 thyrotoxicosis is more common in children, especially prepubertal children).[4]
- The presence of TSH-receptor antibodies (present in 70% to 100% of adult patients at diagnosis) has a positive and negative likelihood ratio of 247 and 0.01, respectively.[12] TSH-receptor antibodies have been reported to be higher in younger (age 5 years or younger) compared to older children.[13] These antibodies are not usually required for diagnosis.
- For children with suspected congenital hyperthyroidism, one author recommends measurements of iodothyronines and antibodies at birth (in cord blood), after one week when the effects of maternal antithyroid drugs have disappeared, and after 6 to 8 weeks of life because TSH-stimulating immunoglobulins persist.[4]
- A thyroid ultrasound can be obtained to document gland enlargement or to detect nodules in an asymmetric or irregular gland. Consider a RAI scan and uptake if there is thyroid nodularity or if the diagnosis is uncertain in the face of a suppressed TSH to rule out toxic multinodular goiter, thyroiditis, or autonomous functioning nodules.[2,4] Distinguishing between the toxicosis that can occur with Hashimoto thyroiditis and GD can be difficult (see Chapter 191, Hypothyroidism).

- Needle biopsy of an isolated thyroid nodule should be considered as differentiated thyroid cancer can be seen in children and adolescents with GD.[2]

DIFFERENTIAL DIAGNOSIS

Other causes of hyperthyroidism:

- Autonomous functioning nodule—This is an uncommon cause of thyrotoxicosis and most nodules do not cause hyperthyroidism. These present as a discrete swelling in an otherwise normal thyroid gland, and thyroid scan would show a discrete nodule.
- Thyrotropin-secreting pituitary adenoma (rare)—Adenomas can cause visual disturbance (in the absence of exophthalmos), and other hormonal stimulation may occur (e.g., elevated serum prolactin).
- Thyroiditis—May be painless or painful, short duration, low update on RAI scan.
- Exogenous thyroid hormone ingestion—History of overdosage of prescribed or acquired thyroid medication.

The differential diagnoses for the eye findings include the following:

- Metastatic disease to the extraocular muscles.
- Pseudotumor—This condition's rapid onset and pain differentiate it from Graves ophthalmopathy.

MANAGEMENT

- Three options are available to treat the hyperthyroidism: antithyroid drugs (ATD), RAI therapy, and surgery, as discussed in the following section.[4,7]

NONPHARMACOLOGIC

- Supportive measures for eye symptoms include dark glasses, artificial tears, propping up the head and taping the eyelids closed at night.

MEDICATIONS

- Symptoms of hyperthyroidism can be controlled with β-adrenergic blockers (e.g., propranolol, 1 to 2 mg/kg divided twice daily).[2] SOR Ⓑ
- The antithyroid drug methimazole (0.5 to 1 mg/kg once daily) is considered the first-line agent for children in the US.[1,2,4,7] SOR Ⓐ Potential side effects include rash, joint pain, liver inflammation, and, rarely, agranulocytosis.[7] Propylthiouracil (PTU; 5 to 10 mg/kg divided every 8 hours) can be considered for children allergic or intolerant to methimazole; however, PTU causes more severe liver injury.[1,14] Baseline liver enzymes and complete blood count (CBC) (including white blood cells [WBCs] and differential) is recommended.[15]
- The ATD dose can be reduced after the patient is euthyroid (typically by one third or one half to maintain a normal serum thyroxine level). Alternatively, the initial dosage can be continued to induce hypothyroidism and initiating L-thyroxine therapy.[4] This approach may reduce frequency of monitoring for development of hypothyroidism.
- PTU is preferred just before and during the first trimester of pregnancy as congenital malformations have been reported approximately three times more often with prenatal exposure to methimazole.[14]
- Pretreatment with methimazole prior to RAI is suggested for patients with GD who are at high risk for complications of extreme hyperthyroidism.[15]
- The optimal duration of titrated antithyroid drug therapy is 12 to 18 months to minimize relapse (see the “Follow-Up” section).[15] SOR Ⓐ If remission (defined as normal thyroid function off ATDs) is not seen, other treatments are considered.[1]
- In one study, predictors of with higher relapse rates following ATD were non-Caucasian race, young patients, and patients with severe disease at

diagnosis (high serum TSH-receptor antibodies and free T_4 levels).[16]

- Children have been reported to have less severe ophthalmopathy than adults, perhaps related to less smoking exposure. Graves' ophthalmopathy can be treated with a course of prednisone (2 to 20 γ daily) depending on severity; side effects of prolonged treatment can include weight gain, immune suppression and growth failure.[17] Somatostatin-analogs have been investigated in adults with limited success.

RADIOTHERAPY

- Radioiodine therapy (RAI) is the most commonly prescribed treatment in the US, but is contraindicated in pregnancy or with breastfeeding. A dose of >150 µCi/g of thyroid tissue is recommended by one author for children.[1] Another author recommended doses of between 220 and 275 µCi/g, increased to 300 µCi/g for larger goiters or less elevated radioiodine uptake.[2]
- RAI can also be used after initial treatment with antithyroid drugs; these drugs should be discontinued for 3 to 7 days before treatment.[7]
- The long-term safety of RAI in children is unknown. Because of concerns about subsequent thyroid cancer, treatment is generally avoided in children under age 5 years,[2,4] although several long-term follow-up studies (up to 36 years) did not find adverse effects on fertility, congenital abnormalities or miscarriage, or increased cancer above the general population.[2]
- RAI can cause painful thyroid inflammation for a few weeks in approximately 1 percent of patients; this condition can be treated with nonsteroidal antiinflammatory agents, β-blockers, and possibly steroids.[8]
- In addition, radiation-induced thyroiditis can aggravate ophthalmopathy. This side effect can be minimized by an oral glucocorticoid starting on or 1 day after RAI treatment and tapering over the next 1 to 3 months).[2]

SURGICAL TREATMENT

- Near-total to total thyroidectomy by a high-volume thyroid surgeon is recommended as one treatment option for patients with GD.[15]
- Indications for surgery are very large goiters, presence of suspicious nodules, pregnant women requiring high doses of ATDs, and allergy or failure of other therapies.
- Children who fail an ATD are candidates for surgery if a high volume surgeon practicing in a hospital capable of providing pediatric anesthesia and post-operative care is available.[2] One author prefers surgery over RAI for children under age 10 years, those with severe ophthalmopathy or large thyroids (more than two times normal), adolescents considering pregnancy, and in cases where adherence with RAI and follow-up are questionable.[2]
- In most cases for patients with GD, pretreatment with methimazole until euthyroid is recommended prior to surgery and levothyroxine is started following surgery.[15] A 7- to 10-d course of concentrated iodine solution (three to five drops [50 to 150 mg/dose] three times daily), given the week before surgery can help to decrease thyroid hormone production with the added benefit of decreasing thyroid vascularity.[2]
- Following surgery, small remnants of thyroid tissue (<4 g) result in rates of hypothyroidism of greater than 50 percent; large remnants (>8 g) have higher rates of recurrent hyperthyroidism (15%).
- Complications following surgery, reported for adults, include hypocalcemia (40%), hematoma (2%), recurrent laryngeal nerve injury (2%), and hypoparathyroidism (1%).[1] Complication rates may be higher for young children; Rivkees reported postoperative complication rates for children aged 0 to 6 years of 22 percent using a national database, which was twice the rate for older children.[1] Postoperative rapid PTH testing, drawn at the end of the procedure, is helpful in predicting postoperative hypocalcemia.[2]
- With respect to the eye findings, most symptoms except for proptosis improve with control of the hyperthyroidism.

REFERRAL

- Children who have or are suspected of having hyperthyroidism should be referred to a pediatric endocrinologist for diagnosis and management.
- Patients with significant eye symptoms or clinical findings should be referred to a pediatric ophthalmologist.

PROGNOSIS

- With use of ATDs, symptoms improve in 3 to 4 weeks; weight gain (about 4.5 kg) often occurs as metabolism normalizes.[7] Cortical bone density has also been shown to normalize by 2 years in children rendered euthyroid on ATDs.[18] Remission rates following ATDs vary from 37 to 70 percent and remission usually occurs within 6 to 8 weeks.
- Following RAI, 50 to 75 percent of patients become euthyroid after 5 to 8 weeks, but 50 to 90 percent of patients with GD eventually become hypothyroid (10% to 20% in year 1 and 5% per year afterward).[8] Transient hypocalcemia has been reported following RAI for GD.[19] Retreatment with radioiodine may be needed in 14 percent of patients with GD, 10 to 30 percent of patients with toxic adenoma, and 6 to 18 percent of patients with toxic nodular goiter.[8] In one large Chinese case series (N=1,874 children with GD), the cure rate for RAI was half with an incidence of hypothyroidism of 37.8 percent.[20] The relapse rate was 6.3 percent and adverse effects were reported in less than 2 percent.
- Delayed diagnosis in prepubertal children can lead to increased height, advanced bone age, and lower weight; with appropriate treatment, pubertal progression can be maintained and final predicted height preserved.[2]

FOLLOW-UP

- The goals of therapy are to resolve hyperthyroid symptoms and to restore the euthyroid state. Close follow-up is needed in the initial treatment period; medications for symptoms of hyperthyroidism can be withdrawn slowly following treatment.
- ATD dosages can be reduced after the patient becomes euthyroid, but drugs should be continued for 12 to 18 months to minimize relapse. SOR Ⓐ Follow-up blood tests (T_4 or T_3, because prolonged suppression of TSH is common) are recommended at 4 to 6 weeks after initial treatment and every 2 to 3 months after the appropriate dose is determined.[2] Despite initial remission, relapse rates are high (50% to 70%).[5] Longer duration of treatment reduces relapse rates, but about half of children require additional treatment.[5]
- There is an association between GD, antithyroid medications, and myeloperoxidase-antineutrophil cytoplasmic antibody (MPO-ANCA) vasculitis potentially involving the kidneys, respiratory tract, joints, eyes, gastrointestinal tract, and brain.[2] An MPO-ANCA level can be obtained if this condition is suspected (normal range, <20 EU/mL).
- Following treatment with RAI, most patients eventually become hypothyroid (20% within the first year) and so periodic monitoring of thyroid function is important. Follow-up blood testing within the first 1 to 2 months (free T_4 and T_3) is recommended and then at 4 to 6 weeks if hyperthyroidism continues; consider retreatment with RAI if there is minimal response at 3 months or hyperthyroidism persists at 6 months.[7]
- Following surgery, patients may become hypothyroid or have a recurrence of hyperthyroidism, depending on the size of the remnant remaining; patients should be monitored with periodic blood tests and for symptoms. For those with GD following surgery and levothyroxine, a TSH is recommended at 6 to 8 weeks postoperation.[15] In cases where hyperthyroidism recurs after surgery, RAI is considered as repeat surgery is associated with increased complications.[13]
- An in-office exophthalmometer can be used to track changes in eye prominence over time.
- Patients with GD are at high risk for development of other autoimmune disease; in one cross-sectional study in the United Kingdom of patients

attending a thyroid clinic, the frequency of another autoimmune disorder (e.g., rheumatoid arthritis [3.15%], pernicious anemia, systemic lupus erythematosus, Addison disease, celiac disease, and vitiligo) was 9.67 percent in patients with GD.[21]

PATIENT EDUCATION

- Patients should be told that the goals of therapy are to resolve the symptoms of thyroid excess and to restore the thyroid function to normal.
- The treatment choices should be discussed, as each has advantages and disadvantages; treatment should be individualized.
- Regardless of the therapy chosen, long-term follow-up is needed to monitor thyroid status; there is a high risk of becoming hypothyroid in the future or to relapse again into hyperthyroidism. Patients should be made aware of symptoms to watch for and to report any recurrent symptoms.
- Following RAI, patients should avoid intimate contact (including kissing) and contact with other children for 5 days; avoid contact with pregnant women for 10 days (maintain distance of approximately 6 feet); limit close contact with other adults to 2 hours for 5 days; sit while voiding and flush twice with the lid closed; not share toothbrushes, utensils, dishes, towels, or clothes, and wash these separately.[8]
- Ophthalmopathy usually runs its own course independent of the thyroid function. Additional treatment may be needed in consultation with an ophthalmologist.
- Smoking cessation can have a beneficial effect on the course of ophthalmopathy.
- Siblings and children should be made aware of their increased risk of developing thyroid disease or associated disorders and should monitor themselves for symptoms.

193 HYPERLIPIDEMIA AND XANTHOMAS

Alia Chauhan, MD, FAAP
Mindy A. Smith, MD, MS

PATIENT STORY

A 5-year-old boy is undergoing a complete physical exam prior to starting kindergarten and the pediatrician notes some papules over the right Achilles tendon (**Figure 193-1A**). She also notes rings around the peripheral corneas of both eyes that could be arcus juvenilis (**Figure 193-1B**). The mom noticed the papules near the foot about 2 months ago but had not noticed anything unusual about the eyes. The pediatrician suspects that these findings could be secondary to elevated lipids and discovers that the mother has type 2 diabetes along with high cholesterol. The child is sent for a fasting lipid panel and blood sugar. The results confirm familial hypercholesterolemia (total cholesterol of 810 mg/dL and a low density lipoprotein of 507 mg/dL). The papules over the Achilles tendon are tendinous xanthomas and the eyes do show arcus juvenilis secondary to the elevated lipids. The child is referred to endocrinologist and the mother is told that all the family should be tested and everyone should be eating a low fat diet.

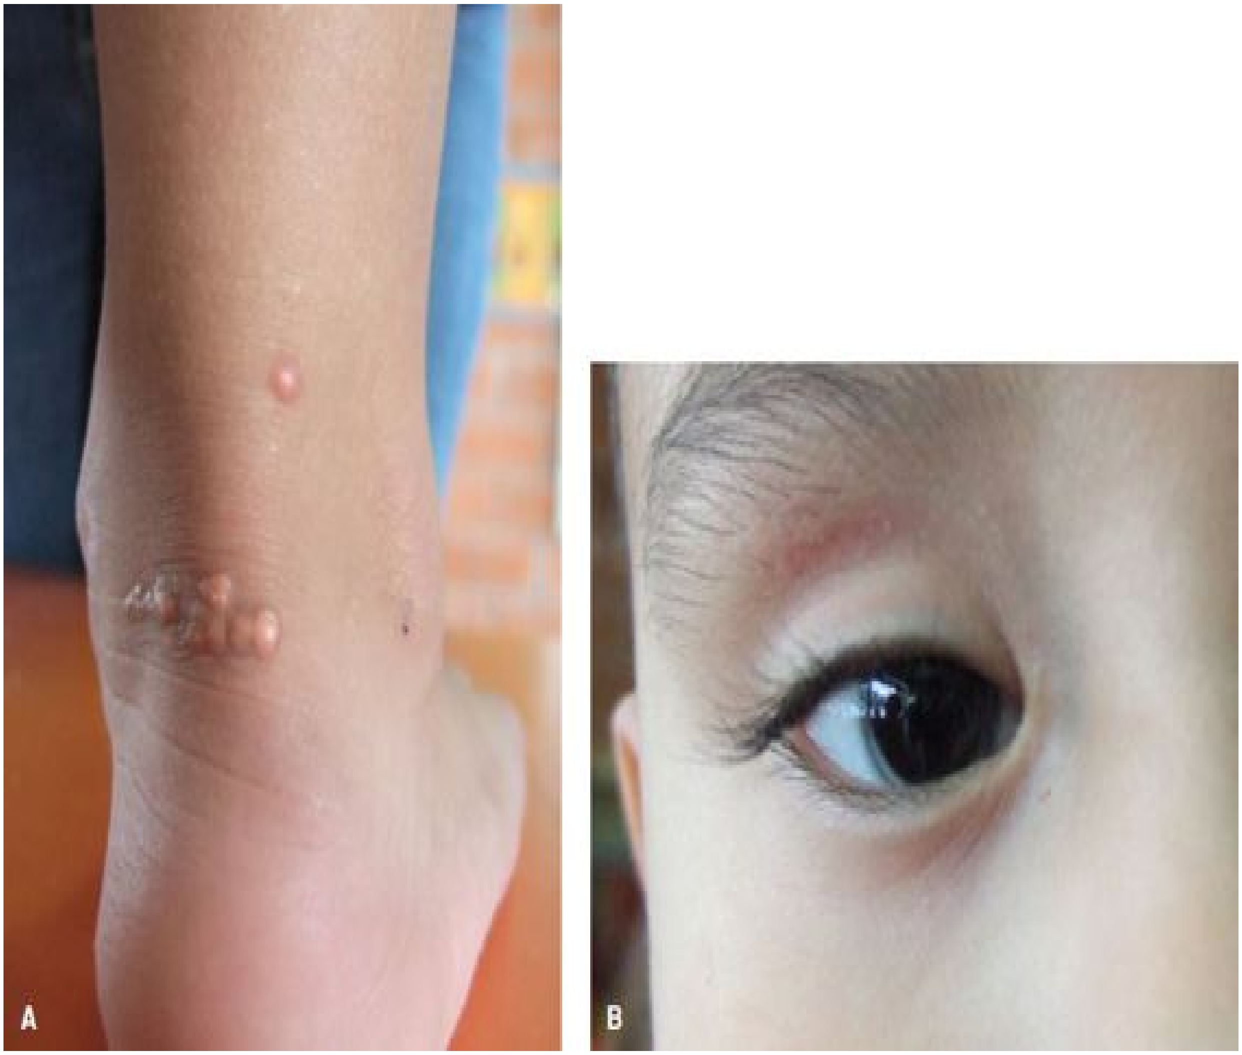

FIGURE 193-1 **A.** Tendinous xanthomas over the Achilles tendon of a 5-year-old boy with familial hypercholesterolemia. **B.** Arcus juvenilis secondary to elevated lipids in the same boy with familial hypercholesterolemia. The white ring is due to lipid infiltration of the corneal stroma and leaves some normal cornea at the limbus. (*Used with permission from John Browning, MD*.)

INTRODUCTION

Hyperlipidemia refers to an elevated concentration of one or more of the measured serum lipid components (total cholesterol [TC], low-density lipid

[LDL], high-density lipoprotein [HDL], and triglycerides [TGs]). Xanthomas are a skin manifestation of familial or severe secondary hyperlipidemia, although they can occur in patients with normal lipid levels. Hyperlipidemia is a major modifiable risk factor for cardiovascular disease.

EPIDEMIOLOGY

- Among young adults, ages 12 to 19 years, 20.3 percent have abnormal lipids; boys are more likely than girls to have at least 1 lipid abnormality (24.3% versus 15.9%, respectively).[1]
- Patients with homozygous familial hypercholesterolemia (FH) (1 in 1 million persons worldwide) present in childhood with cutaneous xanthomas on the hands, wrists, elbows, knees, heels, or buttocks.[2]
- In one population study, children of parents with coronary artery disease were more likely to be overweight and have dyslipidemia in childhood.[3]
- Large epidemiological studies indicate that children's lipid levels correlate with their adult family members levels.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Causes of primary lipid disorders most common seen in children and adolescents are familial combined hyperlipidemia and FH (heterozygous; **Figure 193-1**). Secondary causes include obesity, metabolic syndrome, hypothyroidism, hypopituitarism, diabetes mellitus (type 1 and type 2), polycystic ovary syndrome, juvenile rheumatoid arthritis, chronic renal disease including nephrotic syndrome, Kawasaki disease, and hepatitis.
- Lipoproteins are complexes of lipids and proteins essential for transporting cholesterol, TGs, and fat-soluble vitamins.
- Elevated levels can result from genetically based derangement of lipid metabolism and/or transport or from secondary causes (listed above),

cigarette smoking, obesity, or drugs (e.g., corticosteroids, estrogens, retinoids, and high-dose β-blockers).

- Increased circulating LDL becomes incorporation into atherosclerotic plaques. These plaques can grow to block blood supply and oxygen delivery resulting in ischemia to vital organs. In addition, if the plaque ruptures, it can precipitate a clot, causing for example myocardial infarction.
- Elevated TG is an independent risk factor for CHD and increases the risk of hepatomegaly, splenomegaly, hepatic steatosis, and pancreatitis. Contributing factors include obesity, physical inactivity, cigarette smoking, excess alcohol intake, medical diseases (e.g., type 2 DM, chronic renal failure, nephrotic syndrome), drugs (as previously discussed), and genetic disorders (e.g., familial combined hyperlipidemia).[5]
- Autopsy studies show a correlation between lipid levels and arterial fat disposition in young adults and children.[6,7]
- Xanthomas are deposits of lipid in the skin or subcutaneous tissue, usually occurring as a consequence of primary or secondary hyperlipidemia. Xanthomas can also be seen in association with monoclonal gammopathy.[8] There are five basic types of xanthomas:
    - Eruptive xanthomas (also called tuberoeruptive) are the most common form. These appear as crops of yellow or hyperpigmented papules with erythematous halos in white persons (**Figure 193-2**), appearing hyperpigmented in black persons.
    - Tendon xanthomas are frequently seen on the Achilles (**Figure 193-1**) and extensor finger tendons.

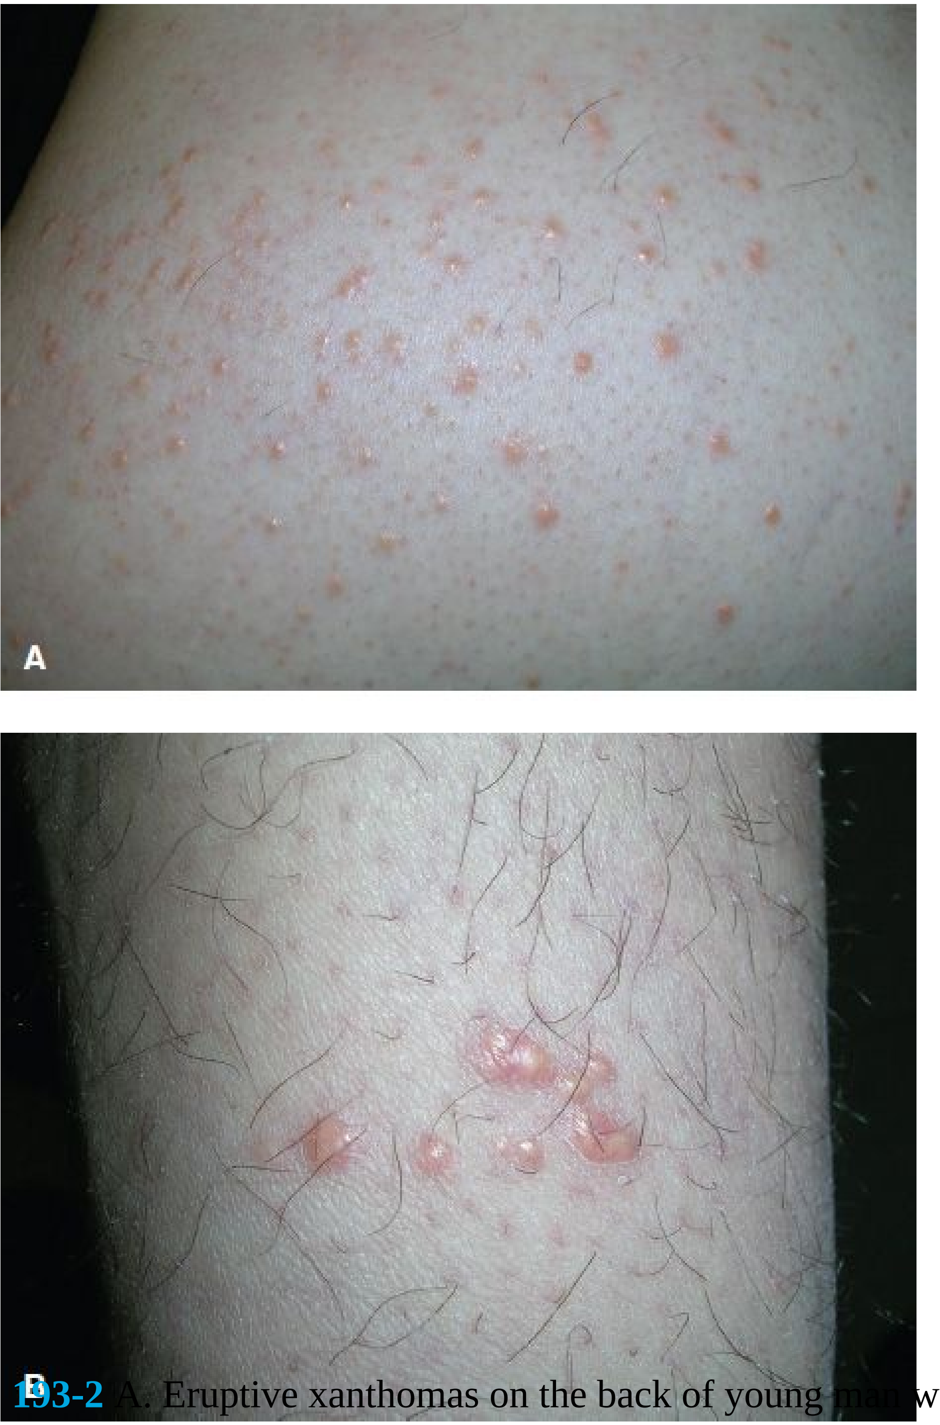

FIGURE 193-2 A. Eruptive xanthomas on the back of young man with uncontrolled diabetes (BS = 350) and elevated lipids (triglycerides >9000 mg/dL, total cholesterol >800 mg/dL) B. Eruptive xanthomas on the arm of the same patient. (*Used with permission from Richard P. Usatine, MD*.)

- Plane xanthomas are flat and commonly seen on the palmar creases, face, upper trunk, and on scars.

  - Tuberous xanthomas are found most frequently on the hand or over large joints.
  - Xanthelasma are yellow papules found on the eyelids (**Figure 193-3**). Fifty percent of individuals with xanthelasmas have normal lipid profiles.

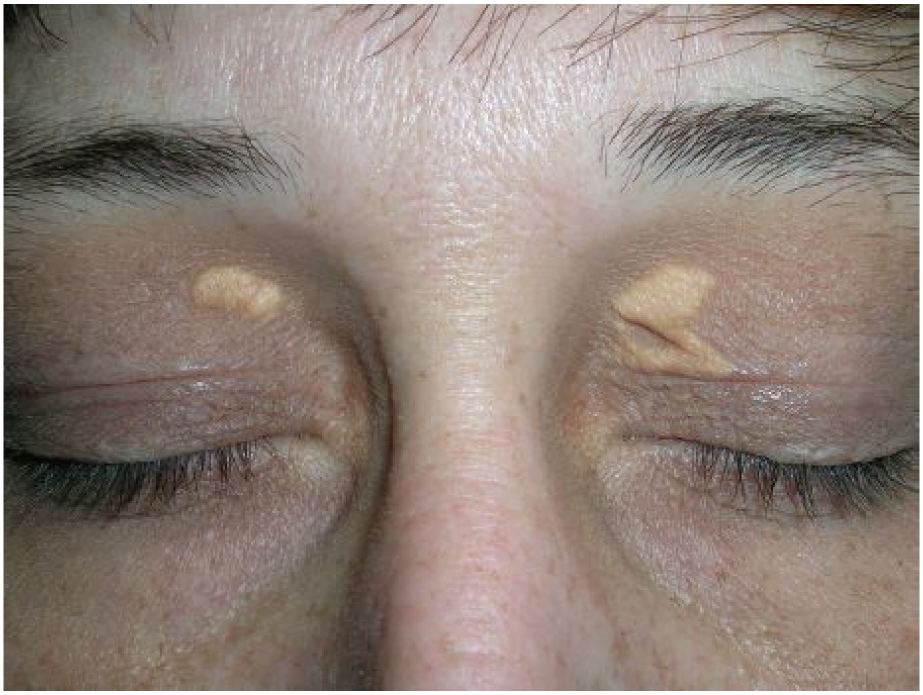

FIGURE 193-3 Xanthelasma around the eyes (xanthoma palpebrarum); most often seen on the medial aspect of the eyelids, with upper lids being more commonly involved than lower lids. This patient has a total cholesterol of over 300 mg/dL. (*Used with permission from Richard P. Usatine, MD*.)

RISK FACTORS/CONDITIONS

Risk factors and high-risk conditions to consider for treatment decisions in children with hyperlipidemia include:[9]

- Positive family history of myocardial infarction; angina; coronary artery bypass graft/stent/angioplasty; sudden cardiac death in parent, grandparent, aunt, or uncle (if male at age <55 years and female at age <65 years).

- High-level risk factors including hypertension requiring drug therapy, BMI ≥97th percentile, and current cigarette smoker.
- Moderate level risk factors including hypertension not requiring drug therapy, BMI ≥95th but <97th percentile, and HDL-C <40 mg/dL.
- The presence of high risk conditions including diabetes mellitus, chronic kidney disease/end-stage renal disease/post renal transplant, post orthotopic heart transplant, and Kawasaki disease with current aneurysms.
- The presence of moderate risk conditions including Kawasaki disease with regressed coronary aneurysms, chronic inflammatory disease (e.g., systemic lupus erythematosus, juvenile rheumatoid arthritis), nephrotic syndrome, and human immunodeficiency virus infection.

DIAGNOSIS

CLINICAL FEATURES

- Most patients with hyperlipidemia are asymptomatic.
- A very high TC level (>2000 mg/dL) can result in eruptive xanthomas or lipemia retinalis (white appearance of the retina; also seen with isolated high TG). Very high LDL can lead to the formation of tendinous xanthomas.
- Xanthomas manifest clinically as yellowish papules, nodules, or tumors (**Figure 193-1**).
- Eruptive xanthomas (**Figures 193-4** to **193-5**) begin as clusters of small papules on the elbows, knees, and buttocks that can grow to the size of grapes.

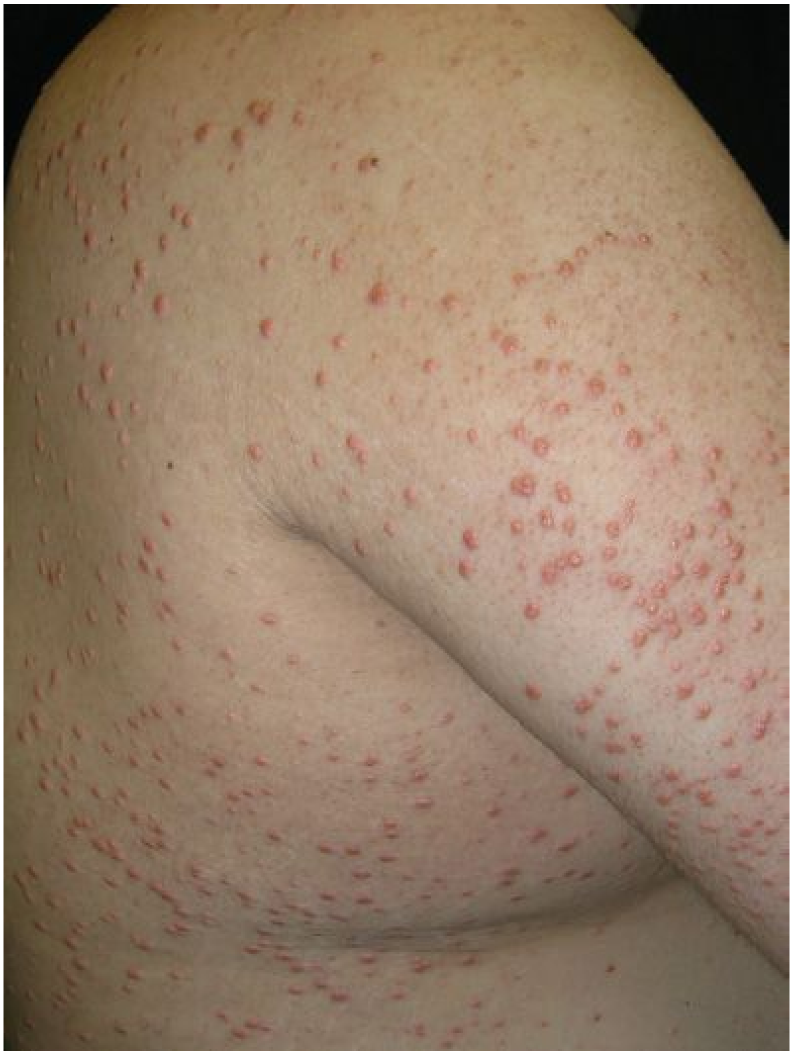

FIGURE 193-4 Eruptive xanthomas on the arm and trunk in an obese patient with untreated hyperlipidemia and diabetes. (*Used with permission from Richard P. Usatine, MD*.)

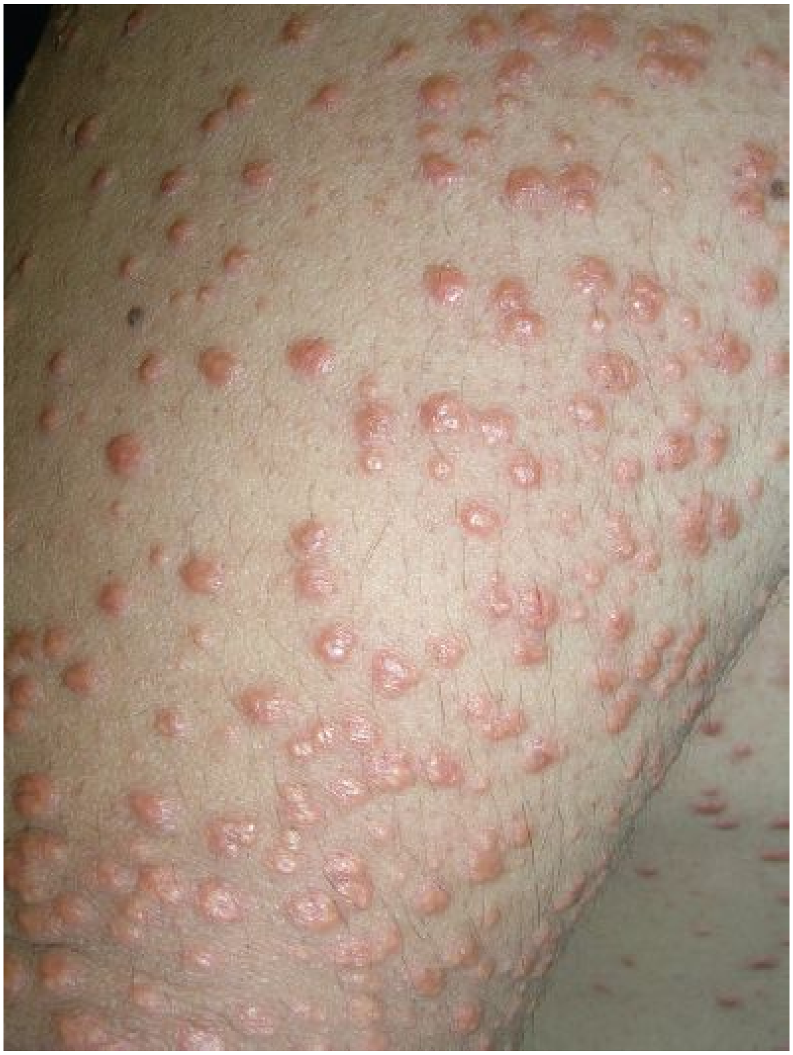

FIGURE 193-5 Close-up of eruptive xanthomas in a patient with untreated hyperlipidemia and diabetes. (*Used with permission from Richard P. Usatine, MD.*)

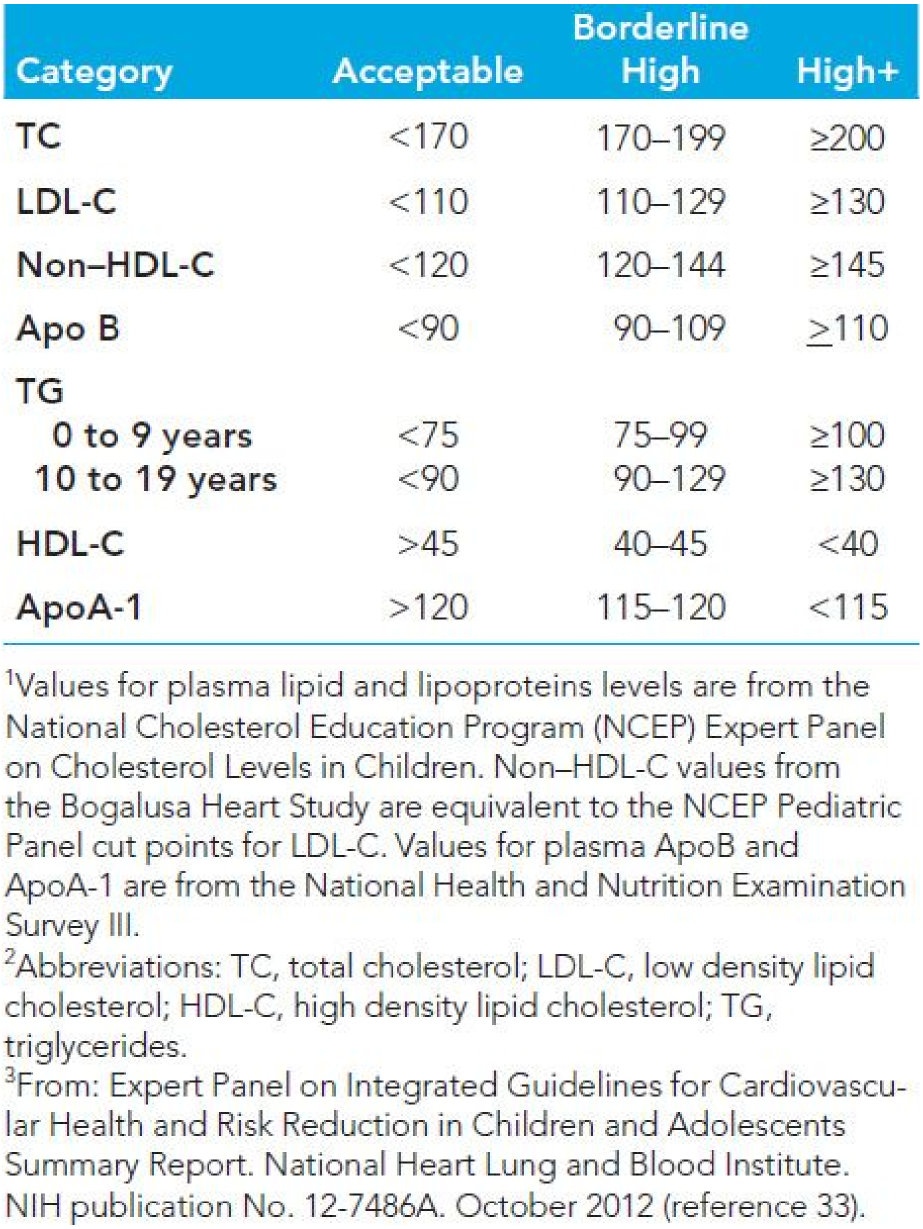
TYPICAL DISTRIBUTION

Xanthomas are most commonly found in superficial soft tissues, such as skin and subcutis, or on tendon sheaths.

LABORATORY TESTING

- Acceptable, borderline, and high values for plasma lipid and lipoprotein levels based on the National Cholesterol Education Program (NCEP) Expert Panel on Cholesterol Levels in Children are shown in **Table 193-1**.[10] The cut points for high and borderline represent approximately the 95th and 75th percentiles, respectively.[11,12] Low cut points for HDL-C represent approximately the 10th percentile.[13]

TABLE 193-1 Acceptable, Borderline, and High Plasma Lipid, Lipoprotein Concentrations (mg/dL) for Children and Adolescents[1,2,3]



Category	Acceptable	Borderline High	High+
TC	<170	170–199	≥200
LDL-C	<110	110–129	≥130
Non–HDL-C	<120	120–144	≥145
Apo B	<90	90–109	≥110
TG			
0 to 9 years	<75	75–99	≥100
10 to 19 years	<90	90–129	≥130
HDL-C	>45	40–45	<40
ApoA-1	>120	115–120	<115

[1] Values for plasma lipid and lipoproteins levels are from the National Cholesterol Education Program (NCEP) Expert Panel on Cholesterol Levels in Children. Non–HDL-C values from the Bogalusa Heart Study are equivalent to the NCEP Pediatric Panel cut points for LDL-C. Values for plasma ApoB and ApoA-1 are from the National Health and Nutrition Examination Survey III.

[2] Abbreviations: TC, total cholesterol; LDL-C, low density lipid cholesterol; HDL-C, high density lipid cholesterol; TG, triglycerides.

[3] From: Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents Summary Report. National Heart Lung and Blood Institute. NIH publication No. 12-7486A. October 2012 (reference 33).

- If thyroid dysfunction is suspected, obtain a thyroid-stimulating hormone level to determine whether thyroid dysfunction is contributing to the lipid abnormalities.

BIOPSY

Biopsy is rarely needed and shows collections of lipid-filled macrophages.

DIFFERENTIAL DIAGNOSIS

Other skin papules that can be mistaken for xanthomas include the following:

- Molluscum contagiosum—Caused by a virus; lesions can be papular and widespread but generally have a central depression (see Chapter 115, Molluscum Contagiosum).
- Pseudoxanthoma elasticum—A disorder caused by abnormal deposits of calcium on the elastic fibers of the skin and eye (see Chapter 169, Genodermatoses).

MANAGEMENT

For children with elevated lipids, diet is recommended as first-line treatment. Referral to a pediatric endocrinologist or dietician may be beneficial.

NONPHARMACOLOGIC

- Smoking cessation should be encouraged and attempts actively supported; cessation lowers both cardiovascular risk and lipid levels. SOR A
- AAP recommends that all children engage in moderate-to-vigorous physical activity for 1 hour/day and <2 hours/day of sedentary screen time.
- The Expert Panel accepts the 2010 *Dietary Guidelines for Americans* (2010 *DGA*) as appropriate recommendations for diet and nutrition in children 2 years of age and older. Consider referral to a registered dietician.
    - CHILD 1—The Cardiovascular Health Integrated Lifestyle Diet (CHILD 1) is the first stage in dietary change for children with identified dyslipidemia, overweight and obesity, children with a risk factor/high-risk medical condition, and children with a positive family history of early cardiovascular disease. Dietary components: Primary beverage: fat-free unflavored milk; limit/avoid sugar sweetened beverages, encourage water; fat content: Total fat 25 to 30 percent of daily kcal/EER; saturated fat 8 to 10 percent of daily kcal/EER; avoid trans fat as much as possible; monounsaturated and polyunsaturated fat up to 20 percent of daily kcal/EER; cholesterol <300 mg/d; encourage high dietary fiber intake from foods.
    - CHILD 2-LDL (for high LDL). Dietary Components: 25 to 30 percent of calories from fat, ≤7 percent from saturated fat, 10 percent from monounsaturated fat, <200 mg/day of cholesterol and avoid trans fat as much as possible, plant sterol esters and/or plant stanol esters up to 2 g/day as replacement for usual fat sources can be used after age 2 years in children with FH. Water-soluble fiber psyllium can be added to a low-fat, low saturated fat diet as cereal enriched with psyllium at a dose of 6 g/day for children 2-12 years, and 12 g/day for those ≥12 years.
    - CHILD 2-TG (for high triglycerides [average fasting levels of TG ≥500 mg/dL or any single measurement ≥1,000 mg/dL related to a primary hypertriglyceridemia]). Dietary components: 25 to 30 percent of calories from fat, ≤7 percent from saturated fat, 10 percent from monounsaturated fat; <200 mg/d of cholesterol, avoid trans fat, decrease sugar intake (e.g., no sugar-sweetened beverages), increase dietary fish to increase omega-3 fatty acids. These children should be treated in conjunction with a lipid specialist.

- Elevated TG levels are very responsive to weight loss, diet composition, and exercise. Most importantly, in overweight and obese children and adolescents with elevated TG levels, even small amounts of weight loss are associated with significant decreases in TG levels and increases in HDL-C levels.[14–16]
- Initial treatment of xanthomas should target the underlying hyperlipidemia (when present).

MEDICATIONS

Decisions regarding the need for medication therapy should be based on the average of results from at least two fasting lipid profiles obtained at least 2 weeks but no more than 12 weeks apart. SOR Ⓒ The cut points used to define the level at which drug therapy should be considered come from the 1992 *NCEP Pediatric Guidelines* which have been used as the basis for multiple drug safety and efficacy trials in dyslipidemic children.[10] The goal of LDL-lowering therapy in childhood and adolescence is a LDL-C below the 95th percentile (≤130 mg/dL).

- The following are indications for drug therapy in children with elevated LDL:[10]
    - Children Younger Than Age 10 Years—In this age group, medication should only be used if LDL-C is ≥400 mg/dL (homozygous hypercholesterolemia), TG is ≥500 mg/dL (primary hypertriglyceridemia), or the child has a high-risk condition that is associated with serious medical morbidity. SOR Ⓒ
    - Children 10 to 20 years—Children with an average LDL-C ≥250 mg/dL should be referred to a lipid specialist for treatment. If, after a 6-month trial of lifestyle/diet changes, the LDL-C remains ≥190 mg/dL, statin therapy should be considered.[10] SOR Ⓐ
    - If LDL-C remains between 130 mg/dL and 190 mg/dL in a child with a negative family history of premature CVD in first-degree relatives and no high-level or moderate-level risk factor or risk condition, management should continue to focus on diet changes plus weight management if BMI ≥85th percentile. Treatment with bile acid

    sequestrants can be considered in consultation with a lipid specialist.[10] SOR B
  - If LDL-C remains between 160 to 189 mg/dL after a trial of lifestyle/diet management in children with a positive family history of premature CVD/events in first-degree relatives or at least one high-level risk factor or risk condition or at least two moderate-level risk factors or risk conditions, statin therapy should be considered.[10] SOR B
  - If LDL-C remains between 130 to 159 mg/dL after a trial of lifestyle/diet management in a child with at least two high-level risk factors or risk conditions or at least one high-level risk factor or risk condition together with at least two moderate-level risk factors or risk conditions, statin therapy should be considered.[10] SOR C
  - For children ages 8 and 9 years with LDL-C persistently ≥190 mg/dL after a trial of lifestyle/diet management together with multiple first-degree family members with premature CVD/events or the presence of at least one high-level risk factor or risk condition or the presence of at least two moderate-level risk factors or risk conditions, statin therapy might be considered.[10] SOR B

- The following are indications for drug therapy in children with elevated triglycerides (TG; average fasting levels of TG ≥ 500 mg/dL or any single measurement ≥1,000 mg/dL related to a primary hypertriglyceridemia) or elevated non-HDL-C:[10]
  - In conjunction with a lipid specialist, the child should be placed on a CHILD 2-TG diet and should consider use of fish oil, fibrate, or niacin to prevent pancreatitis.[10] SOR C
  - Children with fasting levels of TG between 200 to 499 mg/dL after a trial of lifestyle/diet management, should have non-HDL recalculated and be managed to a goal of <145 mg/dL.[10] SOR C
  - Children with fasting levels of TG between 200 to 499 mg/dL, non-HDL >145 mg/dL, after a trial of lifestyle/diet management, consider fish oil supplementation.[10] SOR C
  - Children ≥10 years with non-HDL-C levels ≥145 mg/dL after the LDL-C goal is achieved can be considered for further intensification of statin therapy or additional therapy with a fibrate or niacin, in conjunction with referral to a lipid specialist.[10] SOR C

- Statin therapy is recommended as the initial medication for treating children with elevated LDL-C or non–HDL-C levels as noted above. The efficacy and tolerability of statins has been demonstrated in number of well-designed, short-term trials in children and adolescents.[17–21] In addition to significantly lowering LDL-C levels, statins may increase HDL-C levels and lower TG modestly.
    - Begin the statin with the lowest available dose, given once daily. If LDL-C target levels are not achieved following at least 3 months of adherent use, the dose can be increased by one increment.
    - Adverse effects from statins are uncommon at standard doses but include myopathy and hepatic enzyme elevation. In a meta-analysis of statin use in children, evidence of hepatic enzyme elevation did not differ between the statin and placebo groups.[22] Myopathy (muscle pain and weakness with creatine kinase elevations more than 10 times the upper limits of normal range) typically occurs in less than 1 in 10,000 adult patients. Evidence of muscle toxicity did not differ between the statin and placebo groups in the meta-analysis of statin use in children.[22]
    - Drug interactions with statins occur primarily with drugs that are metabolized by the cytochrome P–450 system. Drugs that potentially interact with statins include fibrates, azole antifungals, macrolide antibiotics, antiarrhythmics, and protease inhibitors.
- Bile acid sequestrants were the first-line medications recommended in the original *NCEP Pediatric Guidelines*. Studies of bile acid sequestrants (cholestyramine, colestipol, or colesevelam) in children and adolescents with FH and hence more extreme elevations of LDL-C levels, show 10 to 20 percent reductions of LDL-C levels and sometimes a modest elevation in TG levels.[23–25]
    - The primary adverse effects of the bile acid sequestrants are gastrointestinal including bloating, nausea, diarrhea, and constipation; these significantly affect adherence.
    - The bile acid-binding sequestrants can be used in combination with a statin for patients who fail to meet LDL-C target levels with either medication alone. One pediatric study that assessed the efficacy of the two agents together found the combination to be additive without increasing adverse effects.[26]

COMPLEMENTARY AND ALTERNATIVE THERAPY

- Consumption of a plant stanol-enriched margarine compared with control margarine as replacement for 20 g/day of dietary fat intake was found to decrease TC and LDL-C levels by 5.4 and 7.5 percent, respectively, in subset of 81 children.[27] There was no effect on HDL-C or TG levels. Safety was judged to be excellent.
- It is not clear whether supplementing with omega-3 fatty acids reduces mortality when combined primary and secondary prevention data are analyzed. A 2006 metaanalysis failed to find a reduction in overall mortality or cardiovascular events in adults.[28]
- In a randomized crossover trial, consuming walnuts (42.5 γ walnuts/10.1 mJ) and fatty fish (113 γ salmon, twice a week) in a healthy diet significantly lowered serum cholesterol and triglyceride concentrations, respectively.[29] In a metaanalysis, nut consumption (67 g) reduced lipid levels.[30]

SURGICAL PROCEDURES

- Xanthelasma lesions can be treated for cosmetic purposes. Methods of treatment include surgery, electrosurgery, cryotherapy, and laser therapy. SOR Ⓒ
- When standard therapy fails, LDL apheresis has lowered lipid levels with subsequent regression of tendon xanthomas in patients with FH.[31] SOR Ⓒ

REFERRAL

- Referral for nutritional counseling should be considered, especially if initial attempts at dietary control fail. Dietary advice has been shown to result in modest improvements in cardiovascular risk factors, such as blood pressure and total and LDL-cholesterol levels.[32] SOR Ⓐ

PREVENTION AND SCREENING

- Screening recommendations are provided by the Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents, updated in 2012 by National Heart Lung Blood Institute.[33]
    - Birth to 2 years—No lipid screening. SOR Ⓒ
    - Two to 8 years—No routine lipid screening. SOR Ⓑ Measure fasting lipid profile twice (as previously discussed for an average level) if the family history is positive for elevated cardiovascular risk or the child has a high level risk factor or condition (see the section “Risk Factors”).
    - Nine to 11 years—Universal screening with non-fasting lipid profile and calculate non-HDL-C (TC-HDL-C). SOR Ⓑ If non-HDL-C is ≥145 mg/dL and HDL <40 mg/dL, repeat fasting lipid profile twice as discussed above to obtain average level.
    - Twelve to 16 years—No routine screening. SOR Ⓑ If new knowledge of positive family history, new risk factor or new high risk condition is identified in the patient, obtain fasting lipid panel (twice and average).
    - Seventeen years to 21 years—Universal screening once in this time period, obtain non-fasting lipid profile and calculate non–HDL-C; if non–HDL-C ≥145 mg/dL, HDL-C <40 mg/dL, obtain fasting lipid panel (twice and average). SOR Ⓑ
- Studies are not available to assess the efficacy of screening children and adolescents for dyslipidemia for delaying the onset and reducing the incidence of CHD-related events.

PROGNOSIS

- Based on observational data, each 30 mg/dL increase in LDL increases the relative risk of CHD by 30 percent.
- Use of strategies to lower elevated lipid levels will likely reduce CHD events and possibly overall mortality.

- With medical (diet or drugs) treatment of hyperlipidemia, many xanthomas and about half of xanthelasma resolve or improve with surgical treatment, recurrence is uncommon.[34]

PATIENT EDUCATION

- Patients should be counseled about benefits and risks of screening.
- Lifestyle changes should be stressed as primary prevention for patients with hyperlipidemia. Working with a registered dietician can be helpful. In one study, a pediatric office-based nutritional education program was effective in decreasing total fat, saturated fat, and cholesterol intakes, with significant decreases in TC and LDL-C levels after 16 weeks.[35]
- If persistent elevations in lipids continue despite lifestyle change, those with high level risk factor or CHD should consider medications.
- Patients with hyperlipidemia and/or diabetes should be encouraged to establish and maintain good control of these diseases, as this often results in regression of xanthomas.

194 OBESITY

Stacy McConkey, MD, FAAP
Angela M. Fals, MD, FAAP

PATIENT STORY

A 13-year-old Hispanic female is brought to her pediatrician with various concerns, including that her neck always appearing dirty no matter how much she washes and scrubs it. The pediatrician notes that the child has acanthosis nigricans of the neck and axillae along with obesity (**Figure 194-1**). The mother is obese and admits to having type 2 diabetes. A diet history reveals that the mother cooks traditional Mexican cuisine and the daughter is very fond of tortillas. She also loves to eat pizza, french fries, and other fast food. The girl is a good student but does not like to exercise or play sports. The pediatrician is concerned that the girl may have insulin resistance or type 2 diabetes so she plans to send the patient for screening labs including hemoglobin A1c and fasting blood sugar. She also recommends a healthier diet with less calories and increased physical activity. A referral to a nutritionist is offered.

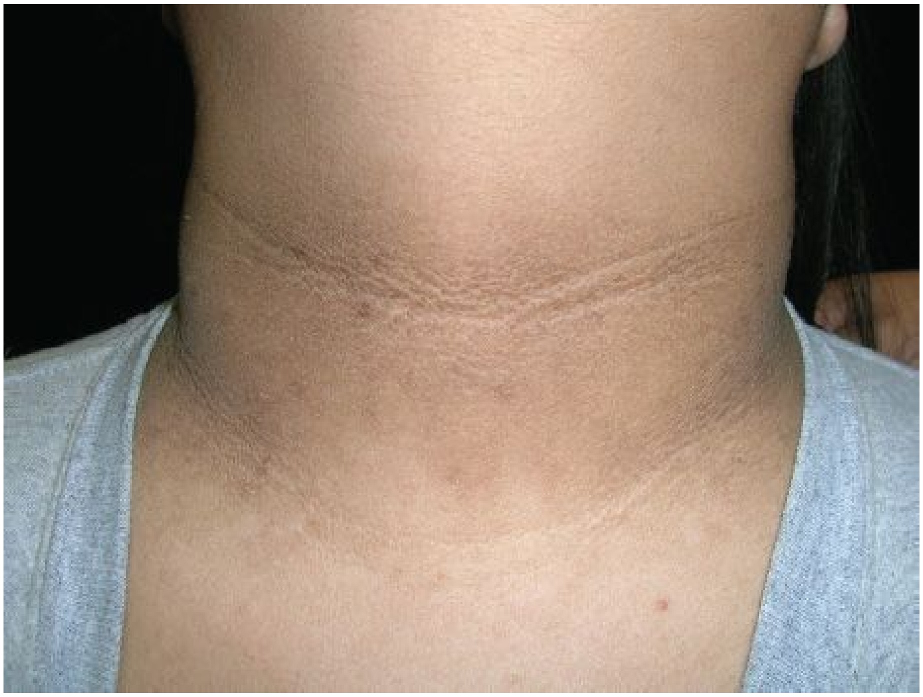

FIGURE 194-1 Acanthosis nigricans of the neck in a 13-year-old obese girl with a family history of obesity and type 2 diabetes. She eats a high-calorie high fat diet and gets little physical activity. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Obesity in children is defined as a BMI greater than or equal to the age- and sex-specific 95th percentiles of the 2000 Centers for Disease Control (CDC) growth charts; a child is considered overweight at the 85thto 95th percentile.

EPIDEMIOLOGY

- Based on the National Health and Nutrition Examination Surveys (NHNS), 12.5 million children and adolescents (16.9%) are obese.[1] Slightly more boys (19.3%) were obese than girls (16.8%) of all included ages in the study. Since 1980, the prevalence of obesity in children has tripled.[1]

- The direct medical care costs (prescriptions, outpatient visits, and ER visits) for children aged 6 to 19 years for complications of obesity are 14.1 billion dollars annually.[2]
- There is an overrepresentation of low-income children in the numbers of obese children, with 1 in 7 lowincome preschool children being obese.[3,4] The National Longitudinal Study of Adolescent Health showed that being obese (BMI > 95%) is highly associated with lower household income.[4]
- Race and ethnicity are also associated with obesity, with high rates present in American Indian/Eskimo children.[3] In the NHNS study (2007 to 2008), Hispanic boys, aged 2 to 19 years, were significantly more likely to be obese than non-Hispanic white males and non-Hispanic black girls aged 2 to 19 years were significantly more likely to be obese than non-Hispanic white girls.[5]
- Interestingly, the effect of ethnicity appears to be mediated by income; Caucasian teenage girls from the lowest income quintile had relative risks for obesity of 2.72 compared to teens in the highest quintile.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

Obesity is a complex problem involving genetics, health behaviors (e.g., diet or exercise), environment, culture, and sometimes medical diseases (see differential diagnosis) or drugs (e.g., steroids or antidepressants). The simplest explanation of obesity is an imbalance between intake (calories eaten) and output (physical activity).

- Genetics—Studies on twins, nontwin siblings, and adopted siblings show that the genetic component of obesity is somewhere between 40 to 70 percent. Researchers using Genome Wide Association Studies have identified 42 different genes likely associated with obesity.[6] Most of these genes only make a small contribution to the overall elevation of BMI (around 0.17 kg/m^2). The cumulative risk for developing obesity not only relies on the individuals genotype, but also on the environment and a wide variety of other factors.[6]

- Diet—Many low-income families live in neighborhoods lacking supermarkets with fresh produce or healthy choices. Calorie dense “junk food” or fast food is more readily available and less expensive than healthier options. Daycares and schools are not regulated or monitored on their ability to provide healthy options for children. Exposure to sugary drinks and snack foods in school vending machines may lead to increased consumption of calorie dense foods.[7] In addition, portion size is commonly much larger than what typical serving sizes for children should be. This leads to overeating and the expectation for increased food consumption at meals and snacks.
- Television viewing—Sedentary TV viewing displaces physical play and exercise, and exposes children to targeted advertising.[8] Authors of a recent study of 1,638 hours of television found 9000 food ads of which only 165 promoted fitness and good nutrition.[9] TV viewing may lead to an increase in snacking behavior and interfere with normal sleep patterns; hours of TV watching predicts higher BMI in adulthood.[8] In addition, having a bedroom TV set is an independent risk factor for obesity.[8]
- Physical activity—School programs have limited the amount of time devoted to exercise, which falls well below the recommended 60 minutes per day for a child. Access to safe and appealing play areas, parks, and recreation facilities may be limited, especially in urban and rural areas.

RISK FACTORS

- Family history of obesity—In a retrospective cohort study of 854 children, children aged 1 to 2 year olds with non-obese parents had an 8 percent chance of being obese adults while children aged 10 to 14 years with one obese parent had a 79 percent chance of being obese as adults.[10]
- Diet—High calorie, low in fruits and vegetables, high number of snack foods, and fast food consumption.

- Low levels of physical activity.
- Mother with gestational diabetes.
- Small-for-gestational-age at birth.
- Stressors—Investigators in the Fragile Families and Child Well Being Study found that cumulative social stressors between the ages of 1 to 3 years were associated with increased odds of early onset obesity among girls.[11] The greater the number of stressors at one time predicted a greater risk for obesity at the age of 5 years.

DIAGNOSIS

- Body mass index (BMI) is calculated by taking the child's weight in kilograms divided by the standing height in m^2. That number is highly variable over the child's growing years, and should be charted on the 2000 CDC growth chart for BMI to determine if the child is normal (<85th percentile), overweight (85 to 94th percentile), or obese (>95th percentile). As the child's age gets closer to 19 years, the adult definition for obesity of 30 kg/m^2 can be utilized. The 2007 expert committee of the American Academy of Pediatrics (AAP) on Child and Adolescent Obesity proposed a new category of severe obesity, defined as BMI of 30 to 32 kg/m^2 for 10 to 12 year olds and >34 kg/m^2 for 14 to 16 year olds.[12]
- Children grow very rapidly in the first 24 months and standards for BMI are not available for children <2 years of age. The BMI as a percentage usually peaks in the first 8 months and then falls to a nadir at around age 6 years. By around 8 years of age, most children are at the percentile that they will follow into adolescence. In general, the earlier a child reaches their nadir, the more likely the child will have an elevated BMI later.
- In adults, increased waist circumference (WC) confers additional morbidity risk for those who have elevated weight. For children, WC and skin fold measurement are not valid indicators of risk or predictors for obesity and are not followed routinely.

CLINICAL FEATURES

- Obese children (**Figure 194-1**) are more likely to have hypertension (2.9 times higher), high cholesterol (2.1 times higher), insulin resistance, and type 2 diabetes mellitus (2.9 times higher).
- Obese children have a higher incidence of increased severity asthma and may suffer from sleep apnea.
- There is an increased prevalence of non-alcoholic fatty liver disease (NAFLD) and gastro esophageal reflux among obese children.
- Acanthosis nigricans is a skin condition that is commonly present in obese children (**Figures 194-1** and **194-2**; see Chapter 190, Acanthosis Nigricans).
- Obese children can also develop striae (**Figure 194-3**).

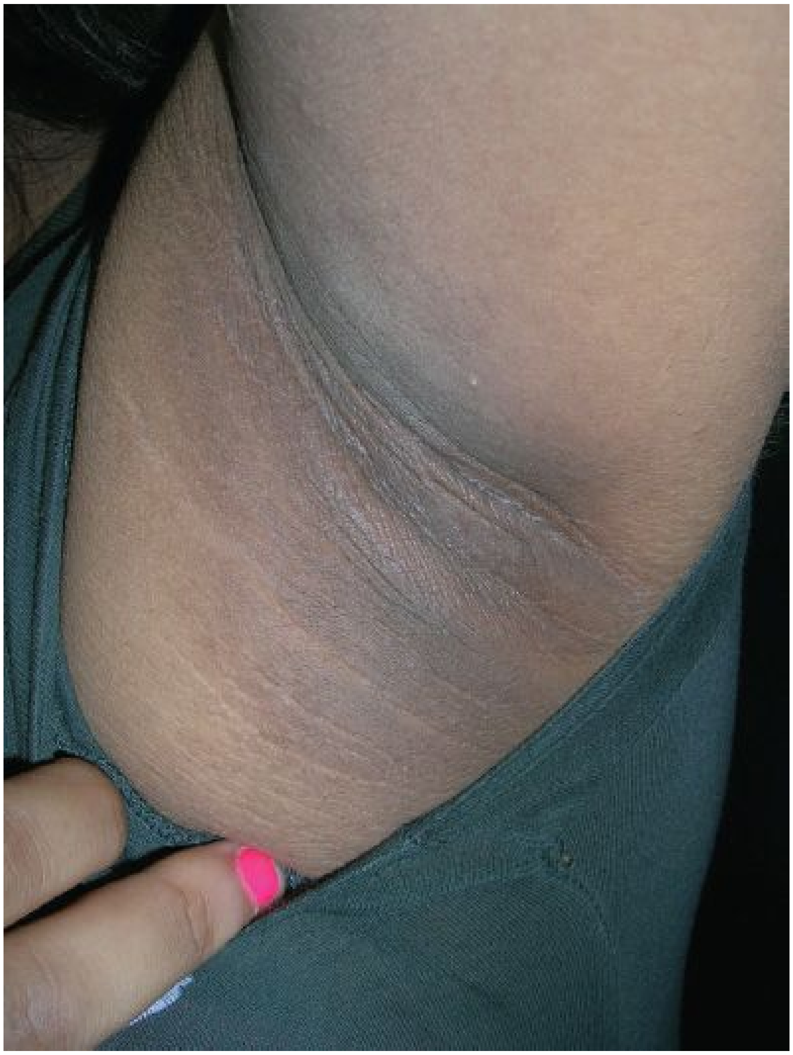

FIGURE 194-2 Acanthosis nigricans in the axilla of on obese Hispanic teenage girl. (*Used with permission from Richard P. Usatine, MD*.)

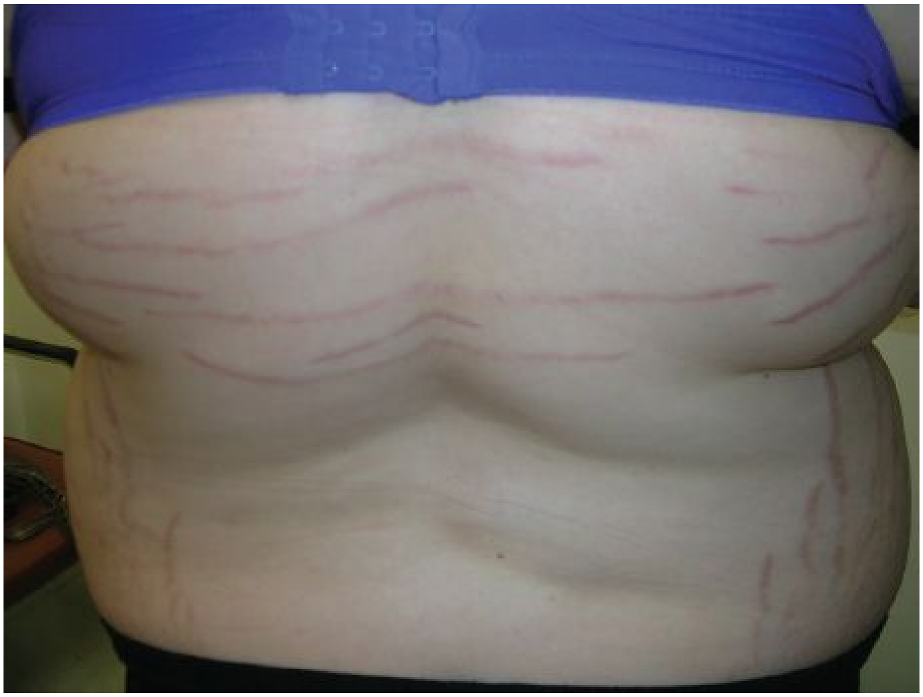

FIGURE 194-3 Striae caused by obesity in this growing teenager. (*Used with permission from Richard P. Usatine, MD*.)

- Obese boys are more likely to have pseudogynecomastia (**Figure 194-4** and **Figure 194-5**). This appears similar to gynecomastia but this is not real breast development just increased adipose tissue.

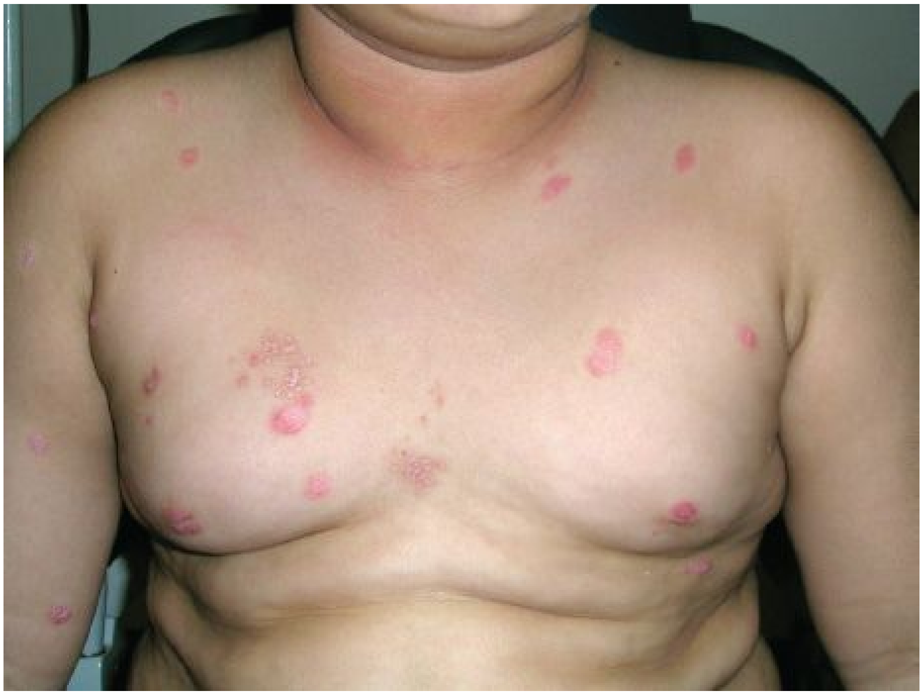

FIGURE 194-4 Pseudogynecomastia in an obese boy who also has guttate psoriasis. (*Used with permission from Richard P. Usatine, MD*.)

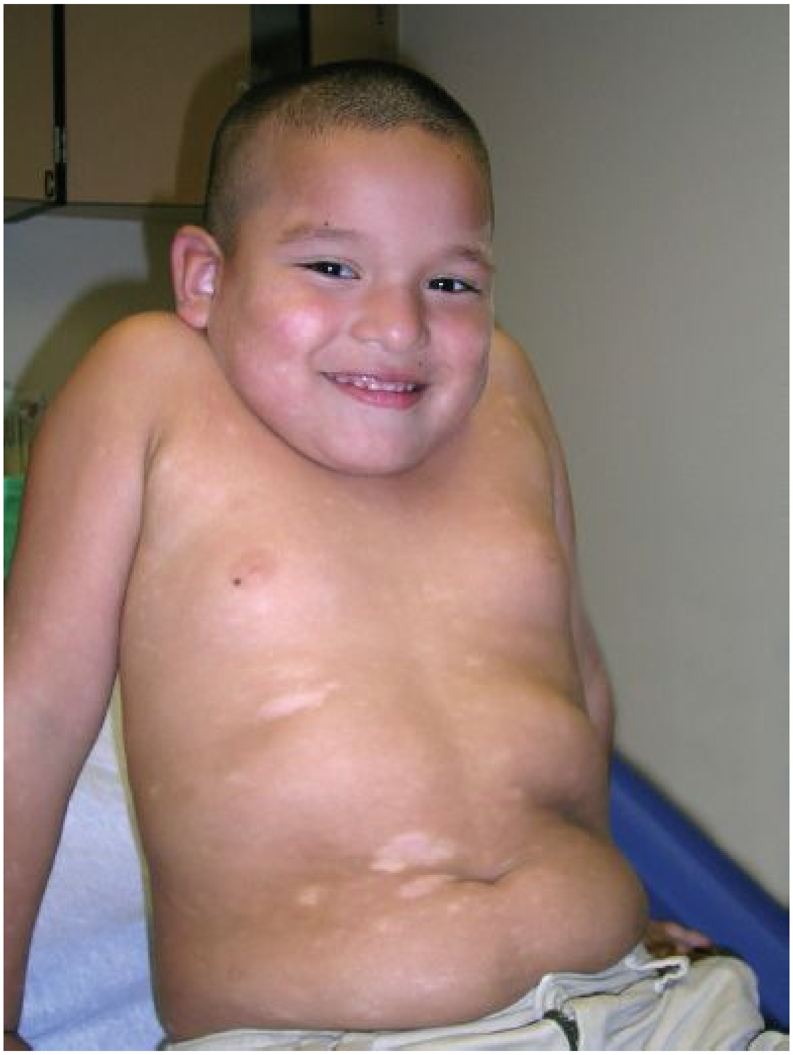

FIGURE 194-5 Pseudogynecomastia in this obese boy with pityriasis alba. (*Used with permission from Richard P. Usatine, MD*.)

- Slipped capital femoral epiphysis, joint problems, and muscle strain/pain often limit obese children's ability to exercise.
- It is common for obese children to experience depression, low self-esteem, discrimination, and bullying.

LABORATORY TESTING

- Laboratory testing is performed to diagnose complications of obesity and recommendations are based on BMI percentile.[12]
- For children between the 5th and 84th percentile, no laboratory testing is recommended.
- For those in the 85th to 94th percentile who are ≥age 10 years and have other risk factors and children with a BMI >95th percentile, biannual fasting glucose, AST, and ALT levels are recommended. Fasting lipids should be checked on all children >10 years of age with a BMI >85 percent (baseline and every 2 years if BMI remains >85%).

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of a patient with obesity includes the following medical conditions:

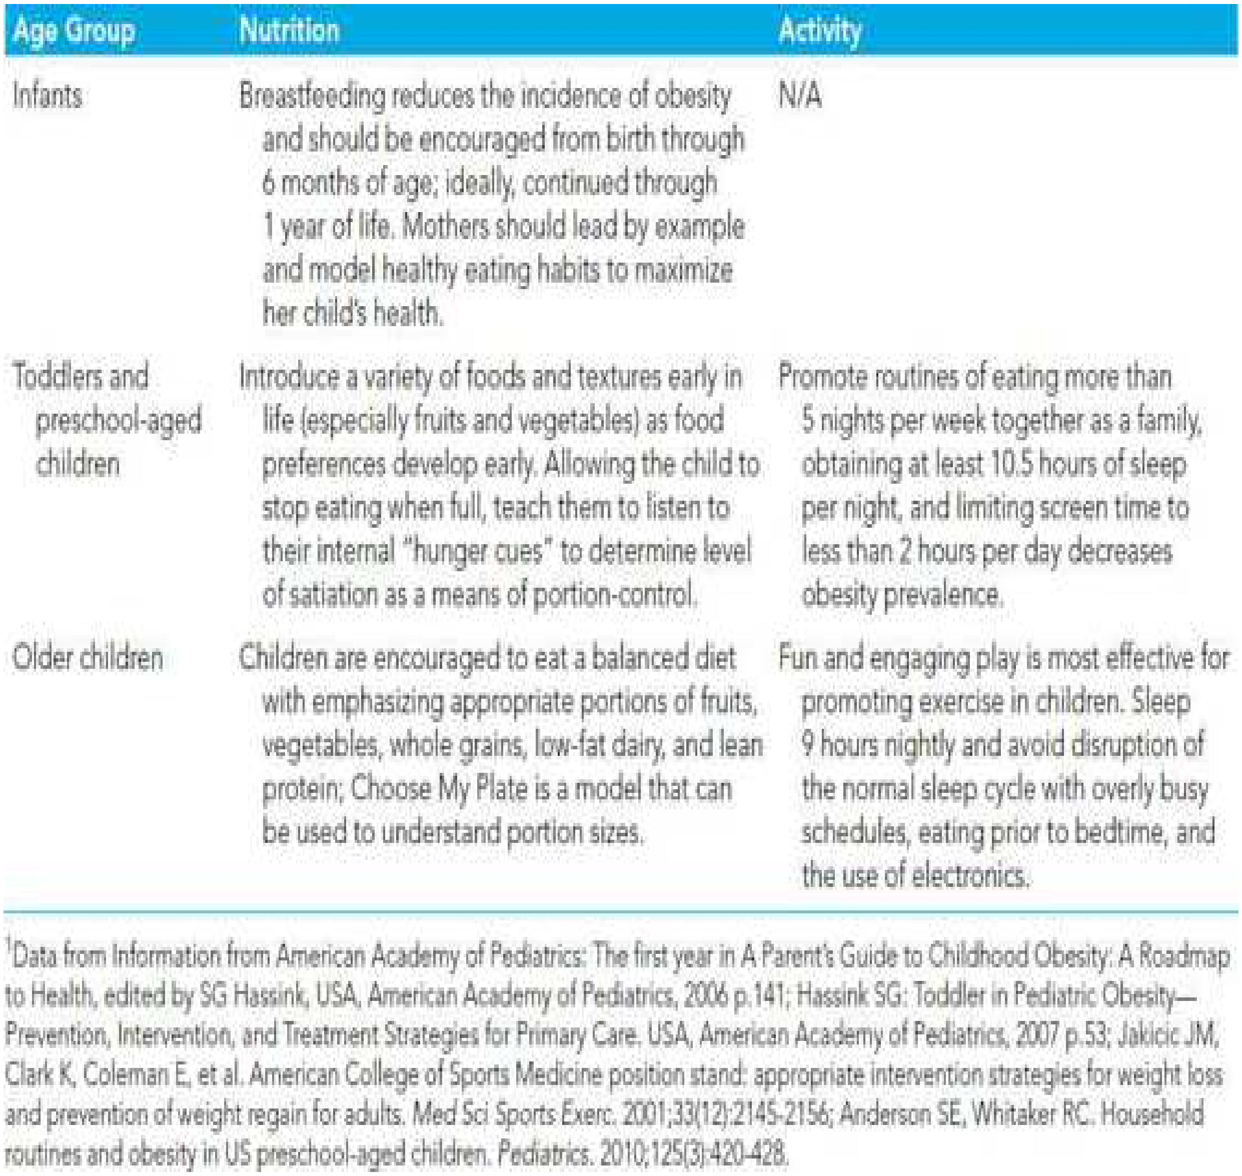
- Hypothyroidism—Uncommon and typically these children's growth has slowed or stopped; laboratory testing (thyroid stimulating hormone and free thyroxine) confirms the diagnosis (see Chapter 191, Hypothyroidism).
- Cushing syndrome—Uncommon in children; caused by prolonged exposure to endogenous or exogenous glucocorticoids. Findings include truncal obesity, purple striae, and linear growth cessation. Diagnosis is confirmed with inappropriately high serum or urine cortisol levels (see Chapter 195, Cushing Disease).
- Polycystic ovary syndrome—Criteria include 2 of 3 of oligo-ovulation or anovulation, hyperandrogenism, and polycystic ovaries.
- Genetic syndromes include Prader Willi, Lawrence-Moon-Bardet-Biedel syndrome, Albright Hereditary Osteodystrophy, Carpenter syndrome, Cohen syndrome; these obesity syndromes in children are frequently associated with developmental delay. Beckwith Wiedemann syndrome is associated with fasting hypoglycemia and Alstrom syndrome with blindness and deafness. If any of these syndromes are suspected, consult a geneticist.

- Medications—Antidepressants, antipsychotic medications, mood stabilizers, and glucocorticoids can cause weight gain.

MANAGEMENT

- The primary goal of obesity treatment in children and adolescents is improvement of long-term physical and mental health through permanent lifestyle and habit changes leading to and maintaining a healthy weight and BMI for life. Depending on age and starting BMI values, this may be accomplished through either gradual, steady weight loss or decreased weight velocity and maintenance of BMI as the child grows taller. Reduced BMI can improve conditions such as hypertension, diabetes, steatohepatitis, and metabolic syndrome.
- Currently, there are effective behavioral, pharmaceutical, and surgical methods for treatment. AAP identifies four stages for treatment of childhood obesity in children ages 2 to 19 years.[12] The first three involve nonpharmacologic approaches. Additional nutritional and activity recommendations by age group are displayed in **Table 194-1**. Tools available to assist primary-care providers in screening and basic strategies for addressing health and wellness are provided in the AAP guidelines.[12]

TABLE 194-1 Nutritional and Activity Recommendations by Age Group[1]



Age Group	Nutrition	Activity
Infants	Breastfeeding reduces the incidence of obesity and should be encouraged from birth through 6 months of age; ideally, continued through 1 year of life. Mothers should lead by example and model healthy eating habits to maximize her child's health.	N/A
Toddlers and preschool-aged children	Introduce a variety of foods and textures early in life (especially fruits and vegetables) as food preferences develop early. Allowing the child to stop eating when full, teach them to listen to their internal "hunger cues" to determine level of satiation as a means of portion-control.	Promote routines of eating more than 5 nights per week together as a family, obtaining at least 10.5 hours of sleep per night, and limiting screen time to less than 2 hours per day decreases obesity prevalence.
Older children	Children are encouraged to eat a balanced diet with emphasizing appropriate portions of fruits, vegetables, whole grains, low-fat dairy, and lean protein; Choose My Plate is a model that can be used to understand portion sizes.	Fun and engaging play is most effective for promoting exercise in children. Sleep 9 hours nightly and avoid disruption of the normal sleep cycle with overly busy schedules, eating prior to bedtime, and the use of electronics.

American College of Sports Medicine position stand: appropriate intervention strategies for weight loss and prevention of weight regain for adults. *Med Sci Sports Exerc.* 2001;33(12):2145-2156; Anderson SE, Whitaker RC. Household routines and obesity in US preschool-aged children. *Pediatrics.* 2010;125(3):420-428.

NONPHARMACOLOGIC

Stage 1—Prevention Plus-Primary Care Office. Initial management for obese children can be undertaken in the office setting by any appropriately-trained provider or clinical staff. It is important to involve the entire family in making permanent lifestyle changes. Changes may need to be slow and in a stepwise fashion, and should be tailored to family behaviors, cultural values, norms, and usual foods.

- Nutrition—Limit or eliminate consumption of sugar-sweetened beverages; encourage 5 to 9 daily servings of fruits and vegetables; provide a healthy daily breakfast; limit eating out (especially fast food), engage in meal planning and preparation at home; provide family meals 5 to 6 times weekly; allow the child to self-regulate meals, and avoid restrictive feeding behaviors.
- Activity—Moderate to vigorous physical activity for at least 60 minutes daily; 2 hour daily limit on TV/screen time (no TV for children <2 years); and removal of TVs and other screens from child's sleeping area. Regular exercise incorporated into the daily schedule is very important in long-term weight maintenance and helps avoid weight regain.[13,22]
- If no progress has been made after 3 to 6 months of attempted Stage 1 interventions, consider moving to Stage 2.

Stage 2—Structured Weight Management, Primary Care Office with Support. This stage combines Stage 1 recommendations for nutrition and activity education with added family support and accountability.

- Offer monthly visits and include other professionals as indicated: a dietician, staff trained in motivational interviewing for follow up care, a counselor, and/or physical therapist. Group sessions can be considered.
- Nutrition—In additional to Stage 1 nutritional recommendations, incorporate a daily eating plan with balanced macronutrients (fats, carbohydrates, and protein), planned snacks, and age-appropriate portions. In 2011, the well-known food pyramid was replaced by the US Department of Agriculture (USDA) with *Choose My Plate* as a way to simplify and facilitate healthy eating to the public.[14] The "plate" emphasizes appropriate portions for fruits, vegetables, whole grains, low-fat dairy, and lean protein.
- Activity—Moderate to vigorous physical activity for at least 60 minutes per day and limitation of TV and other screen time to <1 hour per day. Frequent self-monitoring of nutrition and activity behaviors such as through use of a journal is an effective means of regulating behavior change;[15] planned reinforcement is important for achieving goals and continued motivation.

- If no progress has been made after 3 to 6 months of attempted Stage 2 interventions, consider moving to Stage 3.

Stage 3—Comprehensive Multidisciplinary Team, Pediatric Weight Management Center. Continue Stage 1 and 2 recommendations for nutrition and activity education at a pediatric weight management center run by a trained multidisciplinary team. The team includes a physician, behavioral counselor, registered dietician, and exercise specialist. Implement a structured program with features of behavior modification, monitoring of nutrition and activity behaviors, short-term diet (if indicated), regular (weekly or monthly) visits, and goal setting. Systematic evaluation of body measurements should be performed at baseline and specified intervals.

- Nutrition—The recommended rate of weight loss for children ages 2 to 5 years is <1 pound per month and for children >5 years old, about 1 to 2 pounds per week. The US Preventive Services Task Force (USPSTF) recommends that clinicians screen children aged 6 years and older for obesity and offer them or refer them to comprehensive, intensive behavioral interventions to promote improvement in weight status.[16] This recommendation is based in part on data showing that moderate- to high-intensity programs (>25 hours of contact with the child and/or the family over a 6-month period) improve weight status primarily in children with obesity.[14]

Stage 4—Tertiary Care Center Intervention. For severely obese teens, intensive interventions are reserved for those who have repeatedly had unsuccessful attempts at medical weight management in the prior 3 stages, have the maturity to make life-altering decisions, and have reached skeletal maturity (for bariatric surgery).

MEDICATIONS

- There have been several medications approved for use in children and adolescents, but currently only Orlistat is available. Orlistat can be given to adolescents aged 12 to 18 years under the supervision of a physician and by prescription only. Orlistat prevents fat absorption. Daily exercise and healthy lifestyle must continue as medication alone has demonstrated only modest weight loss effects and discontinuing diet and exercise can result in a major setback with weight regain.

- Metformin is a commonly used medication for the treatment of diabetes and appears effective for decreasing BMI while preventing progression to diabetes in children.[17]

- Bariatric surgery, along with diet and exercise, provides about 25 to 75 kg of weight loss after 2 to 4 years in adults.[18] Long-term outcome data are not available in children, but short-term results appear to be similar to those in adults.[19]
- Specific criteria are used to determine eligibility of an adolescent for bariatric surgery (Roux-en-Y gastric bypass, laparoscopic adjustable gastric banding or sleeve).[20] These include being at Tanner Stage 4 or 5 and at final or near-final height with a BMI >50 or BMI >40 and having comorbidities. Surgery is best performed at one of a few Children's Hospitals and Bariatric Centers of Excellence.

OTHER INTERVENTIONS

- There are many co-morbid mental health issues associated with overweight and obesity in children including depression, low self-esteem, distorted body image, and bullying.
- Excessive caloric intake is linked to many eating habits/eating behaviors including the use of food for non-nutritive purposes (e.g., using food as a reward or punishment and using food for comfort).[21]
- Several techniques can be helpful as adjuncts to improve mental health and social function in children and adolescents struggling with obesity.
    - Mindful eating—It is important to be "in the moment" at mealtimes, not only savoring the food but also enjoying mealtime company. Family meals aid in family bonding and help children reach the goal of eating slowly to promote satiation, tune into internal cues of fullness, and minimize overeating.[22] Yoga has been shown to be an effective means to allay teen fears and help them to deal with anxiety.[23] Patient-centered

communication and motivational interviewing describe a set of counseling techniques directed towards motivating families to make necessary changes towards healthy lifestyles. Key characteristics include: (1) nondirective questions; (2) reflective, nonjudgemental listening; (3) combining family values and current health practices; (4) assessing the patient's (or parent's) level of confidence that they will be successful.[12]

PREVENTION AND SCREENING

Obesity prevention should be a priority for the pediatrician since it is much more difficult to treat rather than prevent child and adolescent obesity. Active involvement and engagement of the entire family is key to successful obesity prevention. The basic approach to prevention and screening of childhood obesity is to identify particular challenges and barriers that a particular family has to changing lifestyles and assess level of readiness to change to tailor messages. Use of motivational interviewing helps patients achieve success.

- The Transtheoretical model for behavior change originally described by Prochaska and Diclemente is still widely used today.[24] There are six proposed stages: precontemplation, contemplation, preparation, action, maintenance, and termination. Depending on level of readiness to change, it may be appropriate to discuss the risks obesity and the benefits of maintaining a healthy weight.
- In order to help individuals work through these stages and frequently through ambivalence towards change, there are five general principles of effective motivational interviewing that can be used: (1) effective empathy, (2) developing discrepancy between present behavior and goals, (3) avoiding argumentation, (4) rolling with resistance, and (5) supporting self-efficacy.[25]
- Pediatricians should calculate the BMI, determine the corresponding percentile, and plot it on standard growth charts at every annual visit for

well child checks.[9] In addition, blood pressures should be taken frequently as well as consideration of family history and medical risks assessment.

- Address parenting style—Studies have shown that between the four parenting styles (authoritarian, authoritative, permissive, and neglectful), authoritarian parenting was associated with the highest risk of overweight in children in the first grade.[26]
- Secretly cooking and baking with hidden vegetables and fruits in kids' favorite dishes is one way to improve nutrition until a taste preference develops for those foods. For example, adding cauliflower to macaroni and cheese.

PROGNOSIS

- Overweight adolescents are more susceptible than their leaner peers to hypertension, type 2 diabetes mellitus, dyslipidemia, lung problems (e.g., asthma or obstructive sleep apnea), orthopedic problems (e.g., genu varum or slipped capital femoral epiphysis) and nonalcoholic steatohepatitis. Obese adolescents may also suffer from depression and low self-esteem.
- The risk of being obese as an adult increases with obesity at different ages as follows:[2] infancy, 14 percent; preschool, 25 percent; age 7 years, 41 percent; age 12 years, 75 percent; adolescence, 90 percent. In addition, over half of obese adolescents remain overweight as young adults.[27]
- In adults, it has been shown that just a 5 to 10 percent weight loss can reduce or eliminate comorbidities such as hypertension, noninsulin-dependent diabetes, and coronary heart disease.[28] Similar results could be anticipated for children as well.

FOLLOW-UP

- Pediatricians should continue to calculate and plot BMI (or weight percentile) yearly and watch for excessive weight gain compared with linear growth, identify and track patients at risk of obesity based on risk factors, encourage and support breastfeeding, routinely promote healthy diets and levels of physical activity, and monitor changes in obesity-associated risk factors.[28]

PATIENT EDUCATION

- Pediatricians should regularly advise parents and families to strive for a healthy life style with a diet that is high in fruits and vegetables, fiber, and calcium while adhering to appropriate portion sizes, and to pursue daily physical activity in the form of different, engaging activities for children and adolescents. Maintaining normal weight and treating obesity-related comorbidities will not only maximize health but also improve quality of life.

195 CUSHING SYNDROME

Elumalai Appachi, MD, MRCP

PATIENT STORY

A 21-month-old girl is brought to the pediatrician for a routine physical examination. The mother notes that the child has recently gained an excessive amount of weight. Examination shows an obese toddler who has a blood pressure of 130/90 mm Hg. The linear growth is noted to be abnormal and her weight has jumped from the 50th percentile at the last visit 6 months ago to above the 90th percentile. The girl has hirsutism and acne on the forehead (**Figure 195-1**). Urinalysis shows glycosuria. The pediatrician is suspicious for hypercortisolism and refers the child to a pediatric endocrinologist. A dexamethasone suppression test reveals lack of suppression of cortisol, consistent with Cushing syndrome. A CT scan of the abdomen reveals an adrenal tumor, which is surgically resected and found to be an adrenal adenoma. The girl is maintained on glucocorticoid therapy and recovers.

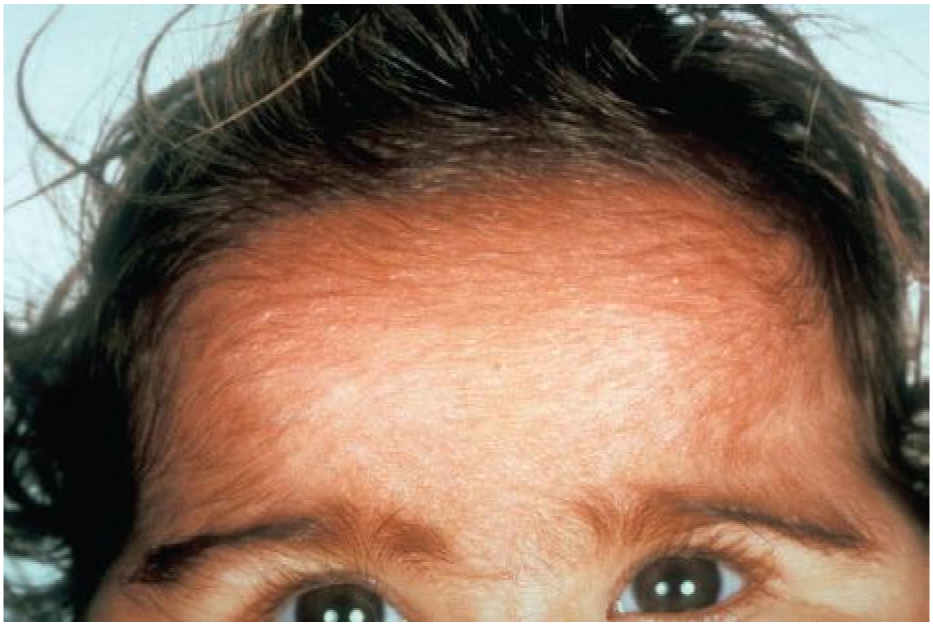

FIGURE 195-1 Acne, milia, and hirsutism on the forehead of a girl with Cushing syndrome caused by an adrenal adenoma. (*Used with permission from Elumalai Appachi, MD.*)

INTRODUCTION

Cushing syndrome occurs as a result of cortisol or glucocorticoid excess from any cause. Excess plasma cortisol production in endogenous Cushing syndrome may be caused by either excess ACTH secretion from the pituitary gland (Cushing disease) or adrenal overproduction of plasma cortisol from adrenal tumors. Cushing syndrome can also be the result of exogenous administration of ACTH or glucocorticoids (iatrogenic).

SYNONYMS

Hypercortisolism.

EPIDEMIOLOGY

- Non-iatrogenic Cushing syndrome is rare in children.
- Children with lymphoproliferative disorders, nephrotic syndrome, and autoimmune disorders are at risk for developing exogenous Cushing syndrome.
- The incidence of Cushing syndrome is higher in obese patients with type 2 diabetes, occurring in 2 to 5 percent of these patients.[1]
- Cushing syndrome is 2 to 3 times more common in girls than boys.

ETIOLOGY AND PATHOPHYSIOLOGY

- Cushing syndrome is most commonly caused by the administration of oral, parenteral, or topical glucocorticoids (exogenous or iatrogenic Cushing syndrome).
- In children over 7 years of age, true Cushing disease (hypersecretion of pituitary ACTH causing adrenal hyperplasia) is the most common cause of Cushing syndrome.[2]
- In infants and young children, Cushing syndrome is most often caused by a functioning adrenocortical tumor. Infants show signs of hypercortisolism along with signs of hypersecretion of other steroids such as androgens, estrogens, and aldosterone.[3–5]
- ACTH-dependent Cushing syndrome may also result from ectopic production of ACTH, although this is uncommon in children. Ectopic ACTH secretion in children has been associated with islet cell carcinoma of the pancreas, neuroblastoma, hemangiopericytoma, Wilms tumor, and thymic carcinoid.[6]

RISK FACTORS

- Lymphoproliferative disorders.
- Nephrotic syndrome.
- Autoimmune disorders.
- Obesity and type 2 Diabetes mellitus.

DIAGNOSIS

The diagnosis is made by the combination of clinical features and specific lab tests.

CLINICAL FEATURES

- Weight gain and growth arrest are the earliest and most reliable indicators of hypercortisolism in children (**Figure 195-2**).[3–5]

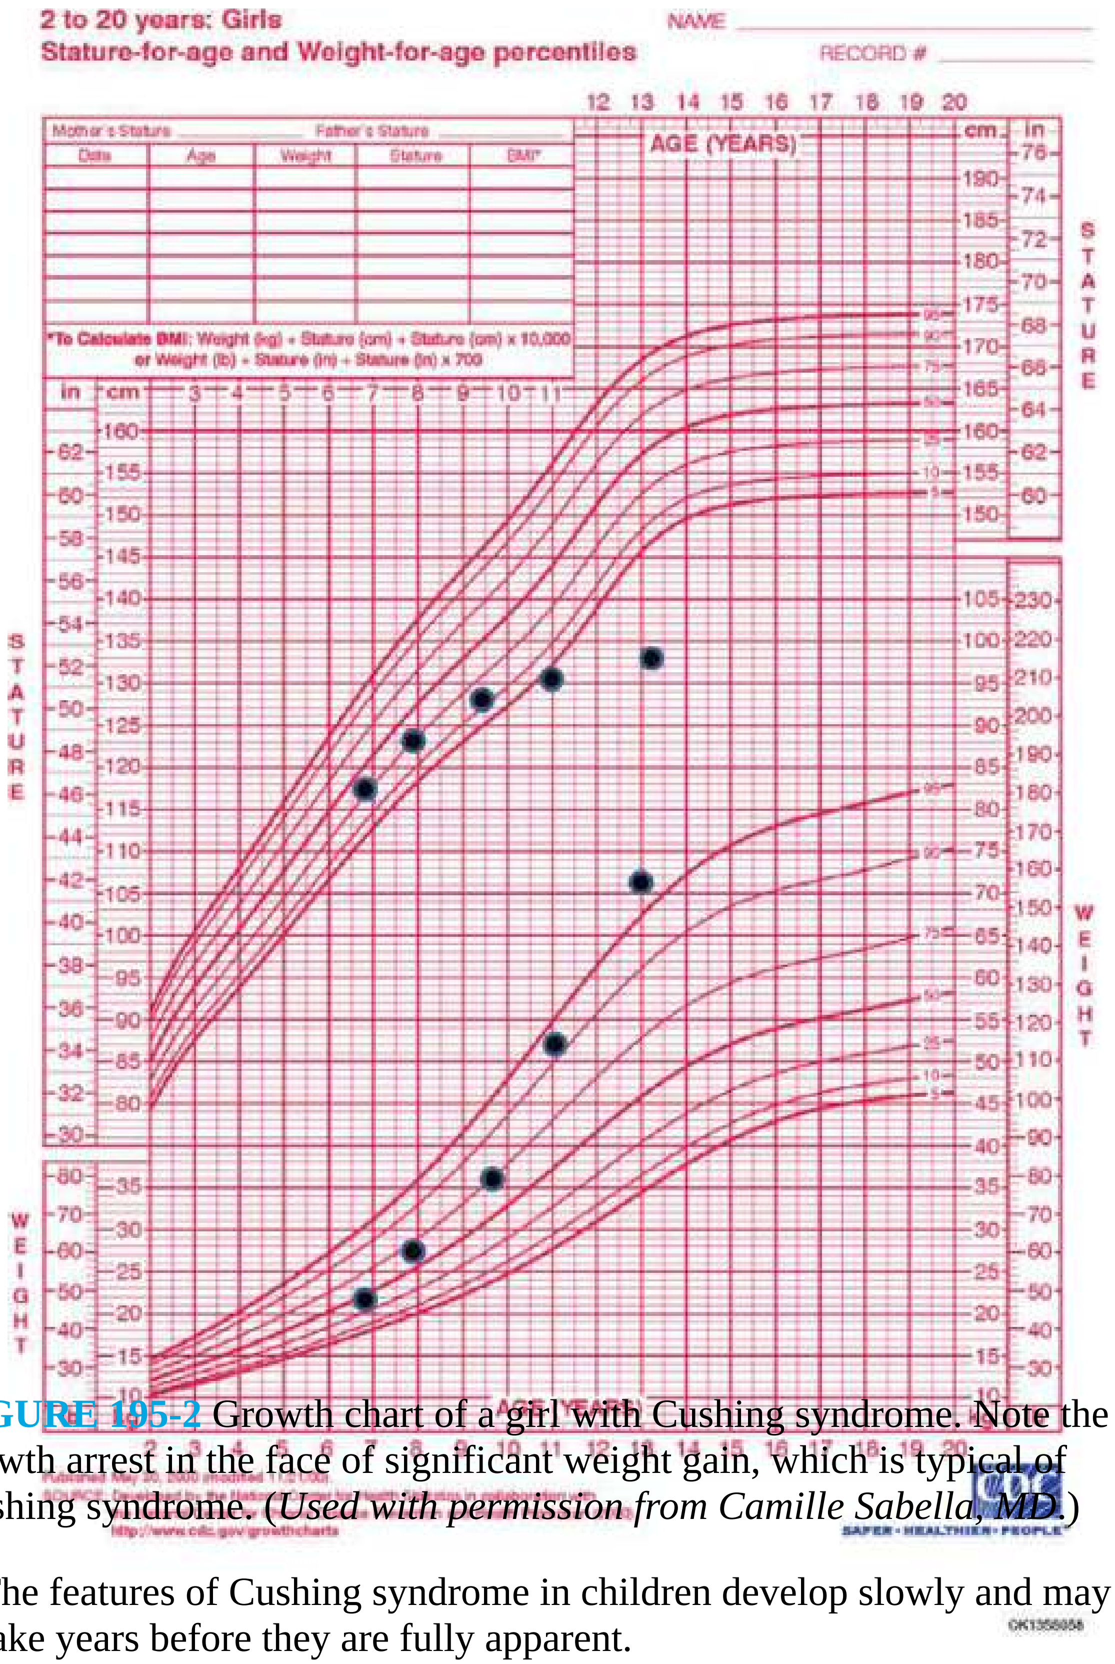

FIGURE 195-2 Growth chart of a girl with Cushing syndrome. Note the growth arrest in the face of significant weight gain, which is typical of Cushing syndrome. (*Used with permission from Camille Sabella, MD.*)

- The features of Cushing syndrome in children develop slowly and may take years before they are fully apparent.
- Rounded face with prominent and flushed cheeks (**Figure 195-3**).

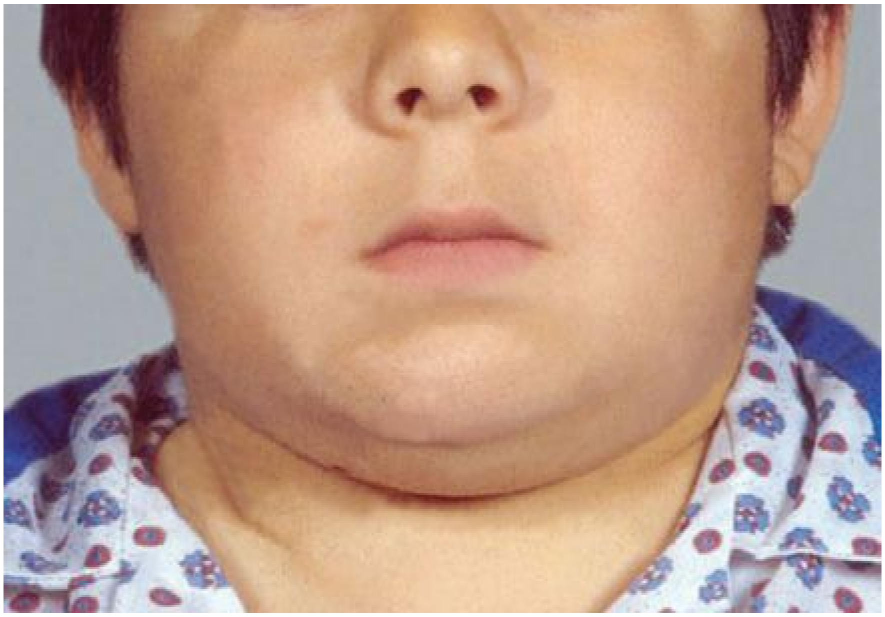

FIGURE 195-3 Rounded face and prominent cheeks in a boy with Cushing syndrome. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Central obesity with "buffalo hump."
- Signs of abnormal masculinization.
- Hirsutism on the face and trunk, pubic hair, acne, deepening of the voice, and enlargement of the clitoris in girls can occur (**Figure 195-1**).
- Hypertension is common and may occasionally lead to heart failure.
- An increased susceptibility to infection may lead to sepsis.
- Hyperglycemia and glucose intolerance is common.
- Purplish striae on the hips, abdomen, and thighs are common (**Figure 195-4**).

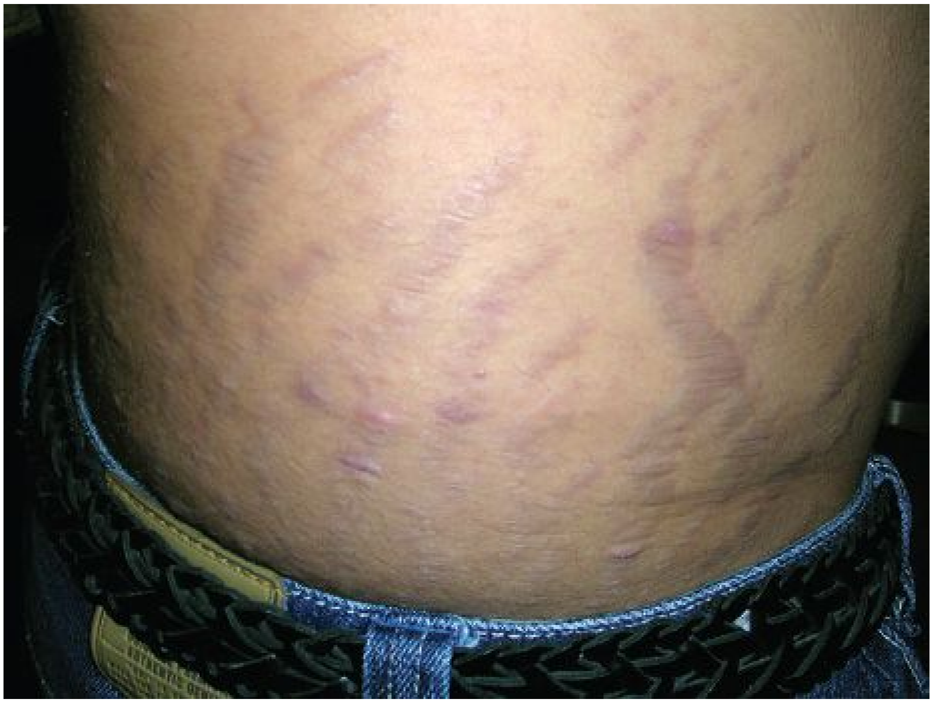

FIGURE 195-4 Striae due to Cushing syndrome caused by exogenous glucocorticoid administration in a 13-year-old boy. (*Used with permission from Richard P. Usatine, MD*.)

- Pubertal development may be delayed, or amenorrhea may occur in girls past menarche.
- Weakness, headache, and emotional lability may be prominent.
- Osteoporosis is common and may cause pathologic fractures.

LABORATORY TESTING

- Loss of the normal diurnal variation of cortisol and ACTH are usually the first laboratory findings in Cushing disease.
- A midnight serum cortisol level greater than 4.4 ug/dL strongly suggests the diagnosis.
- Evening salivary cortisol levels are increased.
- Urinary excretion of free cortisol is increased. This is best measured in a 24-hr urine sample and is expressed as a ratio of micrograms of cortisol

excreted per gram of creatinine.

- Dexamethasone suppression test can be done with a single dose of 25 to 30 µg/kg (maximum of 2 mg) given at 11 PM and the plasma cortisol level is measured the next day. In normal individuals, cortisol level will be suppressed to a level less than 5 µg/dL, but will not be suppressed in children who have Cushing syndrome.[7]
- Measurement of ACTH concentrations show suppressed levels in patients with cortisol-secreting tumors, but may be normal in patients with ACTH-secreting pituitary adenomas.[8]

IMAGING

- CT is the imaging of choice to detect adenomas of the adrenal glands and detects virtually all adrenal tumors larger than 1.5 cm in diameter.
- Contrast MRI may be needed to identify ACTH-secreting pituitary adenomas.

DIFFERENTIAL DIAGNOSIS

Children with simple dietary obesity may have similar clinical features, such as striae and hypertension, but do not have growth failure. These children grow more rapidly and are usually tall for their age (**Figure 195-5**). Furthermore, the urinary excretion of cortisol is also often elevated in simple obesity, but salivary nighttime levels of cortisol are normal and cortisol secretion is suppressed by oral administration of low doses of dexamethasone.

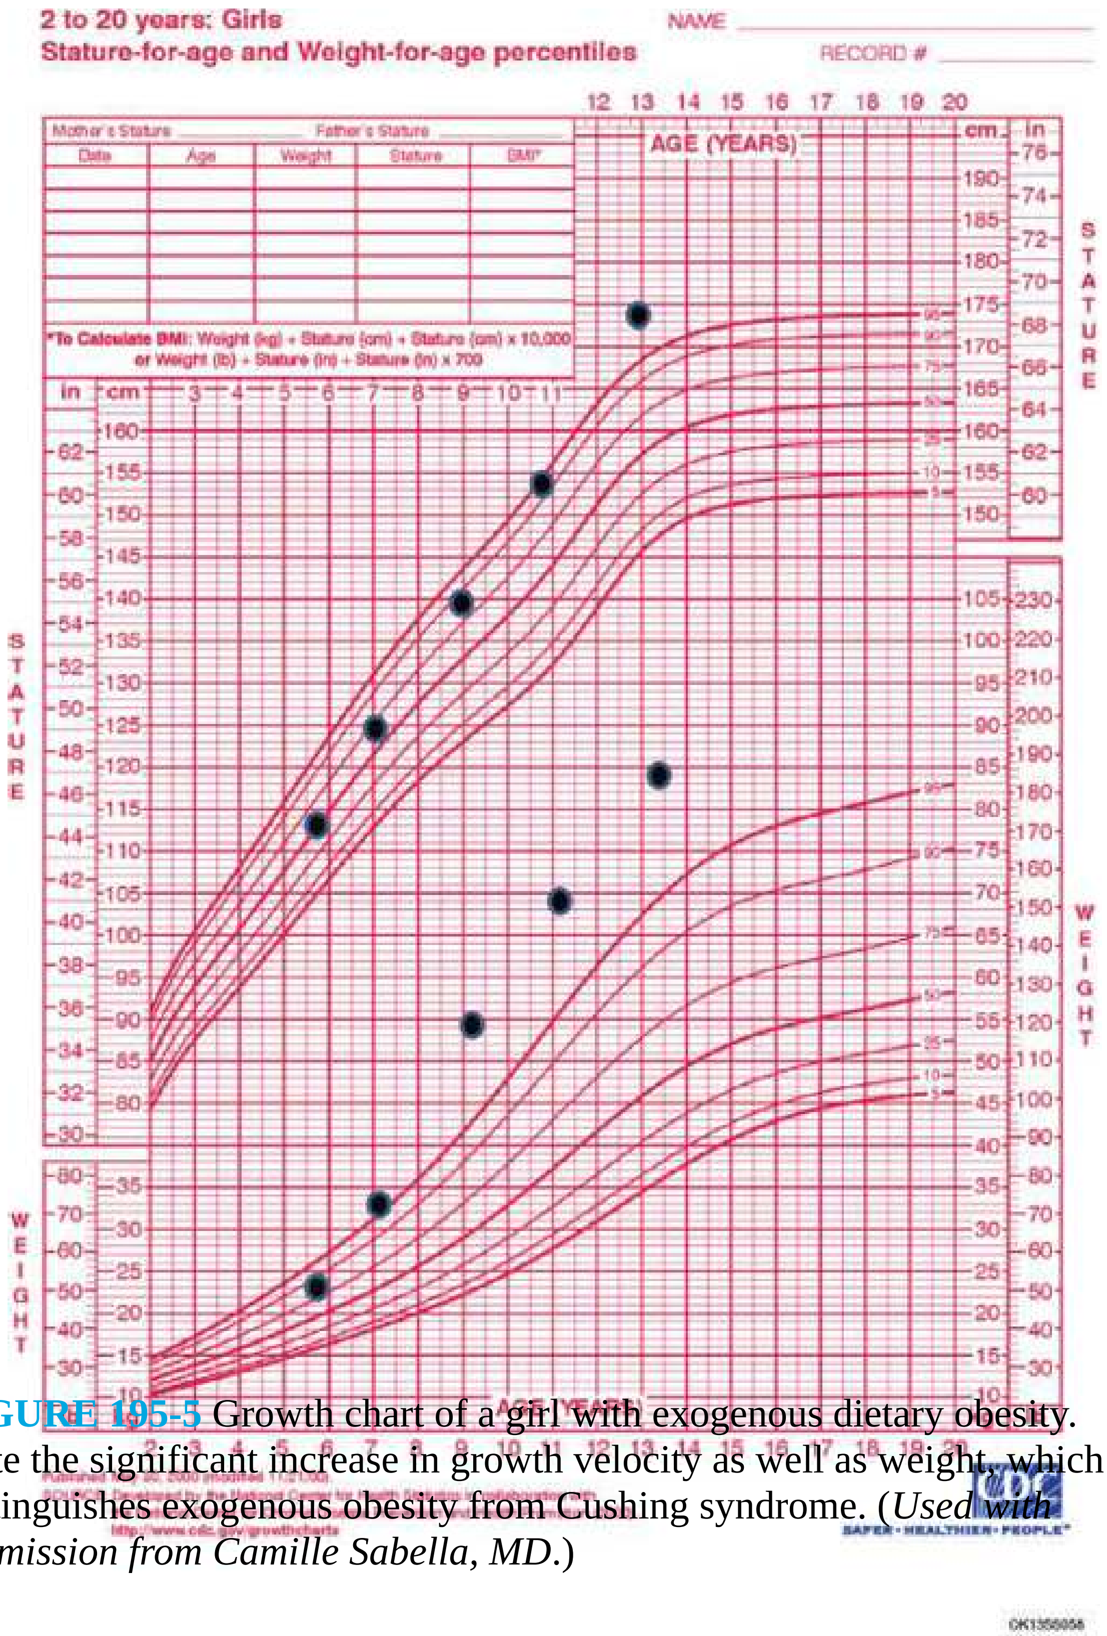

FIGURE 195-5 Growth chart of a girl with exogenous dietary obesity. Note the significant increase in growth velocity as well as weight, which distinguishes exogenous obesity from Cushing syndrome. (*Used with permission from Camille Sabella, MD.*)

MANAGEMENT

- Treatment of Cushing syndrome should be directed at the primary cause of the excess corticosteroids.
- Tumors responsible for the hypercortisolism are generally surgically removed.
- The role of medications that inhibit steroidogenesis and irradiation in the management of Cushing disease in children is not well established.
- Corticosteroid replacement therapy is often necessary following removal of the source of corticosteroids until normal adrenal function returns.

MEDICATIONS

- Cyproheptadine, a centrally acting serotonin antagonist that blocks ACTH release, has been used to treat Cushing disease in adults but is rarely successful in children and has unacceptable adverse effects (weight gain, irritability, and hallucinations).
- Inhibitors of adrenal steroidogenesis (metyrapone, ketoconazole, aminoglutethimide, and etomidate) have been used preoperatively to normalize circulating cortisol levels, but there is very little experience using these agents in the treatment of Cushing disease in children.

SURGERY

- Transsphenoidal pituitary microsurgery is the treatment of choice for pituitary Cushing disease in children.[9,10]
- Complications of transsphenoidal surgery include transient diabetes insipidus and cerebrospinal fluid rhinorrhea.[11]
- Adrenalectomy is usually performed for adrenal tumors.[12]

- Adrenalectomy may lead to increased ACTH secretion by an unresected pituitary adenoma, which can expand and impinge on the optic nerves and produce melanocyte stimulating hormone to produce profound hyperpigmentation of the skin; this condition is termed Nelson Syndrome and is very rare in children.

REFERRAL

- Children suspected of having Cushing syndrome should be referred to a pediatric endocrinologist for work-up and close follow-up.

PREVENTION AND SCREENING

- Although there are no data supporting screening for Cushing syndrome in healthy asymptomatic patients, there may be a role for prudent screening in specific clinical situations as in patients with growth failure, osteoporosis, and easy bruising. Patients on long-term glucocorticoid therapy are at risk and should be closely monitored.

PROGNOSIS

- Prognosis after removal of an adrenal adenoma is good. Adrenal carcinomas are often metastatic and are characterized by a poor 5-year survival rate.
- Initial remission rate after transsphenoidal surgery is 60 to 80 percent, but about 20 percent of children will have a relapse within 5 years.[13,14]

FOLLOW-UP

- Lifelong follow-up and hormone replacement therapy is usually required for nonexogenous causes of Cushing syndrome.

PATIENT EDUCATION

- Patients should be told that the features of Cushing syndrome, including hypertension, glucose intolerance and emotional disturbance may persist after treatment.
- Patients and parents should be educated about stress dose replacement therapy. These patients should wear medical alert labels and carry with them a prefilled glucocorticoid syringe for intramuscular injection when illness develops unexpectedly and oral medication administration is not an option.

196 ADDISON’S DISEASE

Swathi Appachi, BS
Elumalai Appachi, MD, MRCP

PATIENT STORY

A 14-year-old girl with a history of type I diabetes mellitus is brought to her pediatrician because of a 2-month history of fatigue, dizziness, and nausea. On physical exam, she is found to have orthostatic hypotension and the pediatrician notes that she has hyperpigmentation of dorsum of her hands and over her knees (**Figures 196-1** and **196-2**). The pediatrician is concerned about adrenal insufficiency and promptly refers the girl to an endocrinologist. The girl is found to have a low early morning serum cortisol, high serum adrenocorticotropin hormone level, and anti-adrenal antibodies, confirming the diagnosis of primary adrenal insufficiency.

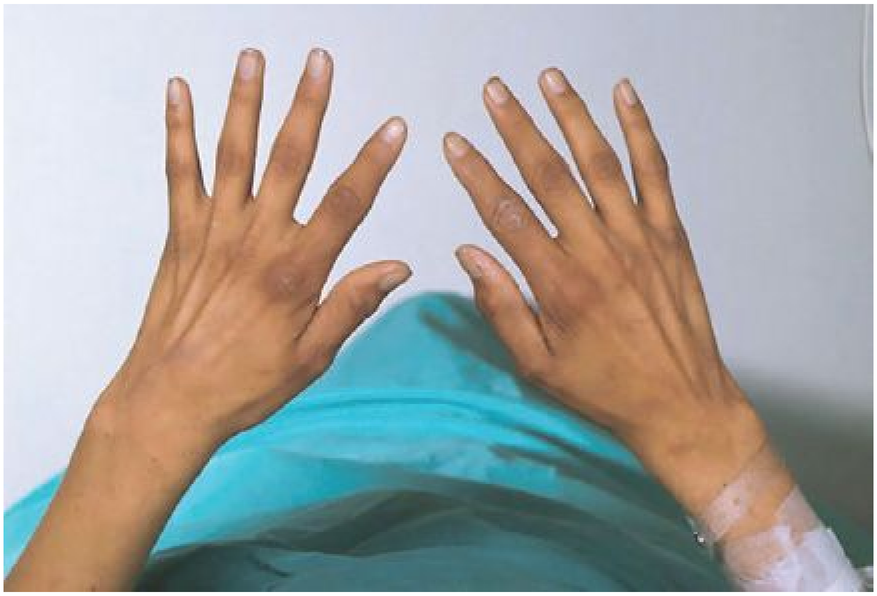

FIGURE 196-1 Hyperpigmentation over the dorsal aspect of the hands in a teenager with primary adrenal insufficiency. (*Used with permission from*

Cleveland Clinic Children’s Hospital Photo Files.)

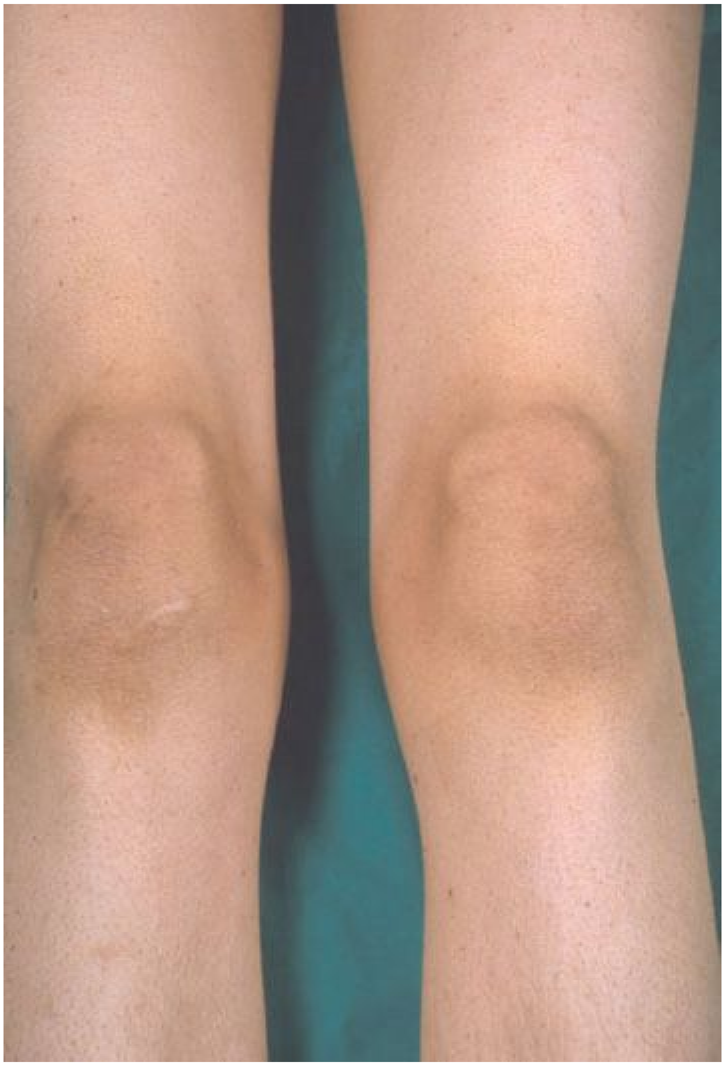

FIGURE 196-2 Hyperpigmentation of the skin overlying the knees in the same girl as in Figure 196-1. (*Used with permission from Cleveland Clinic Children’s Hospital Photo Files*.)

INTRODUCTION

Addison’s disease refers to dysfunction or hypofunction of the adrenal cortex which leads to primary adrenal insufficiency. The adrenal cortex is unable to produce and secrete glucocorticoids (cortisol) and mineralocorticoids (aldosterone), leading to an increase in adrenocorticotropin hormone (ACTH) and systemic effects in children, such as fatigue and gastrointestinal symptoms. Hyperpigmentation of the skin is a distinguishing feature. In children, congenital adrenal hyperplasia is the most common cause of Addison’s disease (see Chapter 197, Congenital Adrenal Hyperplasia). The second most common cause of Addison’s disease worldwide is tuberculosis and other granulomatous disorders. In developed countries, the second most common cause is autoimmune disease, which is the focus of this chapter.[1]

SYNONYMS

Primary adrenal insufficiency, adrenocortical hypofunction.

EPIDEMIOLOGY

- Addison’s disease is rare, with a prevalence of 140 per million.[1]
- Autoimmune Addison’s disease constitutes 15 percent of all cases of primary adrenal insufficiency and usually presents during childhood.
  - Other causes include infection, adrenal hypoplasia congenital (congenital adrenal hypoplasia caused by a mutation in the DAX1 gene), and adrenoleukodystrophy.[2]
- Approximately 1/2 of patients with this disorder also have autoimmune disorders of other endocrine glands. This condition is known as autoimmune polyglandular syndrome (APS) and occurs more often in females (70%).
  - Isolated autoimmune disease is more prevalent in males (71%).[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Addison’s disease is thought to result from autoimmune attack of the adrenal gland, leading to destruction of the cortical parenchyma.
    - There is evidence that both humoral and cell-mediated immunity are involved.[2]
- Autoimmune Addison’s disease is often associated with other autoimmune phenomena, especially polyglandular syndromes.
    - APS1 (also known as autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy, or APECED)—This syndrome includes adrenal insufficiency, hypoparathyroidism, and chronic mucocutaneous candidiasis. Autosomal recessive mutations in the autoimmune regulator (AIRE) gene are responsible.
    - APS2 (also known as Schmidt syndrome)—This entity consists of adrenal insufficiency, thyroiditis, and diabetes mellitus type 1. It is more prevalent than APS1.[3]
- Destruction of the adrenal cortex leads to low cortisol and low aldosterone, producing the symptoms of Addison’s disease. Low cortisol also leads to increased synthesis of the prohormone pro-opiomelanocortin, which is cleaved to form ACTH and melanocyte stimulating hormone (MSH). Increased MSH levels in turn lead to increased melanin synthesis in melanocytes causing hyperpigmentation.[2]

RISK FACTORS

- Family history.[3]
- Other autoimmune diseases such as:
    - Diabetes mellitus type 1.
    - Graves disease.
    - Hypoparathyrodism.
    - Hypopituitarism.
    - Vitiligo.

DIAGNOSIS

CLINICAL FEATURES

- The most common presenting features of Addison's disease in children are fatigue, nausea, and vomiting. Clinical features of Addison's disease are due to hormonal deficiencies.[2–4]
- Low aldosterone leads to sodium wasting which in turn causes hypotension, dizziness, anorexia, weight loss, salt craving, electrolyte abnormalities, and dehydration.[2–4]
- Low cortisol leads to fatigue, weakness, morning headache, nausea, vomiting, diarrhea, and failure to thrive. Severe hypoglycemia can occur as well.[1,2,4]
- Hyperpigmentation from increased MSH is most apparent in areas exposed to sunlight or pressure, as well as the tongue, gingiva, axillary creases, and scars (**Figures 196-1** to **196-3**).

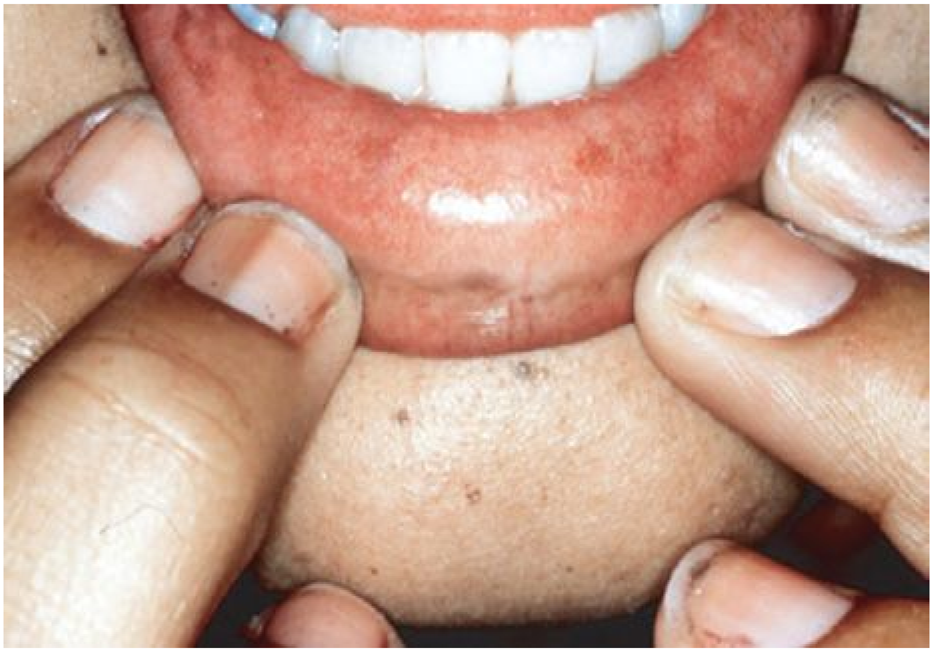

FIGURE 196-3 Hyperpigmentation of the lip, skin, and nails in a child with primary adrenal insufficiency. (*Used with permission from Strange GR, Ahrens WR, Schafermeyer RW, Wiebe RA: Pediatric Emergency Medicine, 3rd edition: http://www.accessemergencymedicine.com. Figure 77-2*.)

- It is important to remember that due to the autoimmune destruction of melanocytes that is sometimes seen in autoimmune Addison's disease, vitiligo and hypopigmentation may actually occur.[2]
- Amenorrhea can be seen in females.

LABORATORY TESTING

- Laboratory testing is essential for the diagnosis of Addison's disease. Adrenal insufficiency must be proven with tests of adrenocortical function.
- An early morning serum cortisol or ACTH stimulation test should be done to establish adrenal sufficiency. In the former, serum cortisol is measured at 8 AM, which corresponds with a peak in cortisol production. Low cortisol indicates adrenal insufficiency. In the latter test, serum cortisol is measured before and 60 minutes after administration of synthetic ACTH (cosyntropin). A low cortisol response demonstrates adrenal insufficiency.[4]
- Plasma ACTH levels should then be measured to differentiate between primary and secondary adrenal insufficiency. High ACTH levels indicate primary adrenal insufficiency.[4]
- To establish the diagnosis of autoimmune Addison's disease, levels of anti-adrenal antibodies, such as adrenal cortex autoantibody or 21-hydroxylase autoantibody, should be measured.[3,4]
  - If positive, antibodies against other glands (such as the parathyroid or thyroid) should be measured to test for APS.
  - If negative, the other causes of primary adrenal insufficiency, such as tuberculosis, adrenoleukodystrophy, or adrenal hypoplasia congenita, should be ruled out.

DIFFERENTIAL DIAGNOSIS

- If the patient's initial presentation is that of a salt-losing crisis with vomiting, hyponatremia, and hyperkalemia, these symptoms can also be seen in obstructive uropathy, pyelonephritis, or tubulointerstitial nephritis. These can especially occur in infants and occurs as a result of secondary aldosterone resistance in the kidneys.[4]
- The differential for autoimmune Addison's specifically includes other causes of primary adrenal insufficiency, such as congenital adrenal hyperplasia, infection, drugs, hemorrhage, adrenoleukodystrophy, or adrenal hypoplasia congenita.[2]

MANAGEMENT

- There is no cure for the autoimmune form of Addison's disease, but it can be managed by physiological replacement of cortisol and aldosterone.

MEDICATIONS

- Cortisol can be replaced with hydrocortisone, prednisone, or dexamethasone. In children, the former two are used more often. Hydrocortisone is less potent than prednisone and has a shorter half-life, allowing for better titration. However, prednisone can be given less frequently. Normal cortisol secretion in children is estimated to be about 7 to 12 mg/m^2/day. Somatic growth should be followed closely.[3]
    - Doses must be increased in times of physiologic stress, such as illness or surgical procedures. Children may not be able to take the medication orally during these times, and thus injection of hydrocortisone is the preferred method of administration.
- Aldosterone is usually replaced with fludrocortisone at 0.05 to 0.2 mg/day. This dosage may need to be increased in infants, and infants

younger than 1 year may require supplementation with sodium chloride. Again, somatic growth should be monitored.[3]

REFERRAL

- An endocrinologist should be involved in care of the patient.

PREVENTION AND SCREENING

- Addison's disease cannot be prevented. Physicians should retain a high index of suspicion in children presenting with nonspecific symptoms such as fatigue and gastrointestinal symptoms.

PROGNOSIS

- With appropriate replacement of glucocorticoids and mineralocorticoids, most patients with autoimmune Addison's disease can live normal lives.

FOLLOW-UP

- Follow-up is contingent on the affected systems. An endocrinologist should be involved with the patient's care.

PATIENT EDUCATION

- Patients and their families should carry prefilled syringes with steroids in case of emergency or sudden physiologic stress. A Medic Alert bracelet should also be considered.

197 CONGENITAL ADRENAL HYPERPLASIA

Elumalai Appachi, MD, MRCP

PATIENT STORY

A 3400-gram infant is being evaluated by the pediatrician after an uncomplicated term gestation and vaginal delivery. The infant is noted to have ambiguous genitalia, characterized by clitoromegaly, enlarged labia, and no palpable testes. A single urethral/vaginal opening is present (**Figure 197-1**). A diagnosis of congenital adrenal hyperplasia is suspected based on these findings. A pediatric endocrinologist is consulted, who orders a serum 17-hydroxyprogesterone level, which is markedly elevated, and a rapid karyotype, which reveals a 46 XX karyotype, confirming the diagnosis of CAH caused by 21-hydroxylase deficiency. The infant is treated with glucocorticoids and the parents receive psychosocial and genetic counseling regarding the diagnosis.

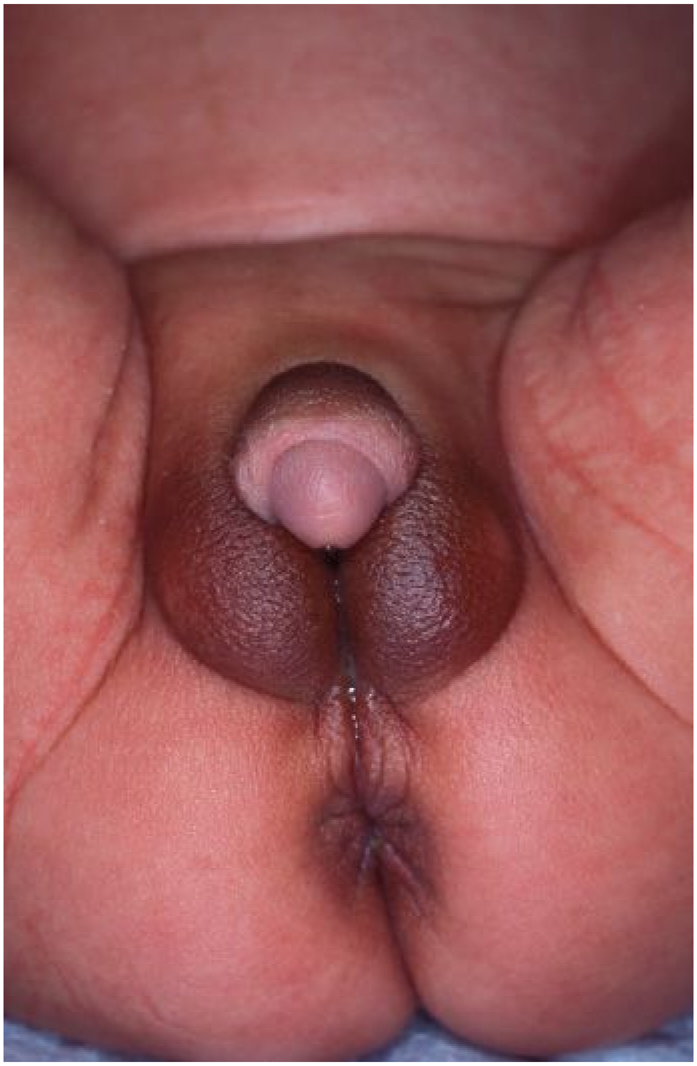

FIGURE 197-1 Ambiguous genitalia, manifested by clitoromegaly, enlarged and hyperpigmented labia, fused urogenital opening, in a female infant with congenital adrenal hyperplasia. (*Used with permission from Elumalai Appachi, MD.*)

INTRODUCTION

Congenital adrenal hyperplasia (CAH) is an autosomal-recessive disorder most commonly (95%) caused by 21-hydroxylase deficiency. Classic CAH refers to the salt wasting and simple virilizing form, while nonclassic, or late onset CAH, refers to a less severe form of the disorder and may not be apparent until later in life. This chapter will focus on classic CAH caused by 21-hydroxylase deficiency. Patients with the salt-wasting variety of congenital adrenal hyperplasia present with failure to thrive, dehydration, vomiting, and anorexia. In female infants, virilization of the external genitalia leads to an early diagnosis; the condition is often diagnosed later in male infants with the salt-wasting variety (2 to 3 weeks of life) because the external genitalia may appear normal.

SYNONYMS

Primary adrenal insufficiency, 21-hydroxylase deficiency, pseudohermaphroditism.

EPIDEMIOLOGY

- 21-hydroxylase deficiency accounts for 95 percent of all forms of CAH.
- The incidence of 21-hydroxylase deficiency is 1 in 15,000 live births and is one of the most common inborn errors of metabolism.[1–3]
- The incidence of CAH is equal among Caucasians and Hispanics and about fourfold less common in African Americans.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Inherited defects in the enzymatic steps of cortisol biosynthesis (steroidogeneses) result in congenital adrenal hyperplasia.
- The resulting decrease in cortisol levels increases the secretion of adrenocorticotropic hormone (ACTH), thereby stimulating the production of adrenal steroids up to and including the substrate for the defective

enzyme. This chronic ACTH stimulation results in hyperplasia of the adrenal cortex (**Figure 197-2**).

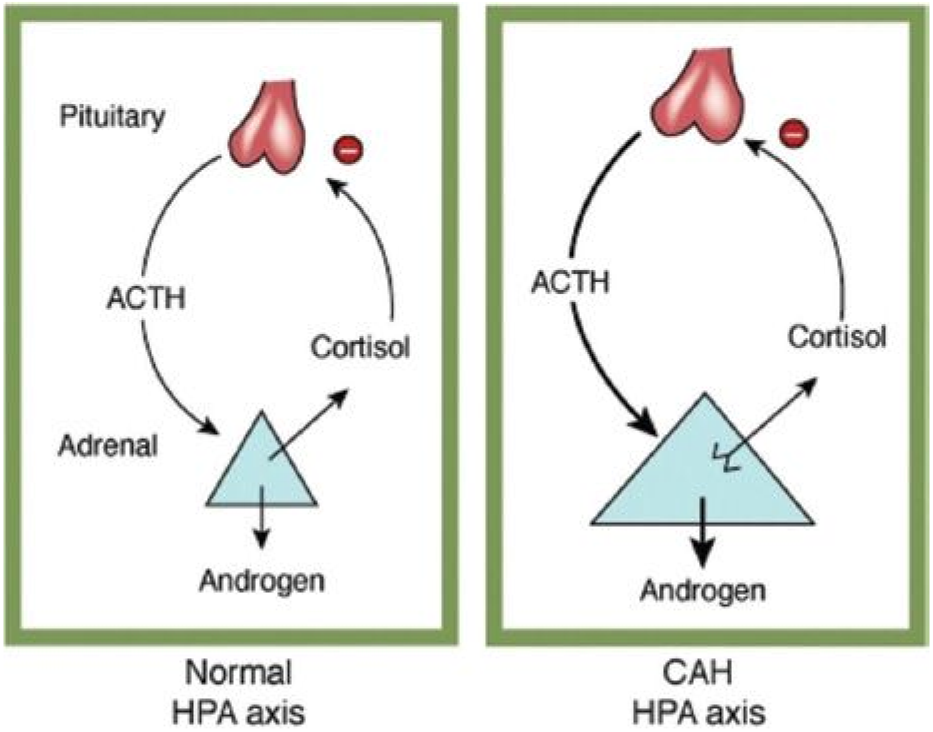

FIGURE 197-2 Classic adrenal hyperplasia (CAH) showing loss of the negative feedback loop caused by impaired glucocorticoid synthesis, resulting in adrenocorticotropic hormone (ACTH) excess resulting in androgen overproduction. HPA = hypothalamic-pituitary axis. (*Used with permission from Kappy, MD, Allen DB, Geffner ME: Pediatric Practice: Endocrinology: www.accesspediatrics.com. Figure 8-6.*)

- Accumulation of 17-hydroxyprogesterone and other steroid precursors results in shunting into a pathway for androgen biosynthesis, leading to high levels of androstenedione that are converted outside the adrenal gland to testosterone. The effects of this shunting begin in affected fetuses by 8 to 10 weeks of gestation and leads to abnormal genital development in females (**Figure 197-3**).

- The clinical manifestations of these disorders are related to one or both of the following pathologic processes:
  - Impaired synthesis of cortisol—Results in increased ACTH secretion causing accumulation of 17-hydroxyprogesterone and other steroids that can be converted to testosterone. In the male fetus with 21 hydroxylase deficiency, the additional testosterone produced in the adrenals has no phenotypic effect. In a female fetus, the testosterone inappropriately produced by the adrenals of the affected female fetus causes varying degrees of virilization of the external genitalia.

  - Impaired synthesis of aldosterone—Resulting in severe hyponatremia, hyperkalemia, and acidosis with concomitant hypotension, shock, cardiovascular collapse, and death in an untreated newborn infant; this usually develops during the second week of life.
- In some forms of CAH (11-hydroxylase deficiency), there is excessive synthesis of mineralocorticoids such as deoxycorticosterone, which can cause hypertension.[1,2]
- 21-hydroxylase deficiency can be caused by a gene deletion, conversion or point mutation in *CYP21A2* (termed *21b*) gene. The severity of the manifestations is related to whether the genetic mutations are heterozygous or homozygous.[4]

RISK FACTORS

- Autosomal recessive inheritance.
- Consanguineous marriage.

DIAGNOSIS

- Neonatal screening for 21-hydroxylase deficiency has become a routine test in the neonatal screening program. This is performed by screening for 17-hydroxyprogesterone (17OHP), which is measured using a filter paper blood sample obtained by a heel puncture, preferably at 2 to 4 days of age.[5]
- Neonatal screening allows early diagnosis and treatment of infants who may be missed on clinical examination. This may prevent adrenal crisis and death and allows earlier gender assignment.

CLINICAL FEATURES

- Female infants usually present at birth with ambiguous genitalia (**Figures 197-1** and **197-4**). This is manifested by enlargement of the clitoris and by partial or complete labial fusion. The vagina usually has a common opening with the urethra (urogenital sinus). The clitoris may be so enlarged that it resembles a penis; because the urethra opens below this organ, some affected females may be mistakenly presumed to be males with hypospadias and cryptorchidism. Hyperpigmentation of the labioscrotal folds is common. The severity of virilization is usually greatest in females with the salt-losing form of 21-hydroxylase deficiency. The internal genital organs are normal, because affected females have normal ovaries and not testes and thus do not secrete antimüllerian hormone.

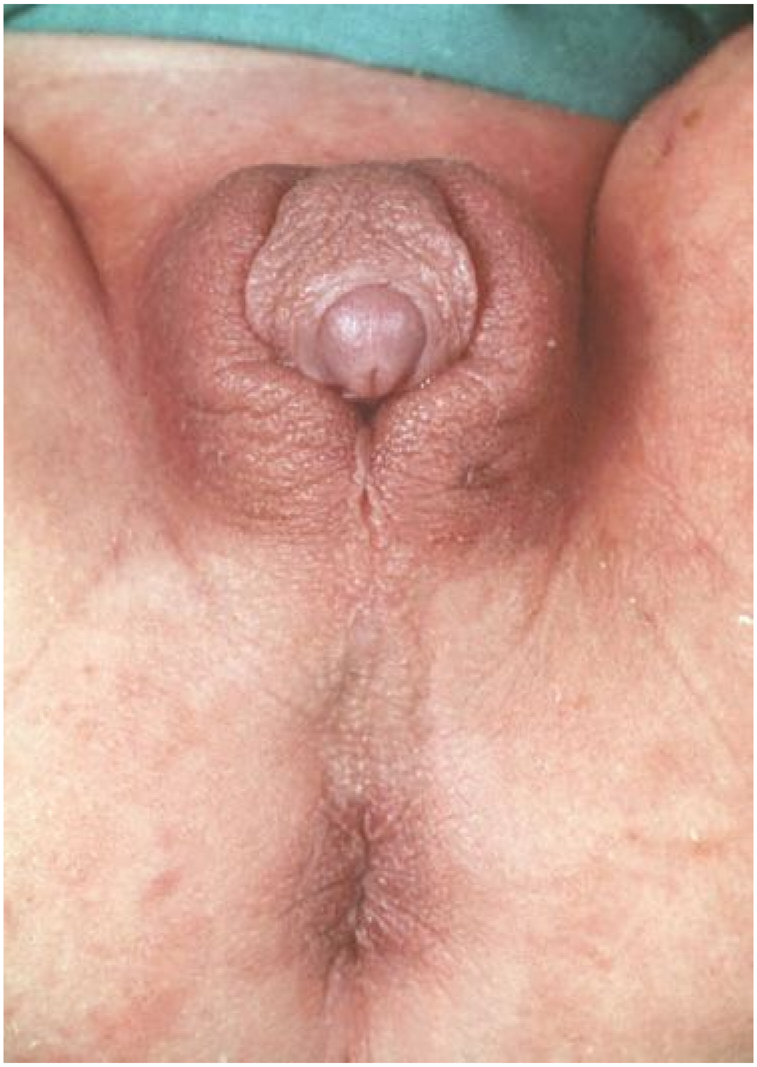

FIGURE 197-4 Clitoromegaly and enlarged labial folds in a girl with congenital adrenal hyperplasia. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Male infants appear normal at birth. They present with weight loss, anorexia, vomiting, dehydration, shock, hyponatremia, hyperkalemia, and azotemia typically at 10 to 14 days of age. Thus, the diagnosis may not be made in boys until signs of adrenal insufficiency develop. Because patients with this condition can deteriorate quickly, male infants are more likely to die than female infants.

LABORATORY TESTING

- Infants with classic CAH have markedly elevated baseline adrenocortical hormones, due to a highly stimulated adrenal cortex. A very high serum concentration of 17-hydroxyprogesterone (random or ACTH-stimulated) is diagnostic of classic 21-hydroxylase deficiency.
- A rapid karyotype (such as fluorescence in situ hybridization of interphase nuclei for X and Y chromosomes) can quickly determine the genetic sex of the infant, and is an important first step in diagnosis and gender assignment.
- Blood levels of cortisol are usually low in patients with the salt-losing type of disease. They are often normal in patients with simple virilizing disease but inappropriately low in relation to the ACTH and 17-hydroxyprogesterone levels.
- In addition to 17-hydroxyprogesterone, levels of androstenedione and testosterone are elevated in affected females; although testosterone levels in affected males are high in relation to levels seen later in childhood, they are not elevated in relation to normal unaffected infants.
- Levels of urinary 17-ketosteroids and pregnanetriol are elevated in affected infants. Because these require 24-hour urine collections, they are rarely used in the diagnostic work-up.[5]

IMAGING

- Ultrasonography is helpful in demonstrating the presence or absence of a uterus and can often locate the gonads in infants with ambiguous genitalia.

DIFFERENTIAL DIAGNOSIS

- The first step in evaluating an infant with ambiguous genitals is a thorough physical examination to define the anatomy of the genitalia, locate the urethral meatus, and palpate the scrotum or labia and the inguinal regions for testes. Palpable gonads almost always indicate the presence of testicular tissue and thus a genetic male infant. Ultrasound and a rapid karyotype can help with gender assignment.
- Neonatal sepsis and infection can present with acidosis, dehydration, and abnormal electrolytes, and should be ruled out by obtaining appropriate cultures (see Chapter 187, Congenital and Perinatal Infections).
- Renal Dysplasia—Infants with renal dysplasia present with hyponatremia and acidosis and can be confused with CAH. Renal work up including renal ultrasound usually points towards the diagnosis.

MANAGEMENT

- The management of CAH in newborns requires consultation with a pediatric endocrinologist.[1,2,6,7]
- Cortisol deficiency is treated with glucocorticoids. Glucocorticoids also suppress excessive production of androgens by the adrenal cortex and will minimize problems such as excessive growth, skeletal maturation, and virilization.

MEDICATIONS

- Newly diagnosed newborns often require larger glucocorticoid doses than are needed in other forms of adrenal insufficiency.
- Infants with salt-wasting disease (i.e., aldosterone deficiency) require mineralocorticoid replacement with fludrocortisone. Infants may have very high mineralocorticoid requirements in the first few months of life, and often require sodium supplementation.[7]

SURGERY

- Significantly virilized females may undergo surgery between 2 to 6 months of age. If there is severe clitoromegaly, the clitoris is reduced in size, with partial excision of the corporal bodies and preservation of the neurovascular bundle; however, moderate clitoromegaly may become much less noticeable even without surgery as the patient grows.
- Vaginoplasty and correction of the urogenital sinus usually are performed at the time of clitoral surgery; revision in adolescence is often necessary.[8]

PREVENTION AND SCREENING

- Because 21-hydroxylase deficiency is often undiagnosed in affected males until they have severe adrenal insufficiency, all states in the US and many other countries have instituted newborn screening programs. These programs analyze 17-hydroxyprogesterone levels in dried blood obtained by heel-stick and absorbed on filter paper cards; the same cards are screened in parallel for other congenital conditions such as hypothyroidism and phenylketonuria. The parents of potentially affected infants are quickly contacted so the infant may receive additional testing (electrolytes and repeat 17-hydroxyprogesterone determination) at approximately 2 weeks of age.
- Prenatal diagnosis may help facilitate appropriate prenatal treatment of affected females. Mothers with pregnancies at risk (when both parents are

known to be heterozygotes) may be given dexamethasone as soon as pregnancy is diagnosed, which can suppress secretion of steroids by the fetal adrenal, including secretion of adrenal androgens, and may ameliorate virilization of the external genitals in affected females.[9] Chorionic villus biopsy is then performed to determine the sex and genotype of the fetus; therapy is continued only if the fetus is an affected female.

- DNA analysis of fetal cells isolated from maternal plasma for sex determination and CYP21 gene analysis may permit earlier identification of the affected female fetus.

PROGNOSIS

- With proper treatment, the prognosis of CAH is good. Most infants will have minimal morbidity and normal longevity with appropriate medical therapy and surgical restoration, if needed.

FOLLOW-UP

- Infants and children with CAH require regular follow-up with a pediatric endocrinologist.
- Increasing doses of glucocorticoids are often required during times of stress.

PATIENT EDUCATION

- Parents should be offered psychosocial as well as genetic counseling on confirmation of diagnosis.

- Children should be informed of their condition in a manner appropriate to their age and development, by both their physicians and parents. Information should be communicated sensitively, simply, and should be repeated at appropriate intervals.
- Parents should receive anticipatory counseling about the possible tendency toward male gender role behavior in affected girls.
- Adolescent girls should receive independent psychosexual counseling.
- Patients must understand the importance of lifelong treatment and monitoring.
- Reduced fertility has been reported in females who have a history of CAH. This should be discussed with patients at the appropriate age.
- The need for increasing dosing of glucocorticoids during times of stress should be discussed with parents and patients.
- Injectable hydrocortisone should be kept in the home and parents should be able to administer this in emergency situations (e.g., if the patient is unconscious or has severe diarrhea).
- Patients with CAH should wear medical identification jewelry with details of their condition and medication.

198 RICKETS

Di Sun, BS, MPH
Elumalai Appachi, MD, MRCP

PATIENT STORY

A 2-year-old boy is brought to the pediatrician by his mother, who reports that the boy appears more irritable lately and does not seem to be growing. After further questioning, the mother mentions that her child has also complained of leg pain and a “waddling” gait. On exam, the boy has widening of the wrists and bowing of his legs and prominence of the costochondral junctions (rachitic rosary; **Figures 198-1** and **198-2**). The pediatrician asks about the child’s diet, and the mother reveals that the patient is a very picky eater and drinks only fruit juice that is not fortified with vitamin D. The pediatrician is concerned about rickets and orders a serum alkaline phosphatase, which is elevated, and vitamin D level (25-OH Vitamin D), which is low. X-ray of the tibia and femur demonstrated widening of the growth plate and metaphysis (**Figure 198-3**). The pediatrician prescribes vitamin D and calcium supplementation for the child. After 3 months of supplementation, the boy’s symptoms have resolved and repeat x-ray showed a dense zone of calcification at the metaphysis with improvement in the widened growth plate.

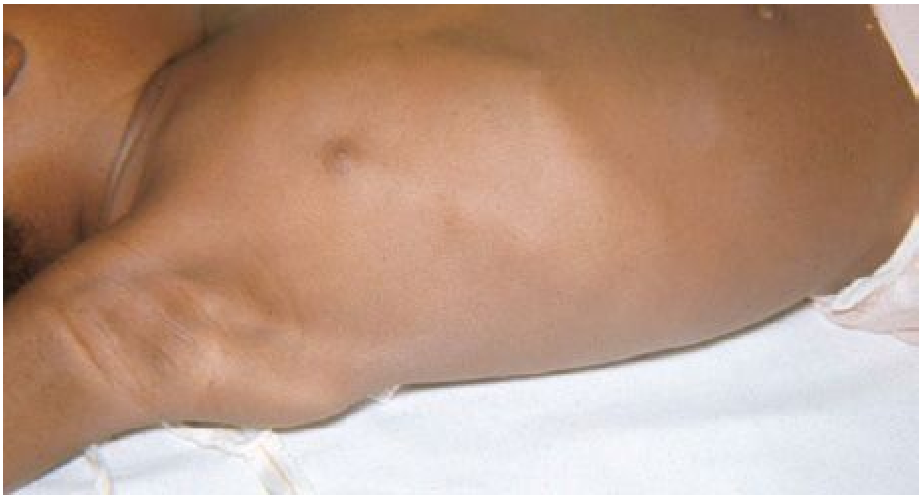

FIGURE 198-2 Prominence of the costochondral junction (rachitic rosary) in the same child as in **Figure 198-1**. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

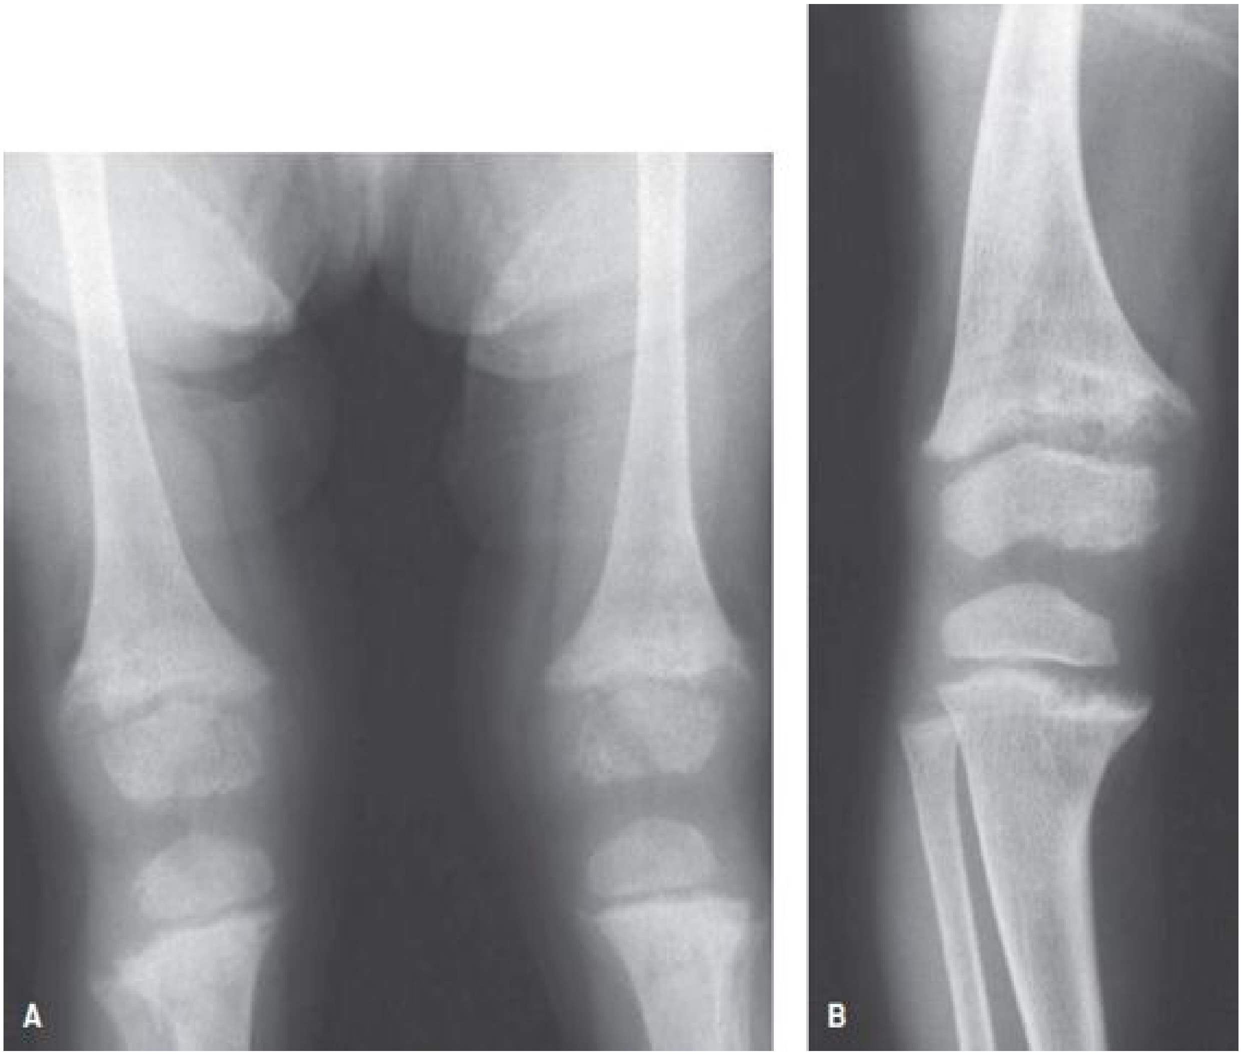

FIGURE 198-3 Cupping and fraying of the metaphyses and bowing of the tibia and femur on (**A**) bilateral and (**B**) unilateral views. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

INTRODUCTION

- Rickets is a defect in bone mineralization that occurs in children prior to epiphyseal fusion, resulting in widening of the growth plates, bone pain, decreased strength of bone, bone deformities, and signs of hypocalcemia.[1–3] This condition is primarily due to nutritional deficiency, specifically vitamin D deficiency, but can also occur with calcium or phosphorus deficiency. There are also hereditary and secondary (renal losses of calcium and phosphate) causes of rickets. Management of rickets depends on the specific etiology. Nutritional deficiencies can be treated with supplementation.

SYNONYMS

Osteomalacia in children, Osteomalacia (Rickets in adults).

EPIDEMIOLOGY

- Nutritional rickets in the US is relatively uncommon; in case reports published between 1986 to 2003, there were 166 cases of documented rickets.[4]
- The prevalence of hypovitaminosis D in the US ranges from 1 to 78 percent with breastfed infants born in the winter being the most likely to be vitamin D-deficient. Vitamin D deficiency was associated with older age, winter season, higher body mass index, African-American race, and elevated parathyroid hormone as a result.[5]
- Hereditary causes of rickets are very rare, the most common being X-linked hypophosphatemic rickets (XLH), which has a prevalence of 1/20,000.[6]

ETIOLOGY AND PATHOPHYSIOLOGY

- Rickets is defined as a defect of bone mineralization of the osteoid, or protein matrix, of growing bone (prior to epiphyseal fusion). The mineral component of bone consists of calcium and phosphate hydroxyapatite crystals. When there is inadequate mineralization of growing bone, there is impaired growth at the metaphysis and a general decrease in bone strength.[1]

- The regulation of bone mineralization depends on the calcium*phosphorus product, which is modulated by vitamin D, parathyroid hormone (PTH), and phosphatonin.
  - The majority of vitamin D is generated from skin following ultraviolet B exposure. Vitamin D can also be obtained from vitamin D_2 found in plants and vitamin D_3 found in animal products such as milk. Vitamin D is converted to Calcidiol (25(OH)-D) via 25-hydroxylase in the liver. 25(OH)-D is then converted to Calcitriol ($1,25(OH)_2$-D) by 1-α-hydroxylase in the kidneys. $1,25(OH)_2$-D is the active form of vitamin D and upregulates calcium and phosphorus absorption.[2]
  - Low ionized calcium stimulates PTH release. To maintain calcium homeostasis, PTH increases bone resorption to release calcium from bone, upregulates $1,25(OH)_2$-D synthesis, and increases phosphorus excretion to decrease the calcium*phosphorus product to promote calcium release.[2]
  - Phosphatonins, specifically fibroblast growth factor-23 (FGF-23), are proteins secreted by osteocytes in bone that decrease renal tubular reabsorption of phosphate and 1-a-hydroxylase activity.[7]
- The etiology of rickets can be widely classified based on the defect in mineralization: vitamin D disorders, calcium deficiency, phosphorus deficiency, and defects in renal regulation.
- Vitamin D disorders can be further classified as nutritional (vitamin D deficiency), secondary (due to malabsorption or chronic kidney disease), or hereditary (vitamin D-dependent rickets type 1 and 2).
  - Nutritional vitamin D deficiencies are due to inadequate sun exposure; darker-skinned children, and those with decreased dietary intake, are more at risk.
  - Secondary vitamin D disorders can occur with gastrointestinal disorders such as Crohn disease or other disturbances impairing fat absorption and thus vitamin D absorption. Chronic kidney disease manifests with impaired synthesis of $1,25(OH)_2$-D, resulting in vitamin D deficiency.

  - Vitamin D-dependent rickets type 1 is an autosomal recessive disorder resulting in a mutation in 1-a-hydroxylase that impairs $1,25(OH)_2$-D synthesis. Vitamin D-dependent rickets type 2 is also an autosomal recessive disorder characterized by a defect in the vitamin D receptor preventing patients from responding appropriately to $1,25(OH)_2$-D.[8]

- Deficiency in calcium, which is found in leafy vegetables and dairy products, typically arises in children who are on unconventional diet or have milk allergies. Phosphorus deficiency rarely occurs in healthy children, but can arise in anorexics and malabsorptive processes.
- Defects in renal regulation of calcium and phosphorus homeostasis can also be classified into hereditary (X-linked hypophosphatemic rickets, autosomal dominant hypophosphatemic rickets, autosomal recessive hypophosphatemic rickets, and hereditary hypophosphatemic rickets with hypercalciuria) and secondary causes (Fanconi Syndrome, renal tubular acidosis, or tumor-induced).
- XLH rickets occurs due to a gene mutation in *PHEX*, which inactivates the phosphatonin FGF-23. Consequently, there is an increase in FGF-23 expression, which normally inhibits phosphate reabsorption and 1-a-hydroxylase. This leads to decreased phosphate reabsorption and decreased $1,25(OH)_2$-D production.
- Autosomal dominant hypophosphatemic rickets (ADHR) involves a mutation in FGF-23 that impairs degradation of the protein. Similar to XLH, increased FGF-23 levels results in decreased reabsorption of phosphate and decreased $1,25(OH)_2$-D production.
- Autosomal recessive hypophosphatemic rickets is a very rare disorder due to a mutation in dentin matrix protein 1 that also leads to elevated FGF-23. This is characterized by decreased reabsorption of phosphate and decreased $1,25(OH)_2$-D production.
- Hereditary hypophosphatemic rickets with hypercalciuria (HHRH) is an autosomal recessive disorder due to a mutation in the sodium-phosphate channel in the proximal tubule. The subsequent decrease in serum phosphate stimulates $1,25(OH)_2$-D production, which suppresses PTH and increases calcium absorption in the gut resulting in hypercalciuria.

- Secondary losses of calcium and phosphate are due to defects in proximal tubule reabsorption. These disorders include Fanconi syndrome, characterized by generalized dysfunction of the proximal tubules that cause hypophosphatemia, and renal tubular acidosis, which can cause impaired calcium reabsorption.[1]
- Another secondary cause of rickets is tumor-induced rickets which can occur when mesenchymal tumors secrete phosphatonins leading to increased phosphate excretion and low 1,25$(OH)_2$-D.

RISK FACTORS

- The most prevalent cause of rickets is nutritional deficiencies. Risk factors for developing vitamin D deficiency in children include being exclusively breastfed, living at higher latitudes (above 40°), darker skin, decreased sun exposure, older age (adolescence), and higher body mass index.[2,4,5]
- Calcium deficiency is uncommon in industrialized countries but can occur in children with milk allergies, malabsorptive disorders, or with unconventional diets.[1]
- Phosphate deficiency is very rare except in anorexia, malabsorptive disorders, or in children using aluminum-containing antacids.

DIAGNOSIS

CLINICAL FEATURES

- The general presentation of rickets is characterized by skeletal deformities such as prominence of the costochondral junction (rachitic rosary), delayed fontanelle closing, softening of cranial bones (craniotabes), bowing of the legs (genu varum), horizontal groove demarcating the diaphragmatic insertion (Harrison groove), waddling gait, and widening of the wrists and ankles (**Figures 198-1**, **198-2**, and **198-4** to **198-6**).

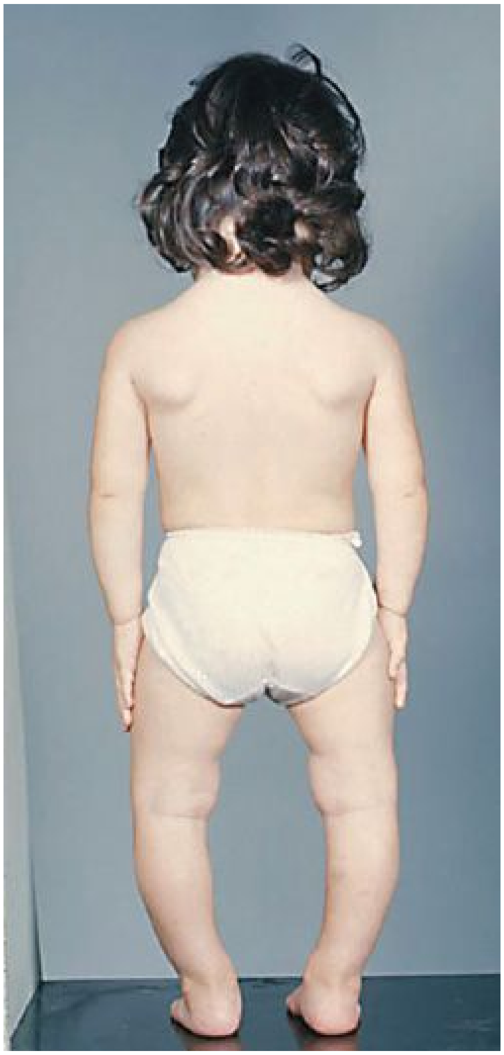

FIGURE 198-4 Bow-legged appearance of a child with rickets. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

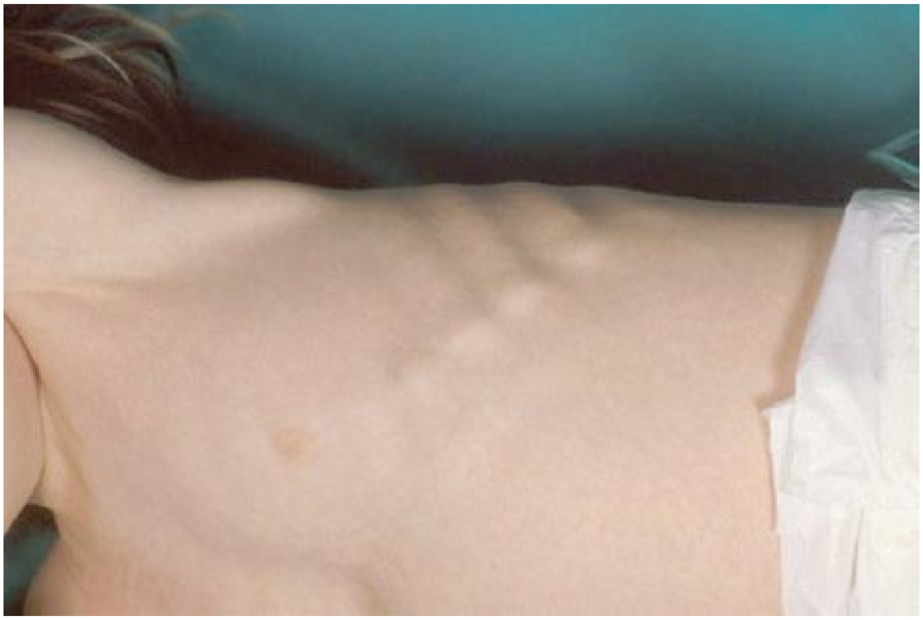

FIGURE 198-5 Prominence of the costochondral junction (rachitic rosary) and indentation of the lower anterior thoracic wall (Harrison groove) in a child with rickets. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

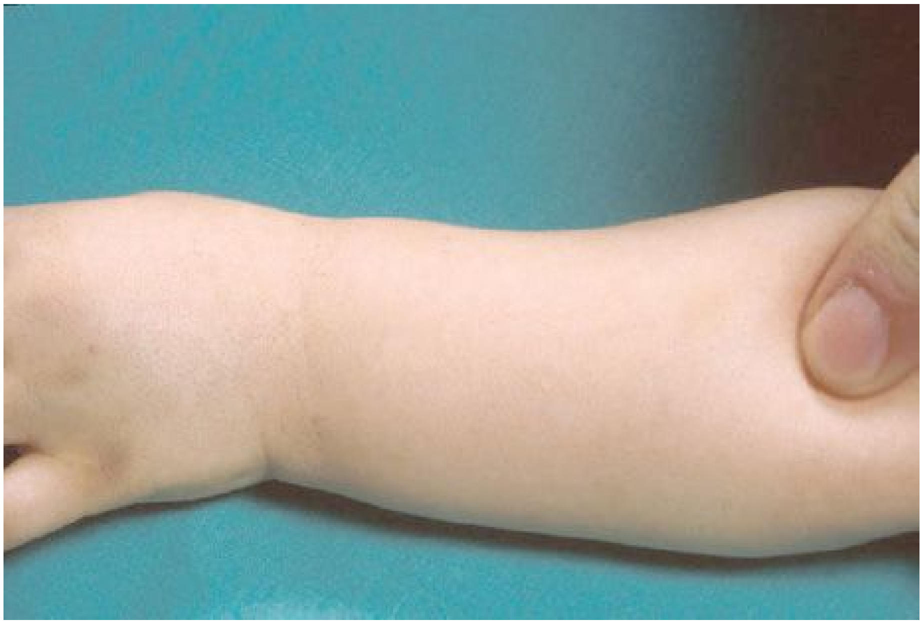

FIGURE 198-6 Widening of the wrist in the same child as in Figure 198-5. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

  - Children may complain of bone pain, weakness, or an inability to walk. Parents may notice failure to thrive or delayed teething.
  - If rickets is due to vitamin D deficiency, children may also be more irritable and present with signs of hypocalcemia. In infants, this can include seizures or tetany. In older children, hypocalcemia can manifest with apneic spells, hypotonia, hyperreflexia, cardiomyopathy, or stridor and wheezing.[2]

LABORATORY TESTING

- Laboratory findings vary depending on the etiology of rickets.
- The first step in laboratory analysis should be to evaluate alkaline phosphatase, a marker of bone turnover, which is increased in all forms of rickets.
- Next, 25(OH)-D should be evaluated. In children, 25(OH)-D should be ≥50 nmol/L. If the patient is vitamin D deficient, 25(OH)-D will be low while 1,25$(OH)_2$-D ranges from low to elevated, phosphate is decreased, PTH is increased, and calcium can be normal to decreased.[2]
- If 25(OH)-D is normal, 1,25$(OH)_2$-D values should be obtained. This is elevated in vitamin D-dependent rickets type 2 and decreased in vitamin D-dependent rickets type 1.[2]
- Calcium, phosphate, and PTH levels should also be checked.
- In chronic kidney disease, there will be elevated phosphate, high PTH, and decreased 1,25$(OH)_2$-D.[2]
- In dietary calcium deficiency, there is decreased phosphate, elevated PTH, and a compensatory increase in 1,25$(OH)_2$-D. Calcium is normal to decreased. In phosphorus deficiency, there is normal calcium, decreased phosphate, decreased to normal PTH, and elevated 1,25$(OH)_2$-D.[2]
- In the hereditary forms of rickets arising from dysregulation of phosphate homeostasis, there is usually normal calcium, decreased phosphate with no compensatory increase in 1,25$(OH)_2$-D, normal PTH, and normal 25(OH)-D. To differentiate among these disorders, urinary phosphate and calcium

can be obtained. Urinary phosphate will be elevated in all of these conditions and urinary calcium is elevated only in HHRH.[2]

- Secondary causes of rickets arising from defects in renal homeostasis are characterized by decreased phosphate with no compensatory increase in 1,25$(OH)_2$-D and increased urinary phosphate.[2]

IMAGING

- Initially, patients present with radiographic findings of osteopenia and blurring of the demarcation between the metaphysis and growth plate. As rickets progresses, there is widening of the growth plate and then of the metaphysis (**Figure 198-3** and **Figure 198-7**).[2]

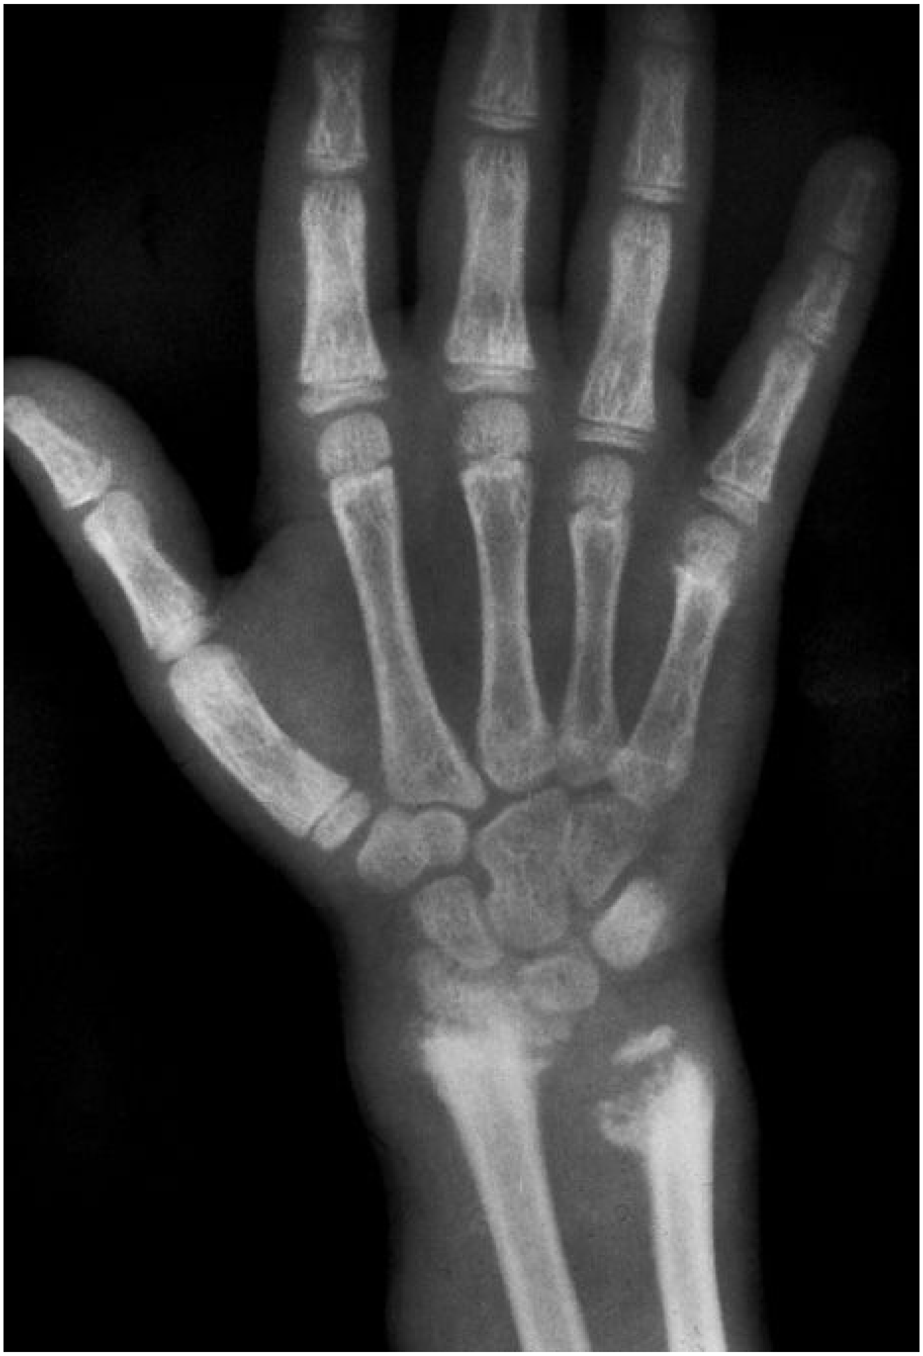

FIGURE 198-7 Diffuse demineralization of the hand bones and severe fraying of the metaphyses of the wrist bones in a child with rickets. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

DIFFERENTIAL DIAGNOSIS

- Juvenile idiopathic arthritis—May present with bone pain, weakness, and fracture. However, these patients have joint swelling and systemic features of disease (see Chapter 172, Juvenile Idiopathic Arthritis).
- Muscular dystrophy—Patients have proximal muscle weakness and elevated creatinine kinase levels (see Chapter 208, Duchenne Muscular Dystrophy).
- Hypothyroidism—Clinical features of hypothyroidism will be apparent, along with abnormal thyroid function tests (see Chapter 191, Hypothyroidism).
- Polymyositis—Muscle tenderness and typical lab studies will point towards the diagnosis.
- Malignancies (either primary of bone or secondary to bone infiltration)—Appropriate tissue study will reveal the diagnosis.

MANAGEMENT

- Management of the disease depends on the etiology and efforts should be made to educate the family regarding the cause.

NONPHARMACOLOGIC

- For vitamin D deficient rickets, moderate exposure to sunlight can help ameliorate the vitamin D deficiency. This needs to be balanced against the recommendation to keep young infants out of direct sunlight and using protective clothing to limit direct sunlight exposure.

MEDICATIONS

- Patients with vitamin D deficiency (≤37.5 nmol/L) should be treated with ergocalciferol and calcium supplementation as per American Academy of Pediatrics recommendations:[2]
    - Ergocalciferol (Vitamin D2).

    - <1 month—1000 IU/day followed by maintenance with 400 IU/day.
    - One month to 12 months—1000 to 5000 IU/day followed by maintenance with 400 IU/day.
    - >12 months—>5000 IU/day IU/day followed by maintenance with 400 IU/day.
    - In teenagers and adults, 50000 IU/week × 8 weeks.
    - Calcium
    - Thirty to 75 mg/kg per day calcium divided in 3 doses and wean toward lower dose of 30 mg/kg over 2 to 4 weeks.

- Cholecalciferol (vitamin D3), which is commonly used to treat vitamin D deficiency in adults, is three times more potent than ergocalciferol and has been suggested as an alternative for the treatment of vitamin D deficiency in children.[9]However, because of concerns regarding toxicity and the lack of safety data in infants and children, this is not the standard recommended formulation at this time.
- Patients with vitamin D–dependent rickets type 1 can be treated with calcitriol (1,25$(OH)_2$-D) supplementation (0.25 to 2 µg/day) to maintain a low-normal calcium and high-normal PTH (target urinary calcium <4 mg/kg/day).[10]
- Patients with vitamin D–dependent rickets type 2 can be treated with high doses of ergocalciferol, calcidiol, or calcitriol (2 µg/day). If there is no response to treatment, patients can be treated with IV calcium.[10]
- Patients with chronic kidney disease can be treated with calcitriol, a low-phosphate diet, and phosphate binders.[10]
- Dietary deficiency in calcium should be treated with a supplement—For ages 1 to 3: 700 mg/day; ages 4 to 8: 1000 mg/day; ages 9 to 18: 1300 mg/day[2]
- Patients with XLH, ADHR, and autosomal recessive hypophosphatemic rickets should be treated with calcitriol (30 to 70 ng/kg/day divided into two doses) and phosphorus supplementation (1 to 3 γ divided into four to five doses).[11]

SURGERY

- If skeletal abnormalities progress without treatment, surgery may be necessary to correct these deformities (e.g., scoliosis).

REFERRAL

- For cases of vitamin D deficiency, refer to pediatric endocrinology if there is no radiographic evidence of healing with current therapy after 3 months of vitamin D and calcium supplementation. Always consider compliance with therapy, concurrent malabsorptive disease, or interactions with other medications (e.g., anticonvulsants, glucocorticoids).
- Refer to pediatric nephrology, if the cause of rickets is renal in nature.
- Refer to pediatric endocrinology, if the cause of rickets is due to a hereditary cause.
- Refer to pediatric gastroenterology, if a malabsorptive process is suspected.

PREVENTION AND SCREENING

- Physicians should have a low index of suspicion to screen for vitamin D deficiency, especially if children are at higher risk or are presenting with poor growth, irritability, and motor delays. Screening involves measurement of serum 25(OH)-D and alkaline phosphatase. If these return normal, but clinical suspicion is high, x-ray of distal ends of the radius and ulna and the tibia and femur should be obtained.[2]
- For exclusively breastfed infants and children not drinking 1L vitamin D–fortified milk daily, supplementation with 400 IU vitamin D should be initiated. Darker-skinned infants at higher latitudes (above 40°) may require 800 IU vitamin D/day.[3] SOR Ⓒ

PROGNOSIS

- In general, children with vitamin D deficiencies or dietary calcium deficiency will respond well to treatment with correction of radiographic abnormalities and clinical symptoms.
- For the hereditary and secondary causes of rickets, prognosis depends on the specific condition.

FOLLOW-UP

- Children with vitamin D deficiency should be monitored as follows:
  - One month—Calcium, phosphorus, and alkaline phosphatase.
  - Three months—Calcium, phosphorus, magnesium, alkaline phosphatase, 25(OH)-D, urine calcium/creatinine, and x-ray.
  - One year and annually—25(OH)-D.
- For all other causes of rickets, patients should follow-up as recommended by pediatric endocrinology or other specialist.

PATIENT EDUCATION

- For patients with vitamin D deficiency, education should be provided regarding the importance of a well-balanced diet with vitamin D fortified milk (including soy-milk), green leafy vegetables (calcium), and adequate dairy products.
- Parents should also be advised on the importance of balancing sun exposure with the risk of skin cancer. While children should be encouraged to play outdoors and participate in outdoor sports, sun protection can be sensibly applied with sunscreens and protective clothing. Sun is still the number one risk factor for skin cancer and photoaging.

There are many foods and high quality vitamin supplements for children that include vitamin D, so there is no reason to send children outside without sun protection to get vitamin D.

199 DELAYED PUBERTY

Elumalai Appachi, MD, MRCP

PATIENT STORY

A 14-year-old boy with an unremarkable medical history presents to his pediatrician with concerns about his short height and lack of pubertal development as compared to his peers. His father relates to the pediatrician that he was a “late bloomer.” His height has been progressing along the 5th percentile and his weight has been at the 10th percentile. His physical exam reveals Tanner stage 1 and prepubertal sized testes, but is otherwise normal. The pediatrician makes the diagnosis of constitutional delay of growth and puberty, reviews the expected growth and development with the family, and recommends watchful waiting (**Figure 199-1**). The boy begins spontaneous sexual development at 15 years of age and his growth velocity increases shortly thereafter.

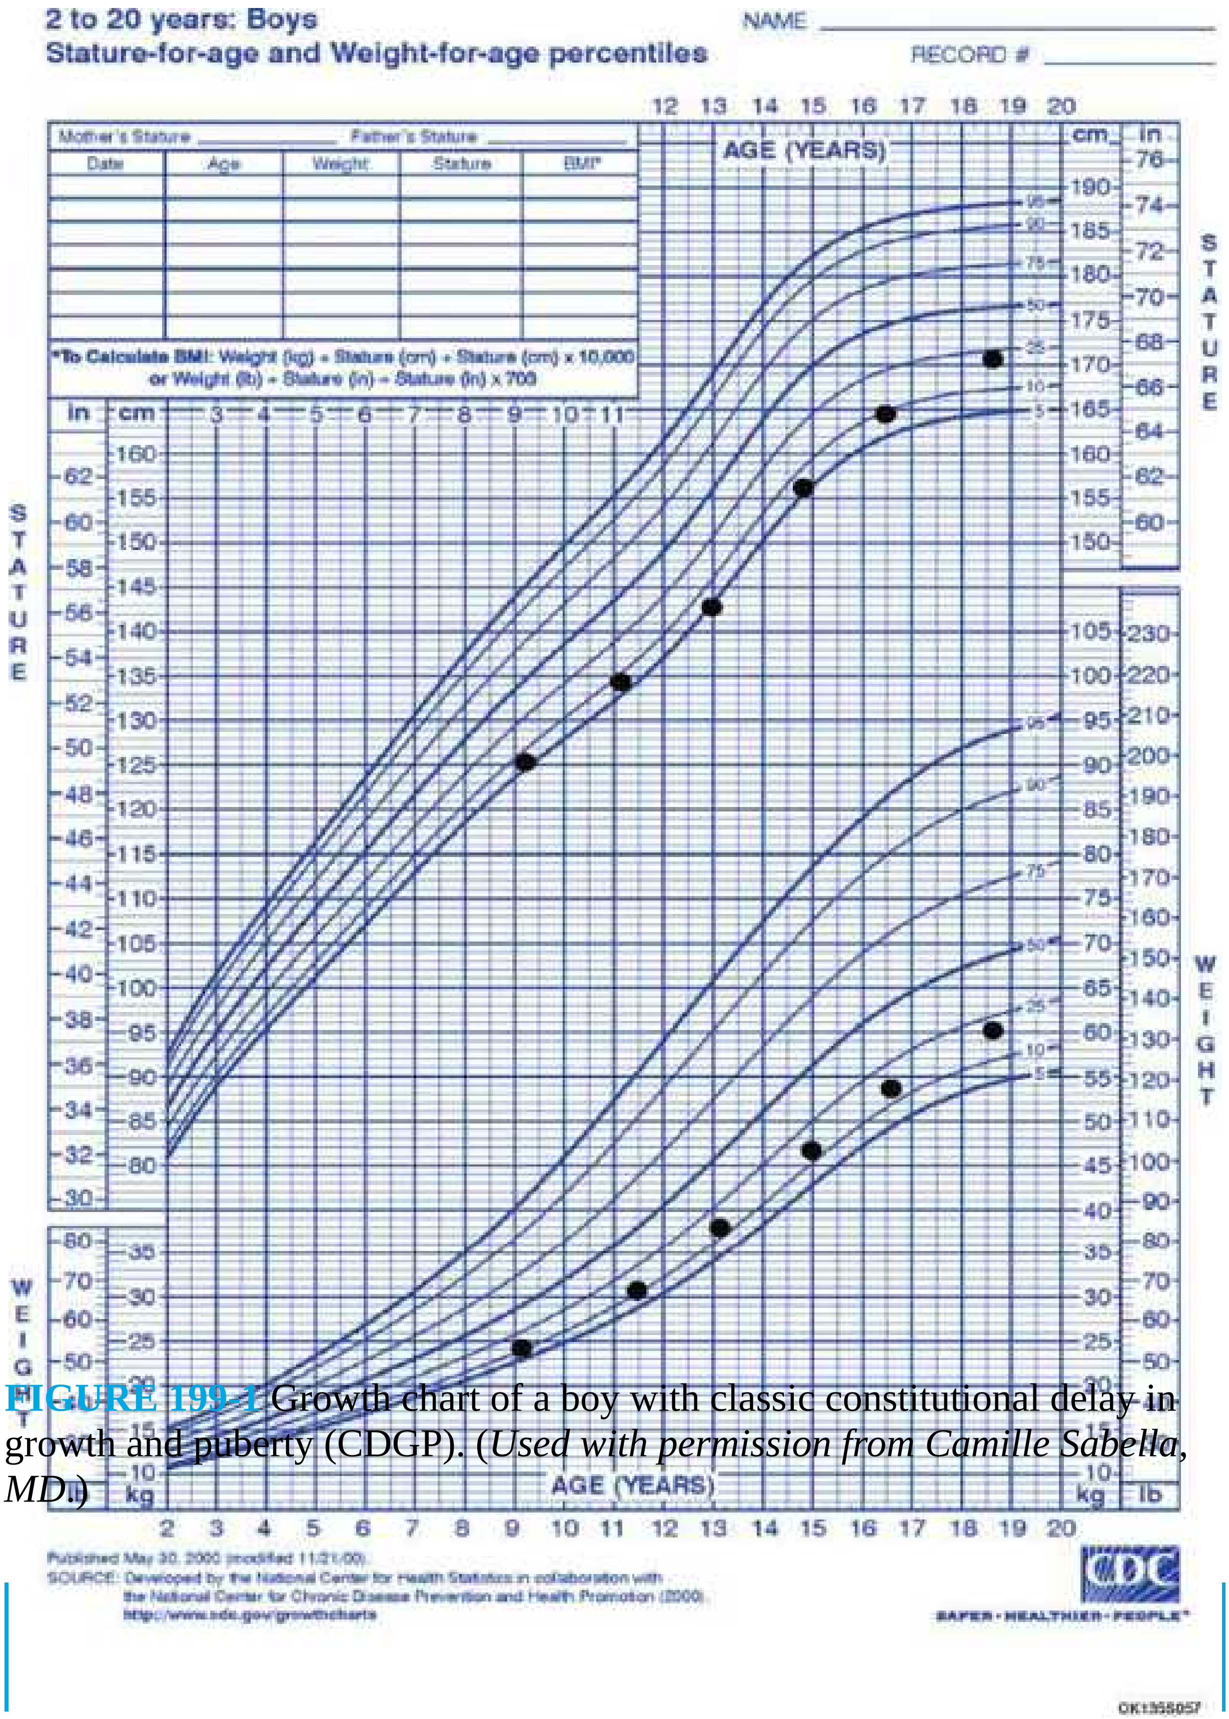

FIGURE 199-1 Growth chart of a boy with classic constitutional delay in growth and puberty (CDGP). (*Used with permission from Camille Sabella, MD.*)

Delayed puberty is defined as a lack of initiation of secondary sexual development in boys 14 years or older and in girls 13 years or older. The majority of boys with delayed puberty have constitutional delay of growth and puberty (CDGP), defined on the basis of a normal physical examination and a growth chart showing short stature but normal growth velocity. Pathologic delayed puberty may be due to primary endocrine disorders such as gonadal failure, isolated gonadotrophic deficiency, panhypopituitarism, or chronic underlying diseases.

EPIDEMIOLOGY

- CDGP is the single most common cause of delayed puberty in both sexes, but it can be diagnosed only after any underlying pathologic causes have been ruled out.[1]
- CDGP occurs more commonly in boys than in girls.
- Hypergonadotrophic hypogonadism, also known as primary gonadal failure, is more common in girls.
- Competitive swimmers, gymnasts, and ballet dancers are at high risk for functional hypogonadotrophic hypogonadism.

ETIOLOGY AND PATHOPHYSIOLOGY

- CDGP represents the single most common cause of delayed puberty in both sexes. The cause is unknown but a genetic predisposition with an autosomal dominant effect as well as environmental modifiers is likely.[1–3]
- Causes of hypergonadotrophic hypogonadism include Turner syndrome, gonadal dysgenesis, chemotherapy, or radiation therapy to testes or ovaries, and autoimmune ovarian function. The diagnosis is based on demonstrating very high levels of Follicle stimulating hormone (FSH).

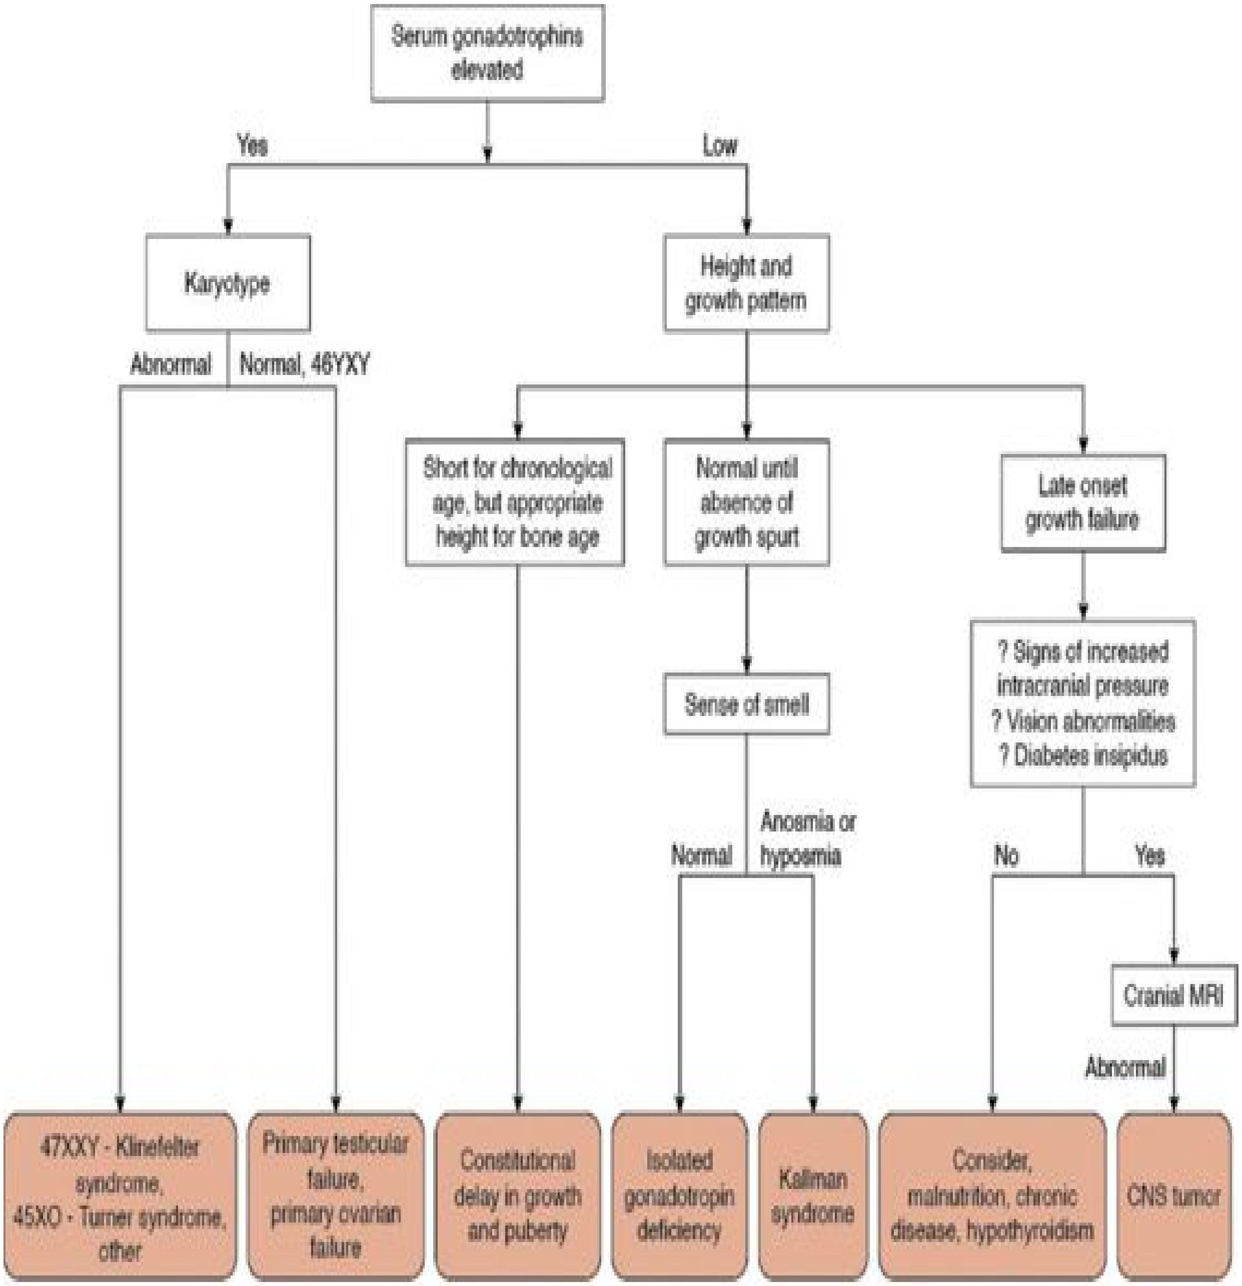
- Functional hypogonadotrophic hypogonadism (FHH) occurs in 20 percent of boys and girls referred for delayed puberty. Underlying conditions include eating disorders (anorexia or bulimia) and other chronic systemic illnesses such as inflammatory bowel disease, celiac disease, cystic fibrosis, and hypothyroidism. Excessive exercise is a relatively common cause of delayed menarche in girls. Although body fat is decreased in those affected, BMI is often in the normal range because of an increase in muscle mass.
- Permanent hypogonadotrophic hypogonadism (PHH) is diagnosed in 10 percent of boys and 20 percent of girls with delayed puberty. Two types occur: (1) Isolated gonadotrophin deficiency (IGD) or (2) Multiple pituitary hormone deficiencies (MPHD).[2,3]
    - Most boys who have not had spontaneous pubertal development by 18 years or girls by 16 years have PHH, if they do not have risk factors for FHH.
    - About half of boys with delayed puberty due to PPH also have defective smell (anosmia or hyposmia), which is called Kallman syndrome. The most common form is due to a mutation in a gene on the X chromosome.
    - Acquired MPHD is caused by tumors of the hypothalamic-pituitary axis or a head and neck tumor requiring radiation therapy with the pituitary gland in field of radiation. Rarely an infiltrative process such as Langerhans cell histiocytosis can be a cause of acquired MPHD.

RISK FACTORS

- Genetic factors—Fifty to seventy-five percent of children with CDGP has at least one parent with pubertal delay and inheritance is often autosomal dominant.[1]
- Decreased body fat in girls is a common risk factor associated with pubertal delay.
- Excessive exercise.
- Chronic illness and obesity are implicated in some cases of pubertal delay.

DIAGNOSIS

- Health maintenance visits are opportunities to screen children and teenagers about eating habits, pubertal delay and chronic illnesses. A complete physical examination including Tanner staging of breast development in girls and genital development in boys must be done.
- Accurate measurement of plotting of height and weight during each visit is important.
- A diagnostic approach to the evaluation of delayed puberty is provided in **Figure 199-2**.



Serum gonadotrophins elevated
Yes
Low
Karyotype
Height and growth pattern
Abnormal
Normal, 46YXY
Short for chronological age, but appropriate height for bone age

Consider, malnutrition, chronic disease, hypothyroidism
CNS tumor

FIGURE 199-2 Diagnostic evaluation of delayed puberty among boys at 14 years and girls at 13 years. (*Used with permission from Rudolph CD, Rudolph AM, Lister GE, First LR, Gershon AA: Rudolph's Pediatrics, 22nd edition: www.accesspediatrics.com. Figure 541-4.*)

- Since CDGP is less common in girls, they may need more diagnostic testing, especially to rule out primary gonadal failure.

CLINICAL FEATURES

- Most boys with CDGP grow below the 10th percentile on the growth chart but have normal growth velocity of 4 to 6 cm per year (**Figure 199-1**).
- Turner syndrome should be considered in girls who have decreased growth velocity and have delayed puberty (**Figure 199-3**). High arched palate, webbing of neck, shield-like chest, and wide spaced nipples are the most common associated findings (**Figure 199-4**).

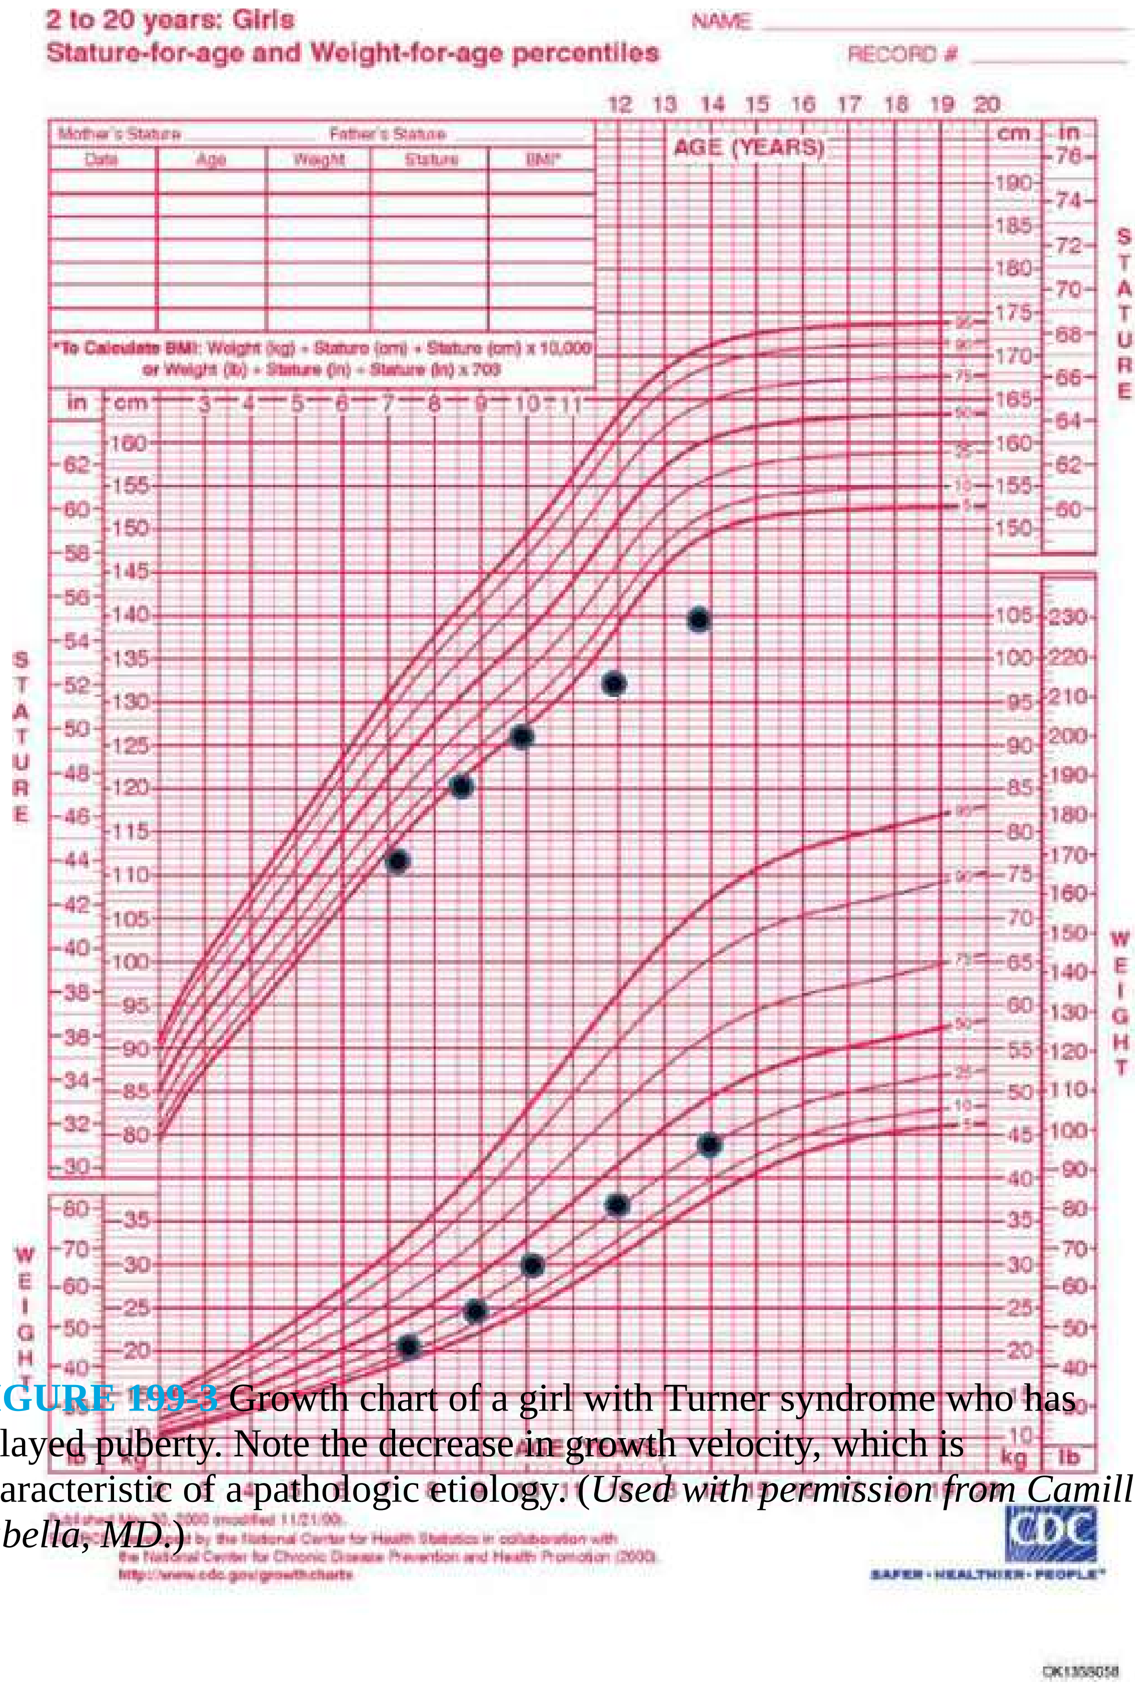

FIGURE 199-3 Growth chart of a girl with Turner syndrome who has delayed puberty. Note the decrease in growth velocity, which is characteristic of a pathologic etiology. (*Used with permission from Camille Sabella, MD.*)

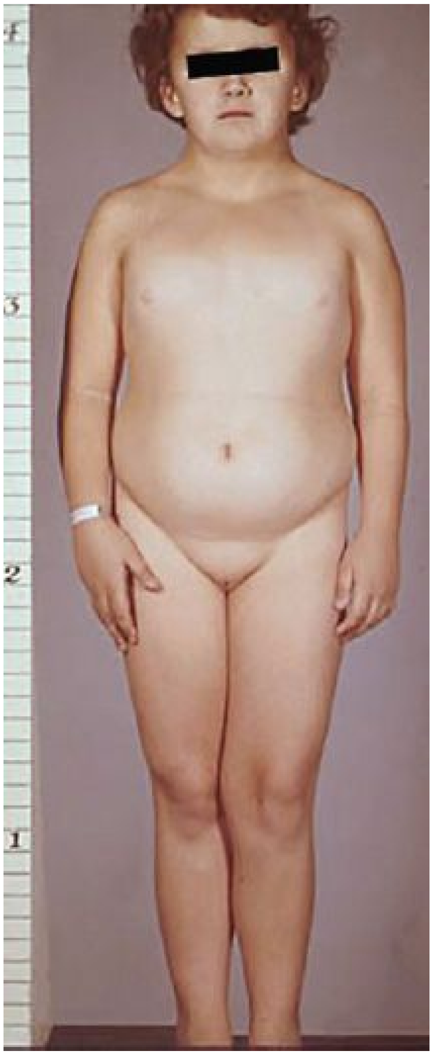

FIGURE 199-4 Delayed puberty in a girl with Turner syndrome. Note the short stature, broad shield like chest, wide spaced nipples, and mild webbing of the neck. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Presence of goiter in neck may indicate hypothyroidism.
- Absence of fat stores in abdomen may suggest chronic illness or an eating disorder or may be due to high level of exercise.
- Presence of pubic hair does not rule out delayed puberty as this reflects adrenal androgen secretion. Girls who have not had menarche within 3 years of breast development require an evaluation for delayed puberty.

LABORATORY TESTING

- Blood tests that assess the activity of pituitary-gonadal axis (luteinizing hormone [LH]), FSH for all and testosterone in boys and estradiol in girls) may be indicated depending on the specific clinical features.[3]
- CBC, CMP, Thyroid function tests and screening for celiac disease and cystic fibrosis are useful testing for children with underlying chronic illness.

IMAGING

- Bone age radiograph of left hand and wrist is often helpful to differentiate benign from pathologic short stature and to predict adult height.

DIFFERENTIAL DIAGNOSIS

- The causes and evaluation of delayed puberty are summarized in **Figure 199-2**.

MANAGEMENT

- Psychosocial support and reassurance should be provided for adolescents with CDGP.
- Expectant observation for puberty to start spontaneously is one option, especially if the child is not distressed about his or her delayed development or short stature.
- Many teenagers, particularly boys, are impatient for puberty to start and can be offered a brief course of sex steroids (intramuscular testosterone for boys and oral estradiol for girls) to trigger growth spurt and pubertal development. This is a safe and effective approach that appears to have no negative impact on adult height.[4,5]

  - The largest published randomized trial of testosterone for CDGP was done in Egypt and included 148 boys aged 14 to 18 years who were given monthly injections of testosterone enanthate for 6 months and a control group of 50 untreated patients. Both groups had a final evaluation at 12 months, at which time the treated group had a more advanced growth rate, more advanced genital development, and a larger mean testicular diameter, than the control group. All of the treated boys, but only 40 percent of the untreated boys, reported satisfaction with the result.[6]
  - A randomized, placebo-controlled trial involving 40 patients with constitutional delay of growth and puberty treated with placebo or oxandrolone for 1 year reported that the treated group grew an average of 9.5 cm versus 6.8 cm in the placebo group and gained 2.4 kg more weight.[7]
- Children with clinical and laboratory evidence of PHH, MPHD, or primary gonadal failure can be treated with long-term sex steroid replacement with escalation of doses over a 2 year period.[8]
- Patients with chronic illnesses causing pubertal delay may need ongoing treatment with sex steroids to maximize nutrition and development.

CONSULTATION

- Patients with the following clinical scenarios should be referred to an endocrinologist for further evaluation:
  - Boys who have not started puberty by age 16 to 17 years old, as they are less likely to have CDGP.
  - Boys who have CDGP but do not start puberty within 6 months of receiving testosterone therapy.
  - Girls who have not started puberty by age 14 or 15 years or who have gonadal failure or elevated FSH levels.
  - Boys and girls with pubertal delay and severe short stature or growth failure.

FOLLOW-UP

- Close monitoring of children who have CGDP and not on treatment, to make sure that they are still growing appropriately and to verify that puberty is progressing (breast enlargement in girl; penis and testicular enlargement in boys).
- Boys receiving testosterone injections should be monitored closely for pubertal changes.

PROGNOSIS

- Children with CGDP will eventually attain puberty after prolonged follow-up or more quickly after a brief course of sex steroids.
- Boys and girls with primary gonadal failure based on absent gonads or history of gonadal failure and supported by increased FSH levels will generally need long term sex steroid replacement. They will usually grow well and develop appropriate secondary sexual characteristics but are unlikely to be fertile.

PATIENT EDUCATION

- Families of boys with delayed puberty likely due to CDGP should be reassured that the condition is a variation of normal development and that, in most cases, it resolves with time.
- If the child is healthy, diagnostic testing can be limited to bone age radiograph to reassure the family and patient that there is still ample time to grow.
- A brief course of testosterone injections can provide early boost in growth and jump start puberty for boys anxious to start growing and developing

sooner.

- If the patient is very thin, athletic, anorexic or with chronic illness, the family may be advised that puberty is likely to progress if the child is able to gain significant weight.

200 PRECOCIOUS PUBERTY

Elumalai Appachi, MD, MRCP

PATIENT STORY

A 4-year-old Caucasian girl presents to her pediatrician because of early development of breast buds, pubic hair, and body odor. On exam, the girl is noted to have Tanner stage 3 breast buds and pubic hair. She is also noted to have clitoromegaly (**Figure 200-1**). The pediatrician refers the girl to a pediatric endocrinologist, who orders a bone age, estradiol levels, and an MRI of the brain. The girl is found to have an advanced bone age of 7 years, and levels of estradiol consistent with her stage of sexual development. An MRI of the brain is normal. She is diagnosed with idiopathic central precocious puberty. The options for management are discussed with the family.

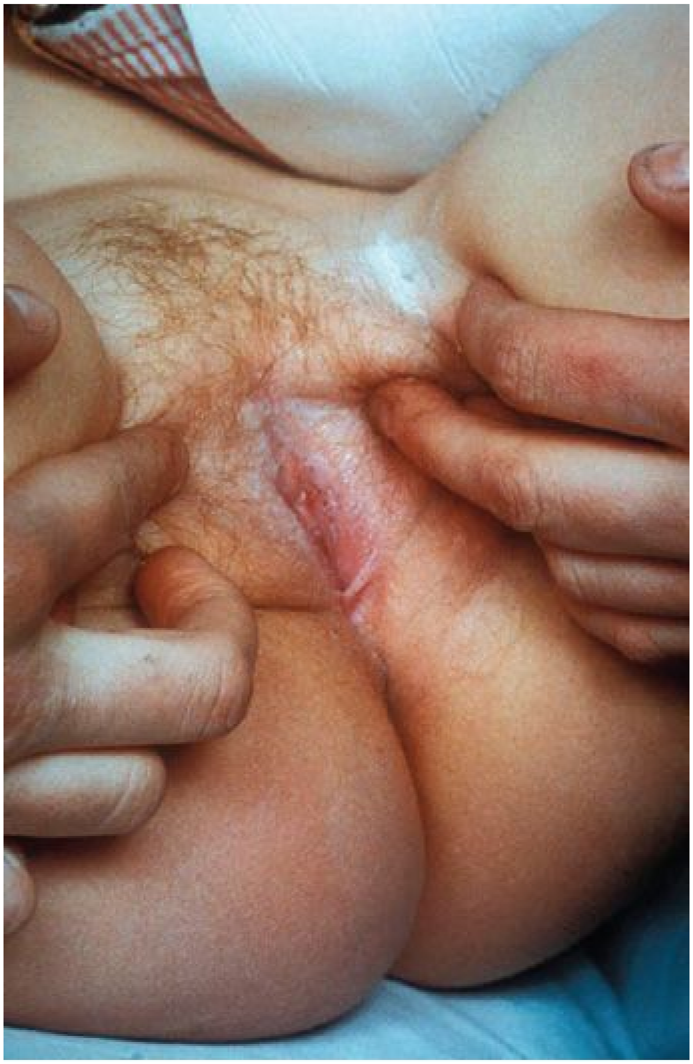

FIGURE 200-1 Pubic hair development and clitoromegaly in a 4-year-old girl with central idiopathic precocious puberty. (*Used with permission from Elumalai Appachi, MD*.)

INTRODUCTION

The age at which puberty begins in normal children varies among the different ethnic groups. Early, or precocious puberty, is defined as the onset of sexual development occurring before the age of 7 years in Caucasian girls, 6 years in African American girls, and 9 years for all boys. Central precocious puberty refers to gonadotropin-releasing hormone (GnRH)-dependent activation from the hypothalamic-pituitary-gonadal axis leading to secondary sexual characteristics. Peripheral precocious puberty refers to GnRH-independent activation.

SYNONYMS

Early puberty.

EPIDEMIOLOG

- The incidence is estimated to be 15 to 30 per 100,000 girls and is 1-to 15-fold less common on boys.[1,2]
- Idiopathic precocious puberty is more common in girls than boys.
- African American girls develop secondary sexual characteristics at an earlier age than Caucasian girls. Thus, age of evaluation of precocious puberty in girls depends on ethnicity and race.
- Boys mature at comparable ages regardless of ethnicity and race.
- Age of onset of precocious puberty varies depending on the etiology; it can present as early as the first month of life.

ETIOLOGY AND PATHOPHYSIOLOGY

Central or GnRH-dependent precocious puberty may be idiopathic or may be caused by a central nervous system (CNS) abnormality.[3,4]

- Precocious puberty is idiopathic in more than 90 percent of girls. This diagnosis is one of exclusion, in that no clinical, biochemical, or radiologic abnormalities are present other than those of precocious puberty.

- Boys with precocious puberty have an idiopathic cause much less commonly than girls; CNS abnormalities are found in 25 to 75 percent of boys with precocious puberty.
- The most common CNS abnormality causing precocious puberty is a hypothalamic hamartoma. This is a GnRH-producing nonmalignant congenital mass that causes pulsatile secretion of gonadotropins leading to stimulation of the gonads during childhood.[5]
- Other structural CNS abnormalities include tumors such as pinealoma, astrocytoma, ganglioneuroma, ependymoma, and optic glioma, or congenital malformations such as ventricular and arachnoid cysts.
- Neurofibromatosis and tuberous sclerosis, as well as CNS insults such as acute head injury, hydrocephalus, CNS infection, or cranial radiation therapy can cause central precocious puberty.

Causes of GnRH-independent precocious puberty include:[6]

- McCune Albright syndrome—More common in girls. Caused by constitutive somatic activation mutations in the GNAS1 gene encoding the α-subunit of the stimulatory G-protein resulting in autonomous hypersecretion of hormones. It may be associated with other endocrine abnormalities including hyperthyroidism, hypercortisolism, hypersomatotropism, and hypophosphatemia.
- Ovarian tumors and cysts may cause isosexual (changes appropriate for same sex) or heterosexual (changes appropriate for opposite sex) pubertal changes.
- Testicular tumors, such as a testosterone secreting Leydig cell tumor, may manifest as isosexual precocious puberty in young boys.
- Familial male-limited GnRH-independent pseudoprecocious puberty—Otherwise known as testotoxicosis. Caused by a luteinizing hormone receptor-activating mutation resulting in significant enlargement of penis without enlargement of testes.

- Congenital adrenal hyperplasia—Occurs in both boys and girls is caused by a deficiency of either CYP21A2 (21-hydroxylase), CYP11B1 (11b-hydroxylase), or 3β-HSD enzyme. Can presents in early childhood with bone age advancement; usually isosexual in boys and manifests as pubic hair development, acne, body odor, and increased penis size without testicular enlargement; usually heterosexual (virilizing features) in girls.
- Adrenocortical tumors—Occurs in both boys and girls; usually isosexual in boys and heterosexual (virilizing) in girls.
- Ectopic human chorionic gonadotropin (hCG)—Secreting tumors such as chorioblastoma, hepatoblastoma, germinoma of the pineal gland. Mainly occur in boys and result in testosterone production in the testes.
- Exogenous estrogen—Can result from oral (contraceptive pills or anabolic steroids) or topical agents. Estrogens are readily absorbed through the skin, so estrogens in cosmetics, hair creams, and breast-augmentation creams can cause breast development in girls and gynecomastia in boys.
- Severe long standing hypothyroidism can cause early puberty in boys and girls.

RISK FACTORS

- CNS insults.
- Positive family history.
- Obesity.
- Adopted child status from a developing country—Maybe due to early malnutrition followed by normal or excessive nutrition with resultant advancement of pubertal age.

DIAGNOSIS

- A careful history and physical examination should provide helpful clues as to the etiology and guide the evaluation. Tanner (sexual maturation rating) charts should be used to stage pubertal development.

CLINICAL FEATURES

- Breast buds or pubic hair development before the age of 7 years in Caucasian girls or age 6 years in African American girls, or the onset of menarche before age 9 years are the signs of early puberty.
    - The first sign of early puberty in girls is breast development; pubic hair may appear simultaneously, but more often appears later. Maturation of the external genitals, the appearance of axillary hair, and the onset of menstruation follow. Clitoromegaly may be present. The early menstrual cycles may be more irregular than with normal puberty (**Figure 200-1**).
- Testicular enlargement or pubic hair development before the age of 9 years are signs of early puberty in boys (**Figures 200-2** and **200-3**).

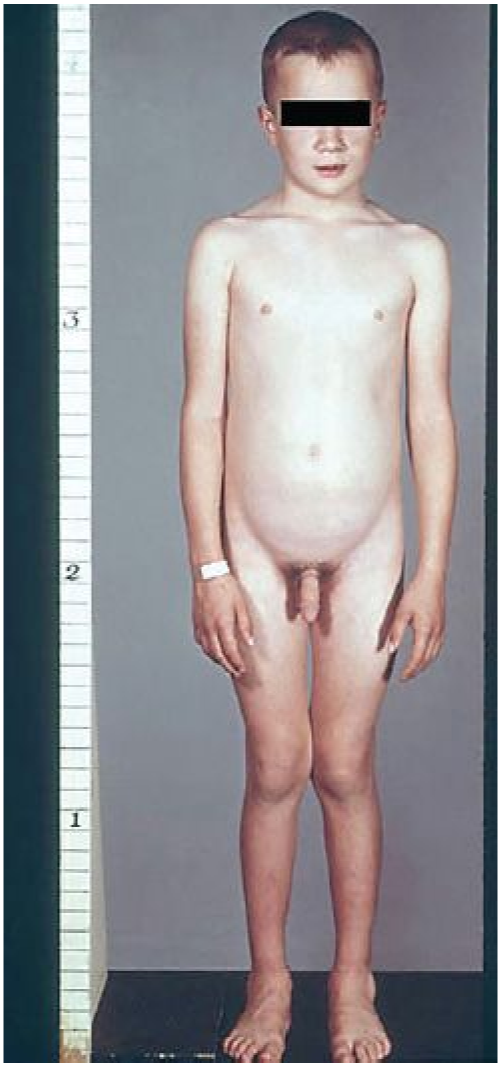

FIGURE 200-2 Enlargement of the penis and pubic hair development in a 5-year-old boy with precocious puberty. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

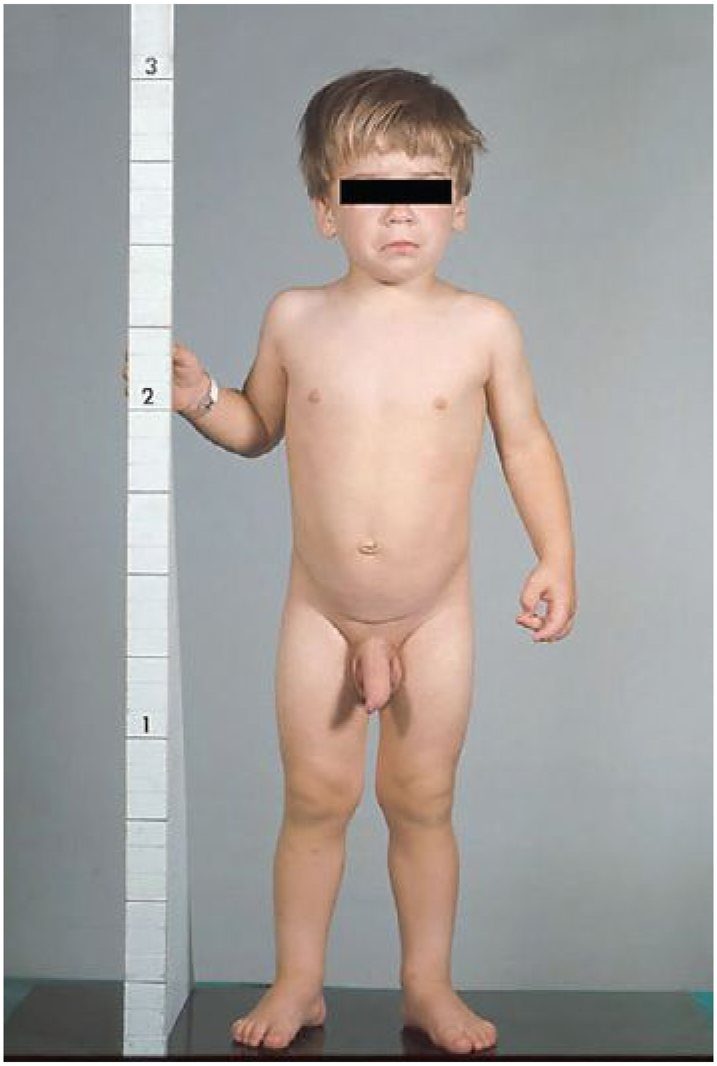

FIGURE 200-3 Enlarged penis and testes in a 2-year-old boy with precocious puberty. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Enlargement of the testes is followed by enlargement of the penis, appearance of pubic hair, and acne. Erections are common and nocturnal emissions may occur. The voice deepens and linear growth is accelerated.
- In boys with central precocious puberty testicular size is disproportionately greater than penile size. In peripheral precocious puberty penile dimensions are disproportionately greater than testicular size.

- Height velocity is increased during sexual maturation, but final adult height is reduced owing to premature fusion of epiphyses (tall child but short adult).
- Body odor, acne, and emotional lability may occur.
- Headaches and visual disturbances may accompany signs of puberty if a CNS abnormality is the cause.
- If hypothyroidism is the cause, intolerance of cold, fatigue, increased sleepiness, hair and skin changes, and constipation may be present.
- Signs of a specific etiology may be present:
    - Myxedema in hypothyroidism.
    - Café-au-lait spots in neurofibromatosis.
    - McCune Albright syndrome—Average age of onset of precocious puberty in affected girls is 3 years and may present with breast development and vaginal bleeding. Patients have café-au-lait macules and fibrous dysplasia of the skeletal system.

LABORATORY TESTING

- Basal luteinizing hormone levels, follicle-stimulating hormone (FSH) levels, and sex hormone (serum testosterone in boys, serum estradiol in girls) levels are generally determined.
    - Luteinizing hormone and FSH measurements fluctuate and must be interpreted in relation to clinical findings, bone age, and sex hormone levels. Single determinations are usually inadequate.
    - Gonadotropin-releasing hormone (GnRH) stimulation test with measurement of gonadotropin (luteinizing hormone, FSH) and gonadal hormones (estradiol in girls; testosterone in boys) are generally more useful than single random measurements.
    - In precocious puberty, serum levels of testosterone and estradiol are appropriate for the child’s level of sexual development but not appropriate for the chronological age.
- Thyroid hormone levels should be obtained if hypothyroidism is suspected.

- Dehydroepiandrostenedione sulfate, androstenedione, and 17-hydroxyprogesterone levels should be obtained if adrenal pathology is suspected.
- Serum hCG levels should be obtained if an hCG-producing tumor is suspected.

IMAGING

- Bone age radiographs should be obtained in cases of precocious puberty and will be advanced (usually by more than 2 years) for chronologic age in children who have true precocious puberty.
- MRI of the head is required to rule out organic causes of central precocious puberty. This should be done in all boys and girls less than 6 years of age.
- Pelvic and abdominal ultrasound or CT scan can be obtained to evaluate the adrenal glands and ovaries for tumors and cysts if non-central precocious puberty is suspected based on the physical exam.

DIFFERENTIAL DIAGNOSIS

Premature thelarche—A benign process in which there is early breast development, but without any other features of puberty such as pubic or axillary hair, or linear growth acceleration (**Figure 200-4**). Typically in girls aged 1to 4 years. Bone age is not advanced.

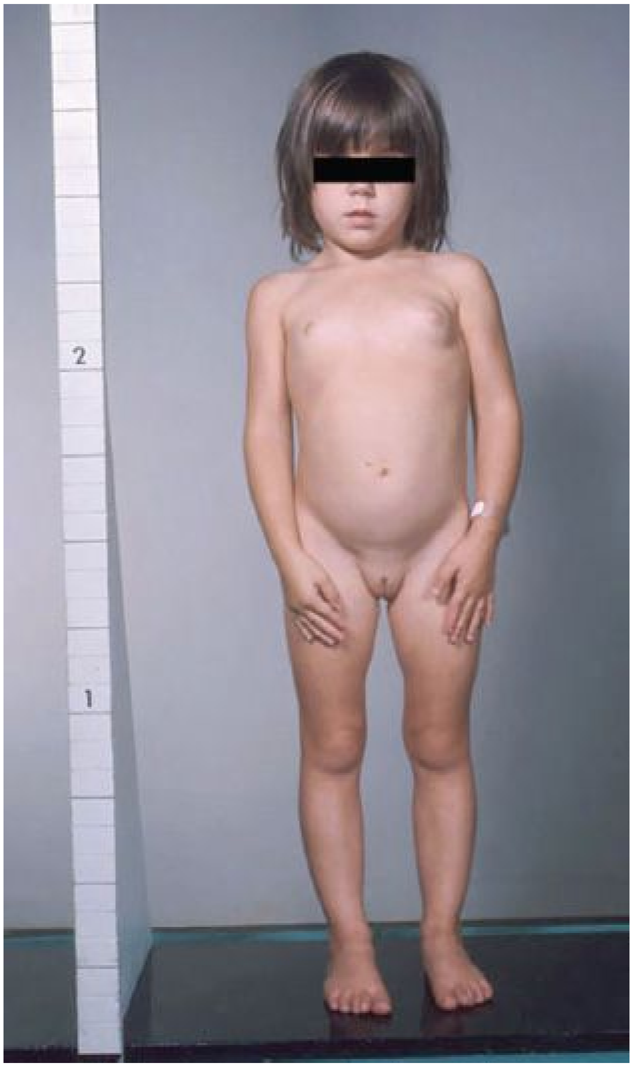

FIGURE 200-4 Premature thelarche (early breast buds) in a 2-year-old girl who has no other signs of sexual development or puberty. (*Used with permission from Cleveland Clinic Children’s Hospital Photo Files*.)

Premature adrenarche—A benign process in which there is isolated pubic or axillary hair and odor, but without any other evidence of virilization. Bone age may be slightly, but not significantly, advanced.

Premature menarche—Isolated menstruation (usually one or two periods) without any other manifestations of puberty. This is a benign process of unclear etiology.

- Transient condition of isolated breast development that most often appears in the first 2 years of life; in some girls breast development is present at birth and persists.

- Growth and osseous maturation are normal or slightly advanced.
- The genitals show no evidence of estrogenic stimulation.
- Breast development may regress after 2 years, although it often persists for 3 to 5 years and is rarely progressive.
- Menarche occurs at the expected age and reproduction is normal.
- The serum concentrations of FSH, luteinizing hormone, and estradiol are generally low and not diagnostic.
- Luteinizing hormone response to GnRHa stimulation is prepubertal.
- Ovarian and uterine volume on ultrasound is prepubertal.
- A benign condition, but 10 percent of cases progress to central precocious puberty, so continued observation is important.
- Isolated appearance of sexual hair and, less commonly, body odor or acne without other signs of puberty or virilization before the age of 7 years in white girls, 6 years in black girls, or 9 years in boys without other evidence of maturation.
- More frequent in girls than in boys and may occur more frequently in black girls than in other patients.
- Hair appears on the mons and labia majora in girls and on perineal and scrotal area in boys; axillary hair generally appears later. It is more frequent in children with CNS abnormalities.
- Independent of gonadal development.
- Affected children are slightly advanced in height and osseous maturation.
- Adrenal androgens (dehydroepiandrostenedione sulfate, androstenedione) level may be slightly elevated, but appropriate for pubic Tanner stage.
- A benign condition that requires no therapy; however, long-term follow-up suggests that girls with premature adrenarche are at a higher risk (20%) for hyperinsulinism, metabolic syndrome, hyperandrogenism, and polycystic ovarian syndrome as adults.

MANAGEMENT

- Management depends on the underlying cause and should focus on delaying sexual maturation until the normal age of onset of puberty, and prevent short stature in adulthood by delaying the premature epiphyseal fusion.
- Psychologic support is important for the child and family.
- Children with exogenous hormone intake usually respond well when the source is removed.
- Functional ovarian cysts are benign and usually regress spontaneously without treatment.

MEDICATIONS

- GnRH analogs are the mainstay of treatment for central precocious puberty. These drugs provide constant serum concentrations of GnRH activity, which in turn overrides the pulsatility of endogenous GnRH.[7–10] SOR A
- The most widely used analog is Leuprolide acetate, which is administered by injection or subcutaneous implant. Injections are painful and a common complication is the development of sterile abscesses.
- The greatest height benefit of GnRH analog therapy has occurred in children who have been diagnosed before age 6 years. These patients achieved a mean height gain of 8.2 cm versus a gain of 4.2 cm in patients who were diagnosed and underwent treatment between ages 6 and 8 years. With GnRH analog treatment, the adult height of children with central precocious puberty is 8 to 12 cm greater than before the therapy was introduced.[8–10]
- GnRH agonists are also used to manage hypothalamic hamartomas, as these congenital lesions generally do not require surgery.[5]
- Children with Gonadotropin-independent peripheral precocious puberty do not respond to GnRH agonist therapy. Treatment of these children

relies on eliminating the underlying cause of estrogen or androgen excess.

- Corticosteroids are indicated for congenital adrenal hyperplasia (see Chapter 197, Congenital Adrenal Hyperplasia).
- The treatment of McCune-Albright Syndrome is challenging. Trials using aromatase inhibition or partial estrogen receptor blockade have been conducted. Most of the agents have shown inadequate efficacy or have been associated with increased ovarian or uterine size.[10]
- Supplemental calcium and vitamin D to the treatment of central precocious puberty may help preserve bone mass density. SOR C

SURGERY

- CNS tumors may require surgical removal depending on the location, size, and type of lesion.
- Testicular, adrenal, and ovarian tumors are generally removed surgically.
- hCG-secreting tumors may be treated with a combination of surgery, radiation and chemotherapy.

REFERRAL

- A pediatric endocrinologist should be involved in the evaluation and treatment of children with precocious puberty.

PREVENTION AND SCREENING

- Routine health maintenance visits with attention to growth and sexual maturation are important in detecting early puberty.

PROGNOSIS

- Prognosis depends on the primary etiology.
- Treatment of central precocious puberty results in enhancement of the predicted height, although the actual adult height of patients followed to epiphyseal closure is approximately one standard deviation below the midparental height.
- Therapeutic failure may occur if GnRH analog pulses are not adequately suppressed because of noncompliance, inappropriate dose, or frequency of administration.

FOLLOW-UP

- In the first few months of GnRH analog treatment, frequent follow-up is required to ensure suppression of the hypothalamic-pituitary-gonadal axis, tolerance to the medication, and adherence to the medication regimen.
- The frequency of follow-up depends on age, etiology, and progression of the problem.
- Hormonal assays and bone age need to be reviewed every 3 to 12 months.

201 HEADACHE

Heidi Chumley, MD

PATIENT STORY

A 15-year-old girl presented to the office with her mother to discuss her migraines. She has episodic unilateral throbbing headaches accompanied by nausea, photophobia, and phonophobia. She also reports a visual prodrome, characterized by a jagged line pattern (**Figure 201-1**). She used to have a migraine about every 3 months, but is now having one almost every week. She misses a day of school with each migraine. She is not under any unusual stressors. Her mother has migraines and benefitted greatly from taking a prophylactic medication.

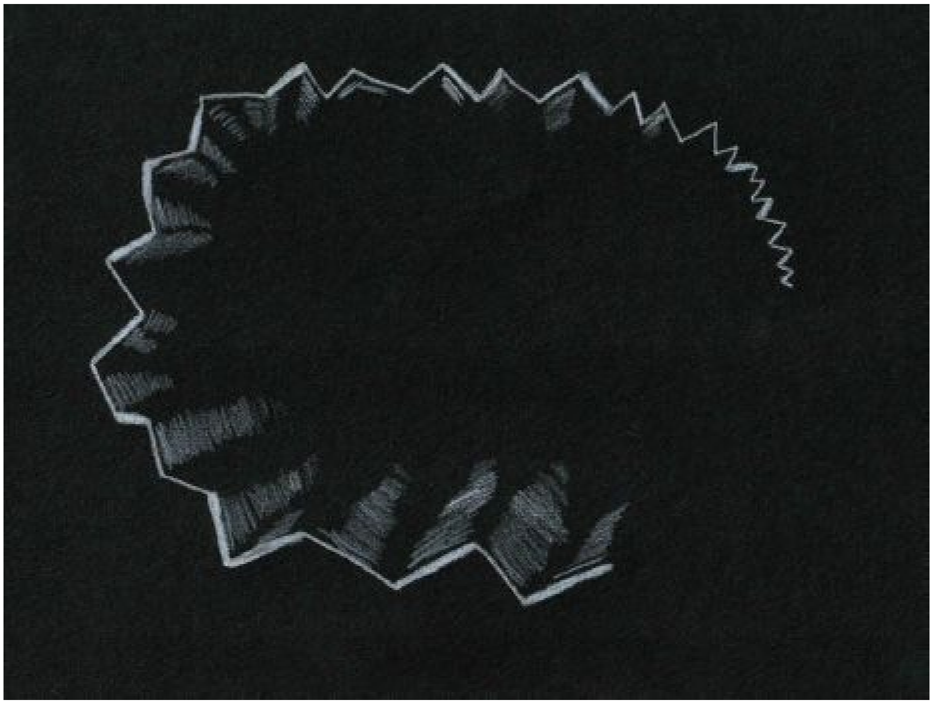

FIGURE 201-1 Jagged line pattern prodrome often described in patients with migraine headaches. This is called teichopsia and may resemble the fortification pattern of a medieval town. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

More than 50 percent of children report a headache in the past year. Headaches are either primary or secondary and the presence or absence of red flags is useful to distinguish dangerous causes of secondary headaches. The most common primary headaches are tension and migraine headaches. Medication overuse can complicate headache therapy. Treatment and prognosis is dependent on type of headache.

EPIDEMIOLOGY

- Prevalence of headache in children increases during childhood, peaking between ages 11 and 13.
- Fifty-three percent of children have had a headache in the past year.[1]
- Episodic tension-type headache (TTH) prevalence is 15.9 percent in children.[1]
- Chronic (>15 days per month) TTH has a prevalence of 0.9 percent in children.[1]
- Migraine has a prevalence of 9.2 percent in children.[1]
- Chronic daily headache has lifetime prevalence of 4 to 5 percent.[2]
- Cluster headache has a lifetime prevalence of 0.2 to 0.3 percent.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- The most common causes of headaches in children and adolescents are migraine and TTH.[3]
- TTH etiology is uncertain, but likely caused by activation of peripheral afferent neurons in head and neck muscles.[4]
- Migraine headache is thought to be caused by central sensory processing dysfunction, which is genetically influenced.[5] Nociceptive input from the meningeal vessels is abnormally modulated in the dorsal raphe nucleus, locus coeruleus, and nucleus raphe magnus. This activation can be seen on positron emission tomography (PET) scan during an acute attack.
- Cluster headache is caused by trigeminal activation with hypothalamic involvement, but the inciting mechanism is unknown.[6]

RISK FACTORS

- For migraines—Family history reported in over 60 percent.

DIAGNOSIS

A headache diary is helpful for diagnosis and follow-up.

CLINICAL FEATURES

- Red flags for dangerous secondary cause:[3]
  - Worst headache of life.
  - Recent onset of headache.
  - Increase in severity or frequency of headache.

- Headache occurring only in the morning with severe vomiting.
- Headache worsened with Valsalva.
- Presence of focal neurological signs, seizures, or papilledema (**Figures 201-2** to **201-4**).

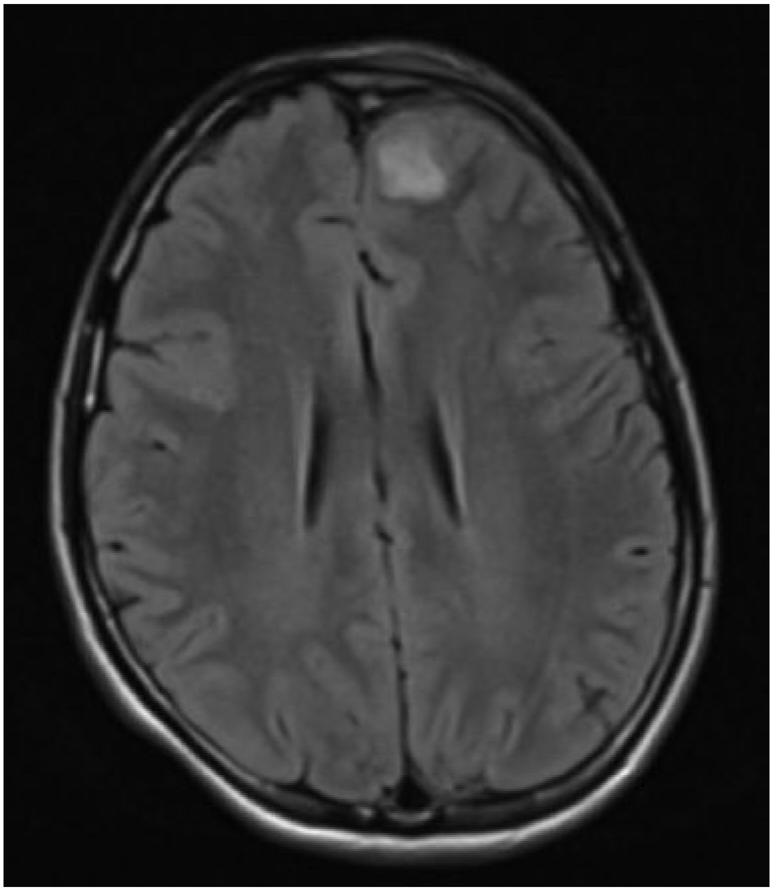

FIGURE 201-2 Intracranial abscess in the left frontal pole on brain MRI as a complication of sinusitis in a 14-year-old boy who presented with a severe headache and focal neurological signs. (*Used with permission from Camille Sabella, MD.*)

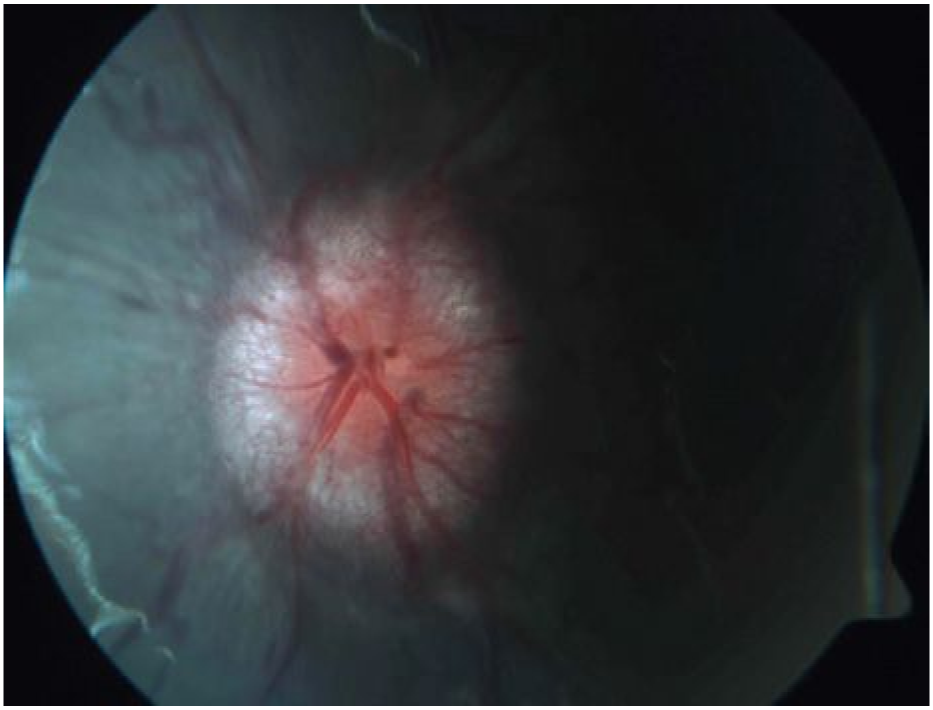

FIGURE 201-3 Papilledema on fundoscopic examination in an adolescent, signifying increased intracranial pressure. (*Used with permission from Paul Rychwalski, MD*.)

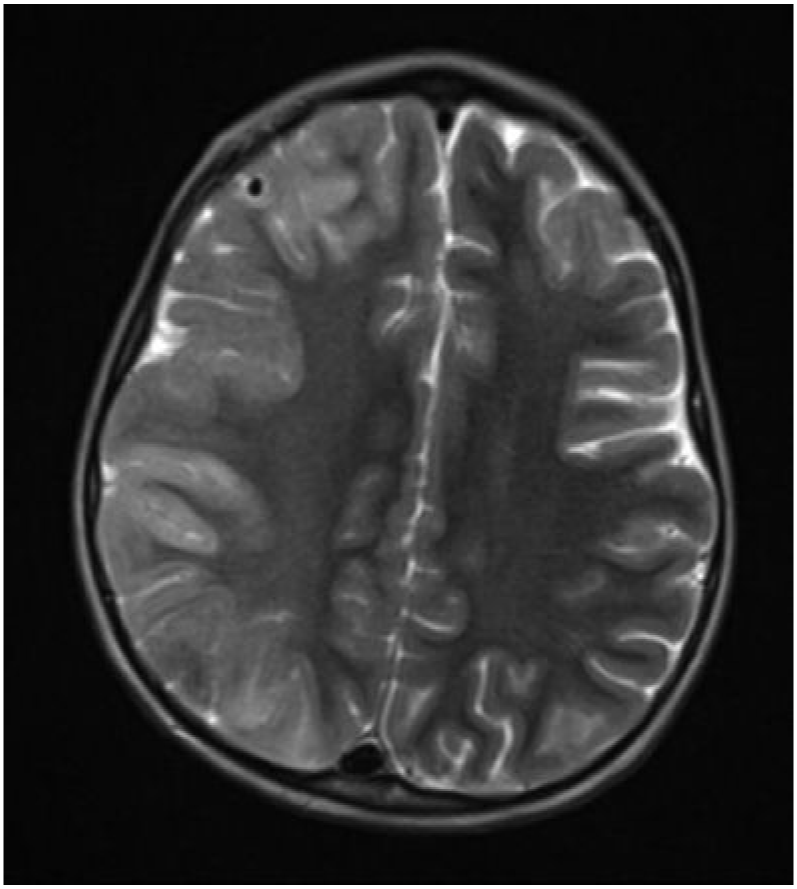

FIGURE 201-4 Diffuse ischemic changes in the right cerebral hemispheres with patchy areas of ischemia in the left frontal and temporal lobes on brain MRI in a young child with pneumococcal meningitis. This child presented with fever, severe headache and lethargy. (*Used with permission from Camille Sabella, MD*.)

  - Headache located in the occipital region.
- Episodic TTH—At least 10 episodes of bilateral, mild to moderate, pressure (nonpulsating) type pain without nausea or vomiting, not aggravated by exertion, and rare photophobia or phonophobia, occurring less than 15 days per month.[7]
- Migraine headache—At least 5 episodes of unilateral, pulsating, moderate-to-severe headache, often with visual prodrome or visual field defects, lasting 1[3] to 72 hours, aggravated by physical activity, accompanied by nausea or emesis or photophobia and

phonophobia.[7]Children may also have a bilateral headache, and symptoms of lightheadedness, difficulty thinking, or fatigue.[3]

- Chronic daily headache (CDH)—A primary headache 15 or more days per month, for 4 or more hours per day, for 3 months.[2] Four types of CDH:
    - Chronic migraine—Episodic migraines increase in frequency while associated symptoms decrease; resembles tension headache with occasional typical migraine; often accompanied by medication overuse.[2]
    - Chronic TTH—Bilateral, nonpulsating, without nausea. Photophobia or phonophobia can be present.[2]
    - New daily persistent headache—Abrupt onset of daily headache in patient without a history of a headache disorder; patient often remembers exactly where and when the headaches started.[2]
    - Hemicrania continua—Chronic unilateral pain with exacerbations, often associated with ipsilateral autonomic features.[2]
- Medication overuse headache—Accompanies one of the CDHs; acute medications, such as triptans or opiates are taken more than 10 days a month, or analgesics more than 15 days a month, for more than 3 months.[7]
- Cluster headache—The most common type of trigeminal autonomic cephalgias; can be episodic or chronic; sharp stabbing unilateral pain in trigeminal distribution, lasting 15 minutes to 3 hours, with ipsilateral autonomic features.[2] Typically occurs in children over age 10 years, but has been reported in younger children.[3]
- Sinus headache—Purulent nasal discharge, co-onset of sinusitis, headache localized to facial and cranial areas.

TYPICAL DISTRIBUTION

- Tension headaches are typically bilateral.
- Migraine and cluster headaches are typically unilateral.

LABORATORY TESTING

- Generally not indicated.
- May be used when a secondary cause, such as infection is suspected.

IMAGING

- Generally not indicated.
- MRI when red flags are present (**Figures 201-2** to **201-4**).

DIFFERENTIAL DIAGNOSIS

- Common primary headaches include episodic TTH, migraine, and chronic daily headache.
- Secondary causes of headache include trauma, vascular disorders, substance use, systemic illnesses/infections, metabolic disorders, or sinus or eye disorders.
- Medication overuse headache is predominately seen with a primary headache, but may also accompany a secondary headache.

MANAGEMENT

General principles include:[8]

- Establish the diagnosis.
- Evaluate for somatic and psychiatric comorbidities.
- Use a headache diary to track progress.
- Educate the child and family.

- Set realistic goals.
- Identify triggers and reduce emotional mechanisms that promote stress.
- Maintain a normal daily schedule.

Episodic TTH

- Acute therapy.
  - NSAIDs, acetaminophen, and aspirin (over age 15 years) are effective treatments for acute episodes.[8]
  - Avoid opiates.
  - Limit acute medications to less than 3 times a week to reduce the risk of medication overuse headache.[4]
- Consider preventive therapy if headaches occur once a week.
  - Amitriptyline 1 mg/kg/day may be effective.
  - Biofeedback may be effective.[4]
  - Acupuncture may be helpful.[4]

Migraine Headache

- Use a stepped approach to treat acute migraine episodes.
  - Start with simple analgesics. Acetaminophen and ibuprofen are often effective.[8]
  - Consider an anti-emetic.[8]
  - Reserve migraine-specific agents such as triptans for patients who fail the preceding therapies.[9]Sumatriptan nasal spray, rizatriptan 5 mg tablets and wafers, and zolmitriptan have been shown to be effective.[8]
- Consider prophylaxis for patients whose migraines occur more than 3 times a month and have a negative impact on their lives or to decrease risk of developing medication overuse headache when frequency requires use of simple analgesics more than 15 days a month or use of opioids, triptans, or combination analgesics more than 10 days a month.
  - Amitriptyline 1 mg/kg/day, divalproex sodium 15 to 45 mg/kg/day, topiramate 2–3 mg/kg daily up to 100 mg daily have each demonstrated greater than 50 percent reduction in migraine frequency.[8]

Propranolol has equivocal results and can activate asthma in children with atopic disorders.[8]

- Cognitive behavioral therapy, biofeedback, stress management, music therapy, and lifestyle modification may also be useful.[9]

Cluster Headache

- Acute episode:
  - Inhaled high-flow oxygen 10 to 15 L per minute.[6]
  - Sumatriptan nasal spray or subcutaneous is an off-label use in children, but may be effective.[8]
  - Prednisone is effective in adolescents.[8]
- Verapamil may be effective for prophylactic therapy.[8]
- Refer refractory patients for evaluations for other medical or surgical therapies.

Medication Overuse Headaches

- Educate patients that chronic medication use is contributing to their daily headaches.[10]
- Abruptly stop (when safe) or taper the overused medication.[10]

REFERRAL

- Refer patients when the diagnosis is unclear or response to therapy is inadequate.
- Consider referral for medication overuse headaches as these are difficult to treat.

PREVENTION

- Closely monitor use of medications for acute episodes. Advise patients to limit simple analgesics to less than 15 days per month; limit triptans and combination medications to less than 10 days per month.
- Appropriately prescribe preventive therapies to reduce frequency of headaches and avoid development of CDHs.

PROGNOSIS

- Migraine headaches—Tend to be recurrent; frequent migraines are often reduced with prophylactic treatment.
- Tension headaches—Unknown; tend to be at risk for chronic headaches as adults.
- Cluster headaches—Unknown; ranges from total remission to chronic form.[6]

FOLLOW-UP

- Dangerous causes of secondary headaches require immediate evaluation and management.
- Frequency of follow-up for primary headaches is determined by type and severity of headache and response to therapy.

PATIENT EDUCATION

Advise patients to limit frequency of acute medications to less than 2 to 3 times a week to reduce the risk of medication overuse headache.

PATIENT RESOURCES

National headache foundation has information for patients on many topics including:

202 BELL’S PALSY

Heidi Chumley, MD

PATIENT STORY

A teenage girl was brought in by her parents because she was unable to move the left side of her face for the past 2 days. She had no history of trauma or recent ear infections and was otherwise well. On examination it was found that she had absent brow furrowing, weak eye closure, and dropping of the angle of her mouth (**Figure 202-1**). She had a normal complete blood count and serum glucose. She was diagnosed with Bell’s palsy and was provided eye lubricants and guidance on keeping her left eye moist. Her physician discussed the available evidence about treatment with steroids and the excellent prognosis without treatment in children. She (with her parents in agreement) chose not to take the steroids. She had a full recovery over the next several weeks.

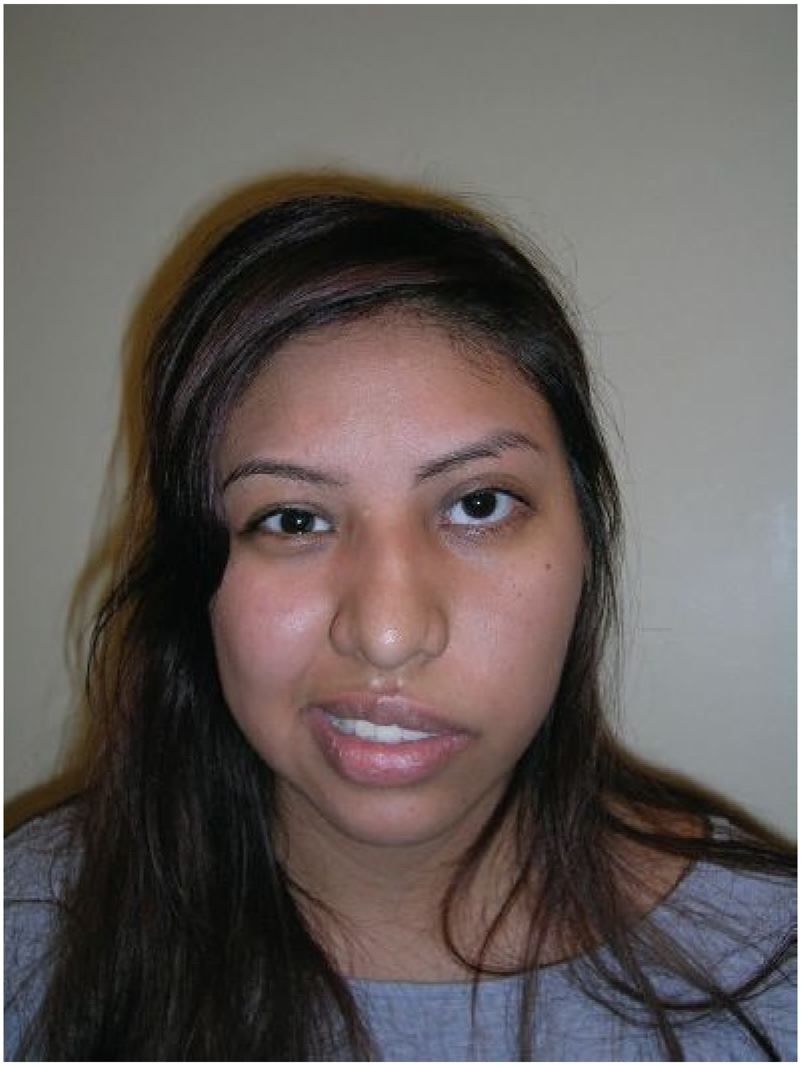

FIGURE 202-1 Bell's palsy for 2 days in a teenage girl. Note the loss of brow furrowing and dropped angle of the mouth on the affected left side of her face demonstrated during a request to smile and raise her eyebrows. (*Used with permission from Richard P. Usatine, MD.*)

INTRODUCTION

Bell's palsy is an idiopathic paralysis of the facial nerve resulting in loss of brow furrowing, weak eye closure, and dropped angle of mouth. Treatment is eye protection. Treatment with oral steroids is standard of care in adults, but controversial in children. Prognosis for full recovery is excellent.

SYNONYMS

Idiopathic facial paralysis.

EPIDEMIOLOGY

- In a population-based study, incidence was 18.8/100,000 children.[1]
- Incident rate increases by age and is higher is female children.[1]
- Seventy percent of cases of acute peripheral facial nerve palsy are idiopathic (Bell’s palsy); 30 percent have known etiologic factors such as trauma, diabetes mellitus, polyneuritis, tumors, or infections such as herpes zoster, leprosy (**Figure 202-2**), or *Borrelia*.[2]

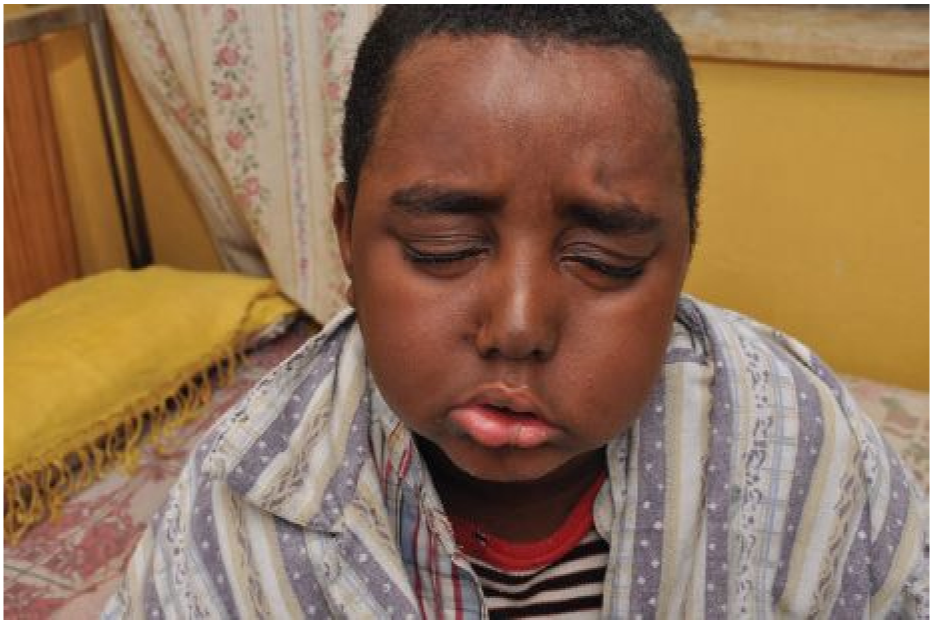

FIGURE 202-2 Bell’s palsy secondary to leprosy. The hypopigmented patches on his face are further signs of the leprosy. He also is Cushingoid from the prednisolone being used to treat the immunological reaction to his leprosy treatment. (*Used with permission from Richard P. Usatine, MD.*)

ETIOLOGY AND PATHOPHYSIOLOGY

- Etiology of Bell's palsy is currently unknown and under debate; the prevailing theory suggests a viral etiology from the herpes family.
- The facial nerve becomes inflamed, resulting in nerve compression.
- Compression of the facial nerve compromises muscles of facial expression, taste fibers to the anterior tongue, pain fibers, and secretory fibers to the salivary and lacrimal glands.
- This is a lower motor neuron lesion; the upper and lower portions of the face are affected (**Figure 202-1**). In upper motor neuron lesions (e.g., cortical stroke), the upper third of the face is spared, while the lower 2/3 are affected as a result of the bilateral innervation of the orbicularis, frontalis, and corrugator muscles, which allows sparing of upper face movement.

DIAGNOSIS

CLINICAL FEATURES

- Weakness of all facial muscles on the affected side—Loss of brow furrowing, weak eye closure, and dropped angle of mouth.
- Postauricular pain.
- Dry eyes.
- Involuntary tearing.
- Hyperacusis.
- Altered tastes.

LABORATORY TESTING

Laboratory testing is not usually indicated:

- Consider complete blood count to rule out leukemia.
- Consider serologic tests for Lyme disease in endemic areas.
- Consider testing for diabetes mellitus in patients with risk factors.

IMAGING

- Consider MRI to look for a space-occupying lesion with atypical presentations.

DIFFERENTIAL DIAGNOSIS

- Facial nerve paralysis is most commonly Bell’s palsy (40 to 70%), but can also be due to:
  - Infection (13 to 36%), including otitis media, herpes zoster, Lyme disease in endemic areas. Facial nerve paralysis is the most common neurologic manifestation of Lyme disease (see Chapter 183, Lyme Disease).
  - Trauma (19% to 21%), including facial injuries or trauma to middle ear.
  - Congenital condition (8% to 14%).
  - Neoplasm (2% to 3%), including cholesteatoma, leukemia, and facial nerve tumor.
- Upper motor neuron diseases including stroke—Normal brow furrowing, eye closure, and blinking.
- Facial nerve damage from microvascular disease—Most commonly in diabetes mellitus.
- Isolated third nerve palsy—Manifestations include diplopia and drooping of the upper eyelid (ptosis). The affected eye may deviate out and down in straight-ahead gaze; adduction is slow and cannot proceed past the

midline. Upward gaze is impaired. When downward gaze is attempted, the superior oblique muscle causes the eye to adduct. The pupil may be normal or dilated; its response to direct or consensual light may be sluggish or absent (efferent defect). Pupil dilation (mydriasis) may be an early sign.

MANAGEMENT

NONPHARMACOLOGIC

- Provide eye protection with artificial tears, lubricants, or closing of the eyelid. SOR Ⓒ

MEDICATIONS

- A systematic review of steroid treatment for children with Bell's palsy found no controlled trials and recommended further trials to determine the role of steroids in children.[3]
- New data and a Cochrane systematic review supports treating adult patients with systemic corticosteroids. Steroids significantly decrease a patient's risk for incomplete recovery from 33 to 23 percent, risk ratio 0.71.[4] SOR Ⓐ
  - Dosing of steroids in the studies analyzed within the Cochrane review varied from oral methylprednisolone 1 mg/kg daily for 10 days, and then gradually withdrawn for another 3 to 5 days to prednisone given as a single dose of 60 mg daily for 5 days, followed by a dose reduced by 10 mg, per day, with a total treatment of 10 days. One trial used high-dose prednisolone given intravenously.
- A Cochrane systematic review does not support using antiviral medications. There is no significant benefit from acyclovir or valacyclovir when compared to placebo. Antivirals are less likely than steroids to produce complete recovery.[5] SOR Ⓐ

REFERRAL

- In longstanding facial paralysis, consider referral to an ear, nose, and throat (ENT) surgeon or plastic surgeon with experience in treating Bell’s palsy with surgery. It is possible to restore some facial movement with specialized surgical procedures including regional muscle transfer and microvascular free tissue transfer.[6] SOR Ⓒ

PROGNOSIS

Prognosis for full recovery is excellent.

FOLLOW-UP

Consider seeing patients in 2 to 3 weeks to evaluate recovery and to reconsider diagnosis if there has been no recovery.

PATIENT EDUCATION

- Most patients recover spontaneously. Steroid treatment is indicated for adults but remains controversial in children.
- Ninety-five percent of children recover; 70 percent recover within 3 weeks.

PATIENT RESOURCES

- The American Academy of Family Physicians has written and auditory information in English and in Spanish—**www.familydoctor.org**.

203 SUBDURAL HEMATOMA

Heidi Chumley, MD

PATIENT STORY

A 2-month-old previously healthy male infant was brought in by his mother after a seizure. She noted that he had seemed irritable and was not feeding well several hours prior to the seizure. She denied any trauma or fever. On examination, retinal hemorrhages were noted, but there were no other signs of trauma, and no signs of infection. The child was irritable, lethargic, and had poor tone. An emergent non-contrast CT was obtained and demonstrated a subdural hematoma (**Figure 203-1**). Neurosurgery was consulted and the infant underwent emergency craniectomy and evacuation of the subdural hematoma (**Figure 203-2**). An evaluation for child abuse was initiated.

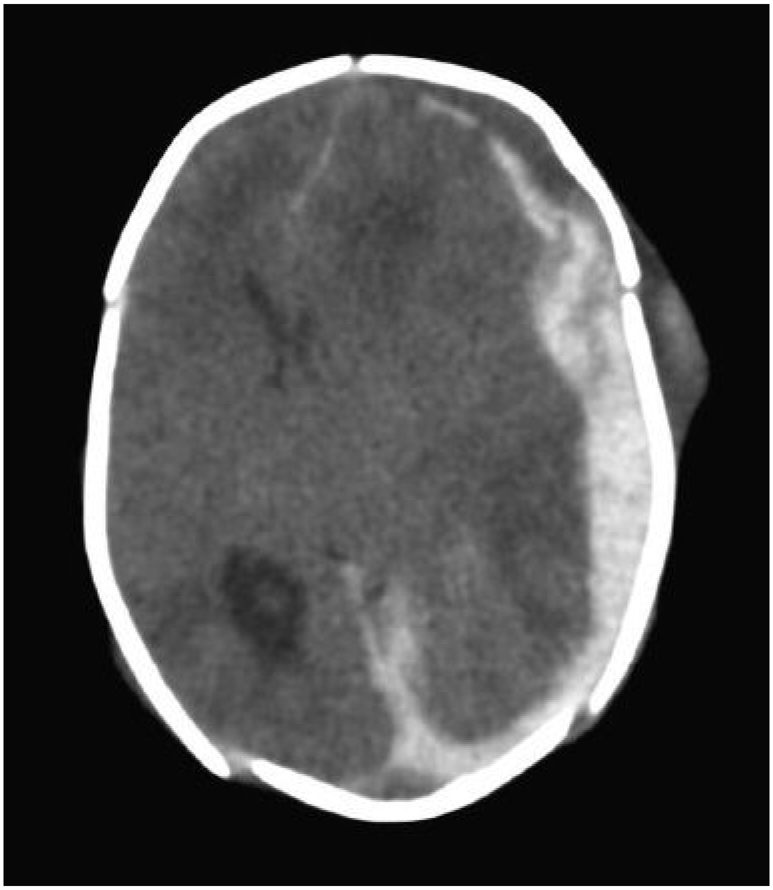

FIGURE 203-1 Large acute left hemispheric subdural hematoma with left to right midline shift on CT scan of the brain in a 2-month-old infant suspected of being the victim of child abuse. (*Used with permission from Camille Sabella, MD*.)

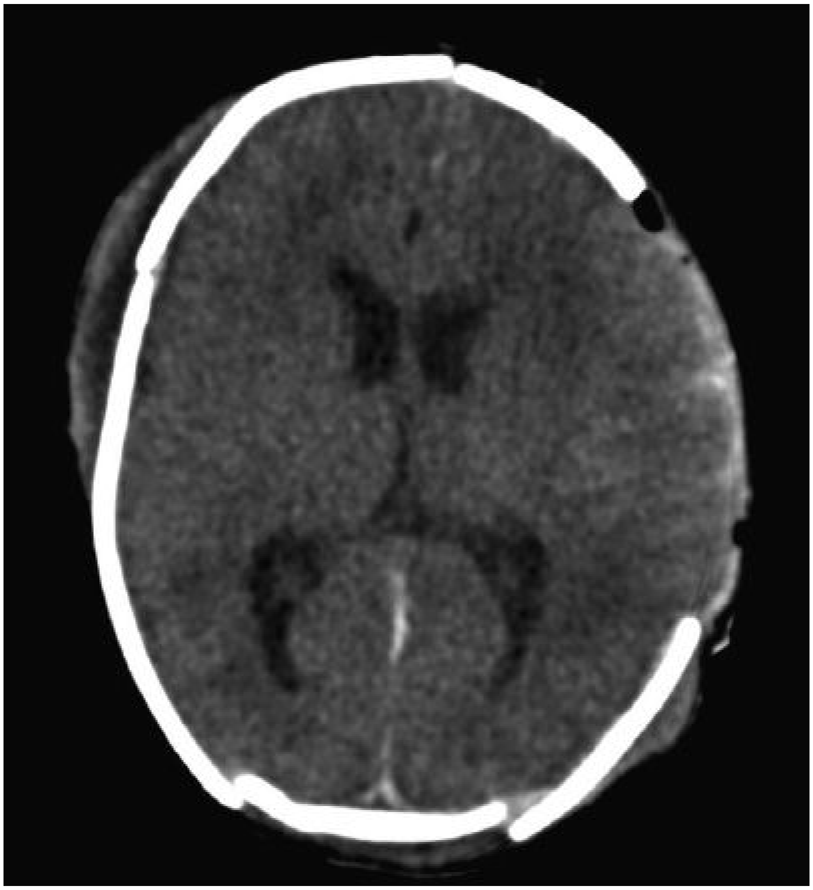

FIGURE 203-2 CT of the brain of the same 2-month-old infant as in Figure 203-1 after craniectomy and evacuation of the subdural hematoma. Note the marked decrease in mass effect. (*Used with permission from Camille Sabella, MD.*)

INTRODUCTION

Subdural hematomas (SHs) can occur at any age, but are most common in infants. Most SHs are caused by trauma. Symptoms are generally nonspecific such as irritability or poor feeding in infants and confusion or headaches in older children. Treatment is prompt consultation with a neurosurgeon.

EPIDEMIOLOGY

- SHs occur at all ages.
- Eight percent of asymptomatic newborns can have an SH.[1]
- Twenty-four of 100,000 infants ages 0 to 1 year in United Kingdom population studies.[2]
- Mortality rate of traumatic SH in treated children ages 0 to 17 is approximately 22 percent.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Most SHs are caused by trauma, either accidental or intentional, from a direct injury to the head or shaking injury in an infant.
- Nonaccidental trauma, falls, and motor vehicle accidents are the most common causes of traumatic SH.
- SHs can occur during a nontraumatic birth.
- Motion of the brain within the skull causes a shearing force to the cortical surface and interhemispheric bridging veins.[2]
- This force tears the weakest bridging veins as they cross the subdural space, resulting in an acute SH as seen in **Figure 203-1**.[2]
- Three days to 3 weeks after the injury, the body breaks down the blood in an SH; water is drawn into the collection causing hemodilution, which appears less white and more gray on noncontrast CT.[2]
- If the hematoma fails to resolve, the collection has an even higher content of water and appears darker on a noncontrast CT; it may have fresh bleeding or may calcify (chronic SH).[2] This is often of the same color as brain parenchyma on noncontrast CT.

- Nontraumatic causes reported in the literature include spontaneous bleeding because of bleeding disorders or anticoagulation, meningitis, and complications of neurologic procedures, including spinal anesthesia.

RISK FACTORS

Poor prognosis is seen in children with:[4]

- Early seizures.
- Apnea.
- Raised intracranial pressure and/or hypotension.
- Retinal hemorrhages
- Skull fractures
- Brain swelling

DIAGNOSIS

The clinical features are often nonspecific, making the diagnosis difficult in the absence of known trauma.

- Infants may present with drowsiness, irritability, poor tone, poor feeding, or new seizures.[2]
- Older children may present with vomiting, seizures, headaches, or confusion.

TYPICAL DISTRIBUTION

SHs by definition occur in the subdural space, most commonly seen in the parietal region.

IMAGING

Acute SHs are seen easily on a noncontrast CT scan (**Figure 203-1**). Subacute and chronic SHs can be similar in color to the brain parenchyma and may be easier to see on a contrast CT or an MRI.

DIFFERENTIAL DIAGNOSIS

Other causes of nonspecific symptoms seen with SH can be differentiated by neuroimaging and include the following:

- Infections such as sepsis or meningitis—Fever, elevated white blood cells, positive blood cultures, and cerebral spinal fluid consistent with meningitis.
- Hemorrhagic (**Figure 203-3**) or ischemic stroke or transient ischemic attacks—Consider risk factors for stroke such as congenital heart malformations, hemolytic anemias, collagen vascular diseases, and thrombophilia (see Chapter 204, Cerebral Vascular Accident).

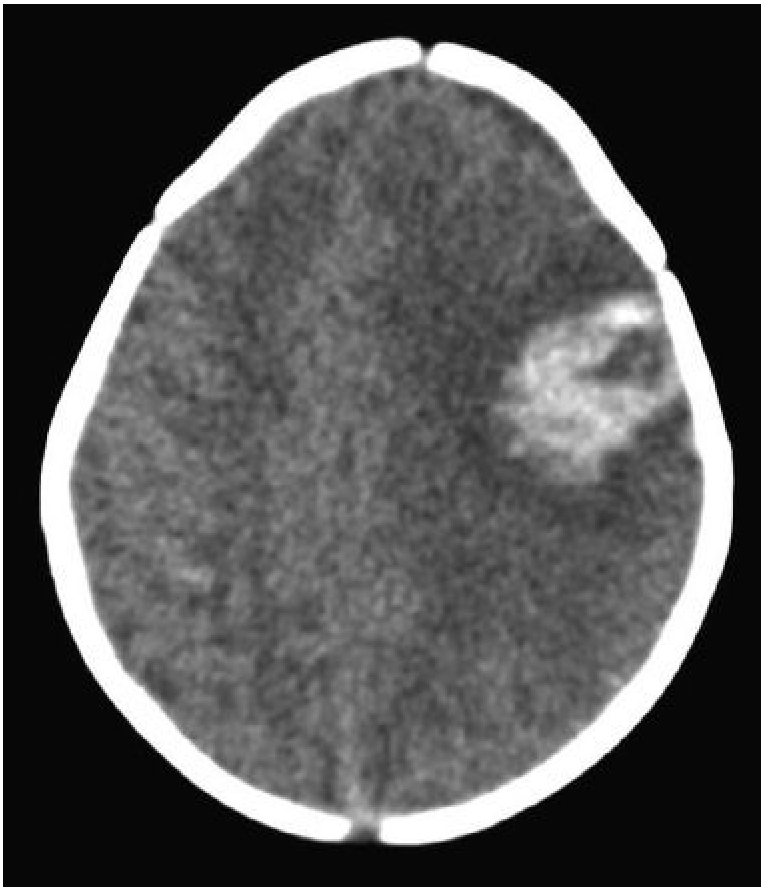

FIGURE 203-3 Hemorrhagic infarct on CT scan of the brain in a young infant with hemorrhagic disease of the newborn. (*Used with permission from Camille Sabella, MD*.)

- Primary or metastatic brain neoplasms—History of cancer and risk factors for cancer.

Other causes of intracranial bleeding can also be differentiated by neuroimaging and include the following:

- Epidural hematoma (**Figure 203-4**)—Well-defined biconvex bright white density that resembles the shape of the lens of the eye.

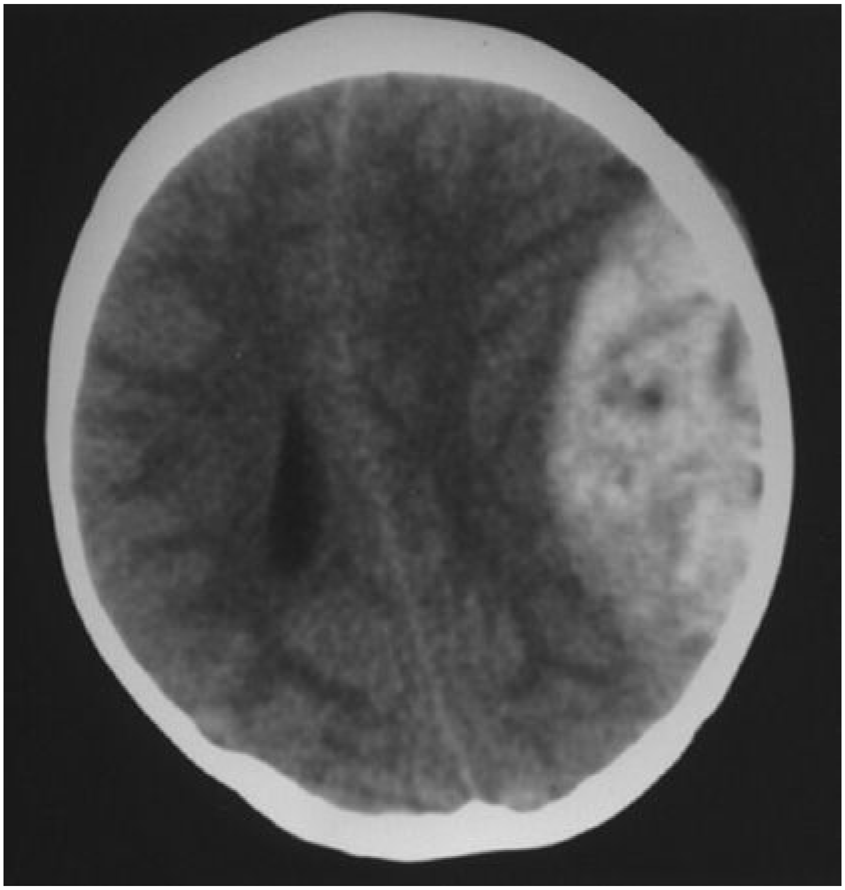

FIGURE 203-4 Epidural hematoma on MRI of the brain. Note the typical lenticular biconvex appearance. (*Used with permission from Strange GR, Ahrens WR, Schafermeyer RW, Wiebe RA. Pediatric Emergency Medicine, 3rd edition: http://www.accessemergencymedicine.com. Figure 29-2, with permission.*)

- Subarachnoid hemorrhage (**Figure 203-5**)—Bright white blood outlines cerebral sulci.

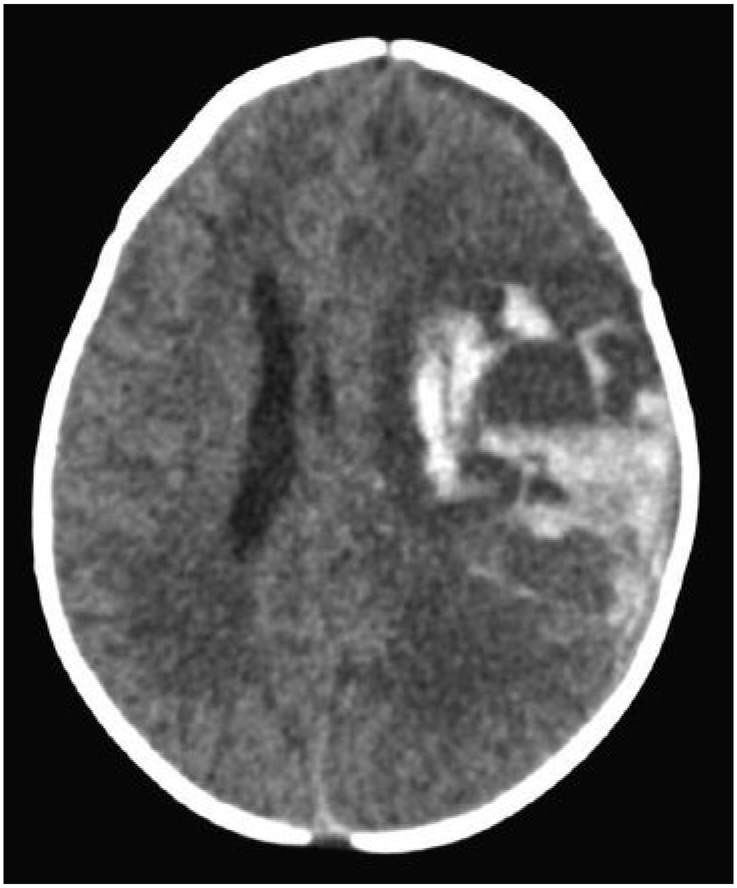

FIGURE 203-5 A subarachnoid hemorrhage appearing as an area of high density (more white like bone rather than the gray of brain tissue) in the same infant as in Figure 203-3. (*Used with permission from Camille Sabella, MD.*)

- Hemorrhage in brain parenchyma—Bright white lesion apart from dura.

MANAGEMENT

Most SHs are managed surgically, and there is little evidence about conservative management (**Figure 203-2**).

- Determine the Glasgow Coma Scale in patients with serious head trauma and consider airway protection in patients with a score less than 12.

- Obtain an urgent noncontrast CT scan on any patient suspected of having an SH.
- If the noncontrast CT scan is nonrevealing, obtain a contrast CT or MRI, particularly if the traumatic event occurred 2 to 3 days prior.
- Emergently refer patients with an SH and deteriorating neurologic status or evidence of brain edema or midline shift to a hospital with neurosurgeons.
- Consult a neurosurgeon expediently in patients with an SH and stable focal neurologic signs.
- Evaluate any infant with an SH for child abuse or neglect.[2,4] SOR Ⓒ

PREVENTION

- Follow safety measures that reduce motor vehicle accidents.
- Use recommended protective gear for sports and recreational activities and follow guidelines for return to play after a head injury.

PROGNOSIS

- Traumatic SH in children ages 0 to 17 years has a mortality of 22 percent.[3]
- Infants with nonaccidental SH have a mortality of 11 to 36 percent. Infants who survive typically have long-term complications that range from learning difficulties to severe cognitive and physical impairment.[4]
- Children with SH from accidental trauma have a better prognosis and over half have a good outcome.[4]
- SH occurring from the birth process are typically asymptomatic and resolve without treatment within 4 weeks.[4]

FOLLOW-UP

- Follow-up is determined by severity of SH and type of treatment.
- Ideally, follow-up is conducted jointly between the neurosurgeon and primary care physician to ensure resolution of the SH and maximal return of function.

PATIENT EDUCATION

- Advise patients to seek medical care immediately for head trauma, which can cause several emergencies including an SH.
- Discuss with parents or guardians the need for a thorough evaluation for child abuse and neglect in infants with an SH.

204 CEREBRAL VASCULAR ACCIDENT

Heidi Chumley, MD

PATIENT STORY

A 16-year-old boy with a history of idiopathic dilated cardiomyopathy and severe ventricular dysfunction was admitted to the hospital for vomiting, confusion, involuntary movements, and slurred speech. On physical examination, he was found to be lethargic and to have dysmetria with the finger-to-nose test, ataxia, and incoordination of rapid alternating movements. He was found to have decreased biventricular systolic dysfunction and a large thrombus at the apex of the left ventricle on cardiac echocardiogram, and a left cerebellar stroke on CT scan of the brain (**Figure 204-1**). He was treated with anticoagulation and supportive care, with improvement of his neurologic symptoms. He eventually underwent a successful orthotopic heart transplant.

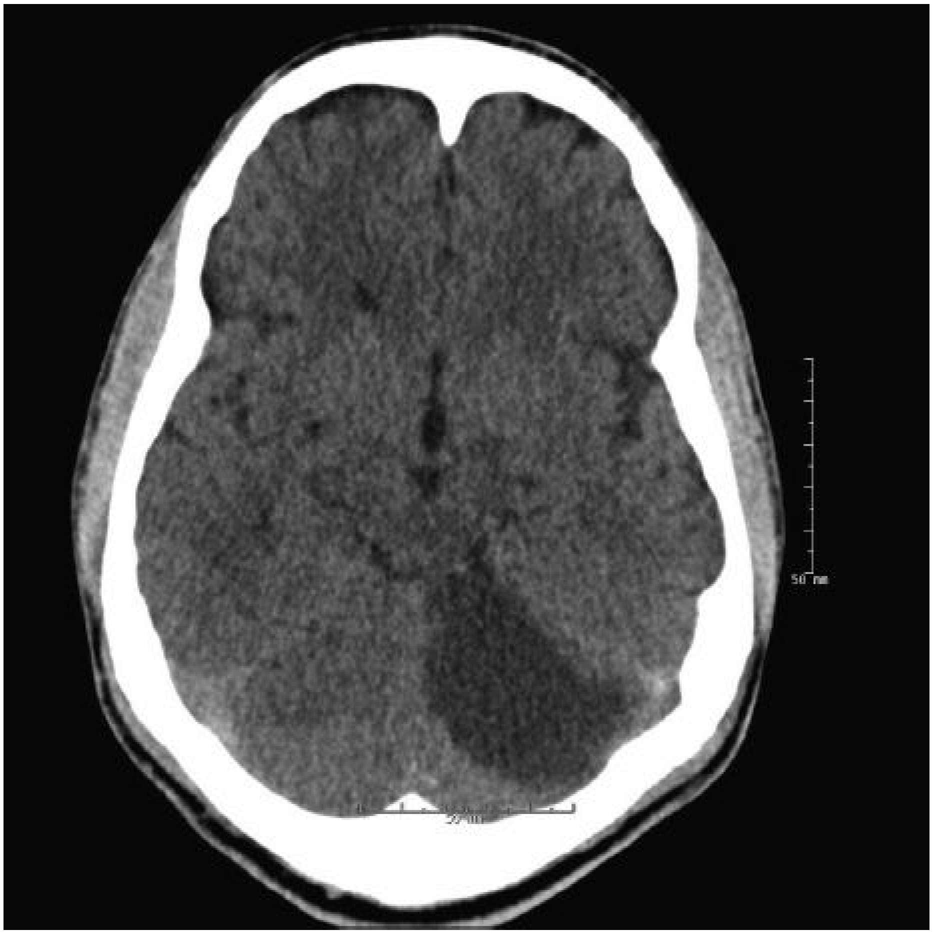

FIGURE 204-1 Acute/subacute left cerebellar infarct on brain CT of a 16-year-old with dilated cardiomyopathy and severe ventricular dysfunction. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

Cerebral vascular accidents are uncommon in children. Ischemic and hemorrhagic strokes are often due to an underlying cause which should be identified and addressed. Acute treatment is largely supportive. Prevention of recurrence is critical.

SYNONYMS

Stroke.

EPIDEMIOLOGY

- Approximately 2 CVAs per 100,000 person per year.[1]
- Approximately 50 percent of strokes are ischemic and 50 percent are hemorrhagic.[1]
- Ten percent of hemorrhagic strokes are due to central venous sinus thrombosis.[2]
- Fifty percent of patients presenting with a focal neurologic deficit have a previously identified risk factor for stroke.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- Ischemic CVAs can be secondary to a wide range of underlying causes.
  - The cause can be determined in approximately 2/3 of patients.[2]
  - Major causes include congenital heart disease, sickle cell disease, infections, and prothrombotic states.
  - Moyamoya is rare in the US, but the most common cause in Japan.
  - Fibromuscular dysplasia more commonly presents in young adults.
- Hemorrhagic CVAs occur when vessels bleed into the brain, usually as the result of a vascular abnormality or clotting disorder.

RISK FACTORS

Ischemic Stroke

- Congenital heart malformations (**Figure 204-1**).
- Cerebrovascular abnormalities.
- Sickle cell disease (10% have a clinically evident stroke by age 20 years; **Figure 204-2**).

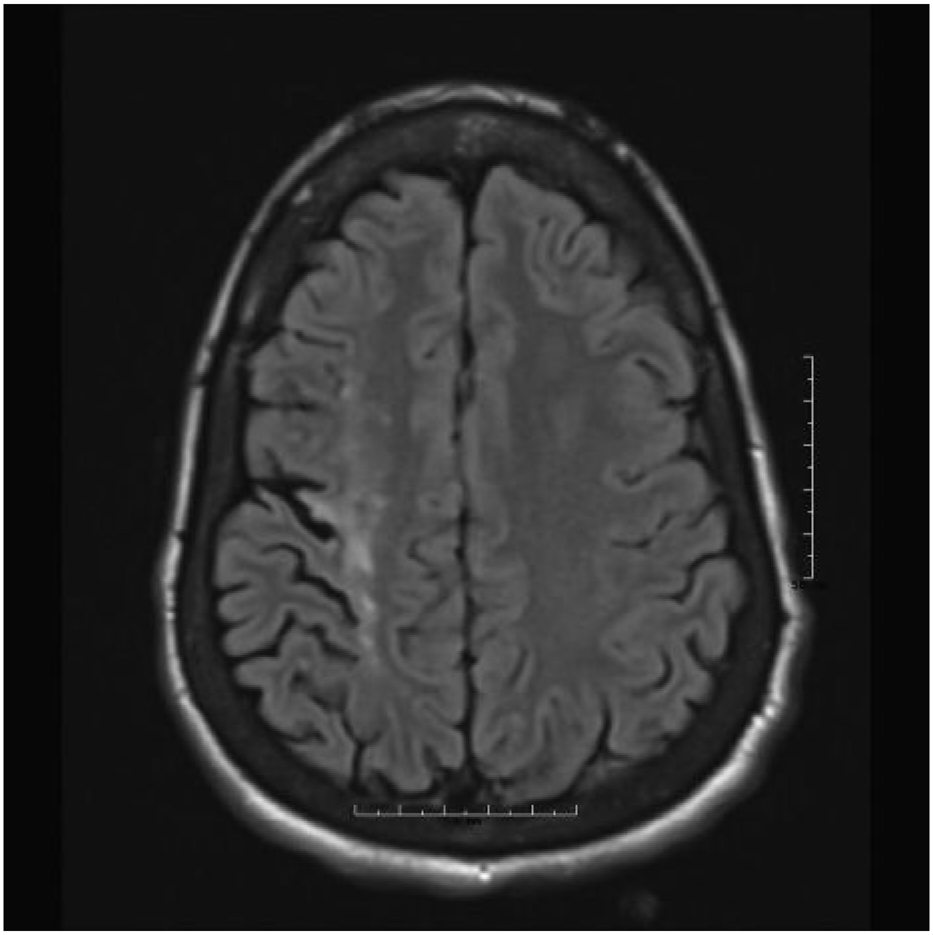

FIGURE 204-2 Brain MRI showing remote infarction in the distribution of the middle cerebral artery and volume loss at the right frontoparietal cortex in a patient with sickle cell disease. (*Used with permission from Stefanie Thomas, MD*.)

- Collagen vascular diseases.
- Infection (meningitis and sepsis).
- Prothrombotic risk factors (elevated homocysteine, elevated lipoprotein (a), protein C and protein S deficiencies, Factor V Leiden, and anti-phospholipid antibodies).

- Migraine with aura, especially with smoking, pregnancy, or oral contraceptive use.
- Trauma.

Hemorrhagic Stroke

- Arteriovenous malformation or fistula or another vascular anomaly.
- Coagulation disorders (**Figure 204-3**).

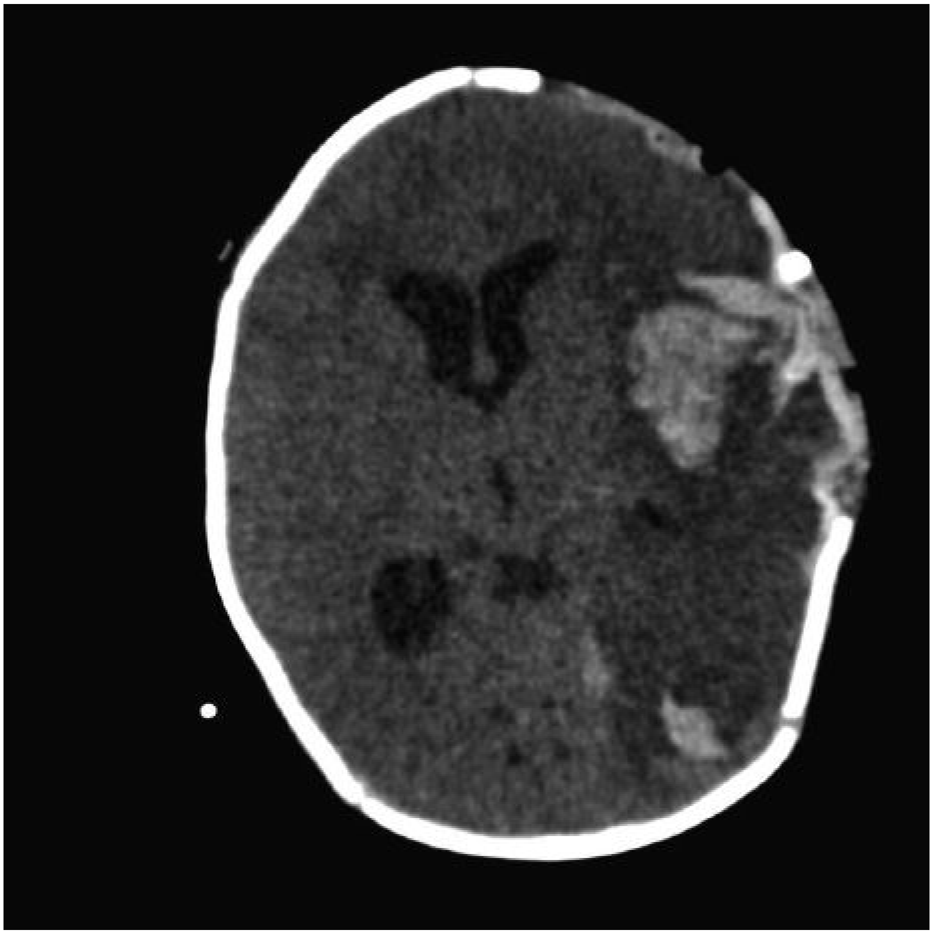

FIGURE 204-3 Left middle cerebral and posterior cerebral artery hemorrhagic infarct in a patient with hemorrhagic disease of the newborn. This CT was performed after craniectomy for evacuation of multifocal hemorrhages and mass affect. (*Used with permission from Camille Sabella, MD*.)

- Sickle cell disease.

- Trauma.

DIAGNOSIS

Diagnosis of CVA must be made expediently to minimize mortality and morbidity.

CLINICAL FEATURES

- History of risk factors or previous transient ischemic attack (TIA) or stroke.
- Acute onset of neurologic signs and symptoms based on the site of the CVA (see the following section "Typical Distribution").
- Hemorrhagic strokes present with headache and deteriorating neurological function. In younger children, headaches, emesis, and seizures with hemiparesis are less common.

TYPICAL DISTRIBUTION

TIA or stroke can occur in any area of the brain; common areas with typical symptoms include the following:

- Middle cerebral artery.
    - Superior branch occlusion causes contralateral hemiparesis and sensory deficit in face, hand, and arm, and an expressive aphasia if the lesion is in the dominant hemisphere.
    - Inferior branch occlusion causes a homonymous hemianopia, impairment of contralateral graphesthesia and stereognosis, anosognosia and neglect of the contralateral side, and a receptive aphasia if the lesion is in the dominant hemisphere.
- Internal carotid artery (approximately 20 percent of ischemic strokes) occlusion causes contralateral hemiplegia, hemisensory deficit, and

homonymous hemianopia; aphasia is also present with dominant hemisphere involvement.

- Posterior cerebral artery occlusion causes a homonymous hemianopia affecting the contralateral visual field.

LABORATORY TESTING (INCLUDE ANCILLARY TESTING)

These tests may be helpful in the context of an acute stroke, particularly when the cause of the stroke is not immediately evident:

- Complete blood count (CBC) for thrombocytosis or polycythemia.
- Erythrocyte sedimentation rate (ESR) for collagen vascular diseases when suspected.
- Serum glucose to eliminate hypoglycemia as the cause of the neurologic symptoms.
- Sickle cell disease screen if status is unknown.
- Prothrombotic factors including elevated homocysteine, elevated lipoprotein (a), protein C and protein S deficiencies, Factor V Leiden, and antiphospholipid antibodies. Further testing of less common prothrombotic factors may be considered.

IMAGING

- Imaging should be completed as soon as possible. CT or MRI can distinguish ischemic from hemorrhagic and localize the lesion. MRA noninvasively identifies the majority of vascular lesions.[2]
- Cardiac echocardiography when an embolic event is suspected.

DIFFERENTIAL DIAGNOSIS

Other causes of acute neurologic dysfunction include the following:

- Brain mass—More common presentation is headache or seizure; however, may present with focal neurologic signs based on location. CT or MRI will help to diagnose a brain mass and differentiate this from stroke.
- Migraines—Throbbing, unilateral headache with photophobia, and nausea; hemiparesis or aphasia may be part of the aura.
- Hypoglycemia—Confused state is similar to large stroke syndromes but is easily differentiated by a blood glucose measurement.
- Multiple sclerosis—Multiple anatomically distinct neurologic signs and symptoms that occur over time and resolve; vision is often affected. MRI findings should help to distinguish multiple sclerosis from CVA.

MANAGEMENT

Acute Ischemic Stroke (AIS)

- Supportive therapy for AIS includes—Control fever if present, provide oxygen if hypoxic, correct systemic hypertension or hypotension, correct glucose levels, treat dehydration and anemia.[2] SOR Ⓒ
- Prophylactic administration of antiepileptic medications is NOT necessary.[2]
- Consider anticoagulation with low molecular weight heparin or unfractionated heparin for up to 1 week while evaluating for underlying risk factors that would be mitigated by anticoagulation.[2]
- Evaluate children with one stroke risk factor for prothrombotic states.

Acute Hemorrhagic Stroke

- Optimize respiratory effort, control systemic hypertension, prevent epileptic seizures, medically manage increased intracranial pressure.

- Consult neurosurgery.
- Evaluate children with nontraumatic hemorrhagic stroke for vascular abnormalities and clotting disorders. An underlying treatable cause can be found in most cases.

Special Situations

- Sickle cell disease.
    - Order transcranial Doppler to identify patients with sickle cell disease at high risk for stroke. Children with cerebral blood flow velocity rates >/= 200 cm/s have a stroke rate of 10 percent per year.[4]
    - Refer patients with SCD and a high cerebral blood flow velocity for chronic transfusion to decrease the risk of stroke by 90 percent.[4] SOR Ⓐ

PREVENTION

- Primary prevention for SCD (follow cerebral blood flow velocity and refer for exchange transfusion when indicated) and congenital heart disease (refer for repair).
- Secondary prevention.
    - Ischemic.
        - Anticoagulation for children with substantial risk of recurrent cardiac embolism, CVST, and hypercoagulable states.[2] SOR Ⓒ
        - Three to 5 mg/kg per day aspirin can be considered win children without SCD with AIS without a high risk of recurrent embolism or severe hypercoagulable disorder.[2] SOR Ⓒ
        - Lower homocysteine level in children with AIS through diet or supplementation of folate, B12, or B6.[2] SOR Ⓒ
        - Avoid oral contraceptives in adolescents with history of acute ischemic stroke
- Hemorrhagic.

  - If a severe coagulation factor deficiency is present, provide appropriate factor replacement therapy.
  - Refer patients with congenital vascular anomalies to be evaluated for surgical correction.

PROGNOSIS

CVA prognosis varies based on size and location of ischemia or hemorrhage, time to recognition, and institution of appropriate management.

- Twenty percent mortality rate.[5]
- High recurrence rate.
- Over 50 percent with permanent cognitive or motor disability.[5]

FOLLOW-UP

- Patients with symptoms of an acute stroke should be hospitalized, evaluated immediately for treatment of reversible causes, and managed, if possible, in a stroke unit or using the "best practices" associated with these units.
- After a stroke and rehabilitation, patients should be followed at regular intervals based on appropriate strategies for secondary prevention.

PATIENT EDUCATION

Educate patients who have had a stroke about the need for a work-up to identify underlying causes, the high risk of having a second stroke, and the need for secondary prevention strategies to reduce this risk.

PATIENT RESOURCES

205 TUBEROUS SCLEROSIS

Carla Torres-Zegarra, MD
Elumalai Appachi, MD, MRCP

PATIENT STORY

A 2-year-old girl was brought to her pediatrician for her well child visit. On exam, she was noted to have several hypomelanotic lesions over her trunk (**Figures 205-1** to **205-3**). Based on the presence of these lesions, the pediatrician orders an MRI of the brain, which revealed subependymal tubers, which also projected into the ventricles. She was diagnosed with Tuberous sclerosis, and a renal ultrasound and cardiac echocardiogram were obtained, which did not reveal any abnormalities. A multidisciplinary approach to her care was planned and included a pediatric neurologist, developmental pediatrician, and dermatologist.

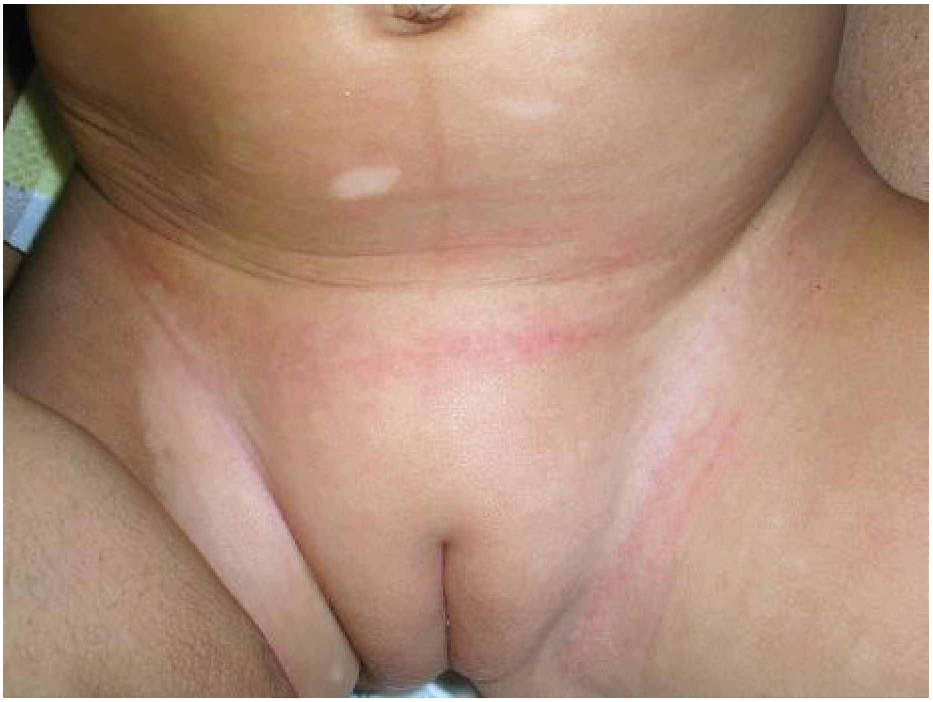

FIGURE 205-1 Hypomelanotic, or “ash leaf” lesion on the abdomen of a 2-year-old girl found to have tuberous sclerosis. She presented with over five hypomelanotic lesions on exam. This prompted the physician to order an MRI of the brain. Tubers were found to confirm the diagnosis. (*Used with permission from Richard P. Usatine, MD*.)

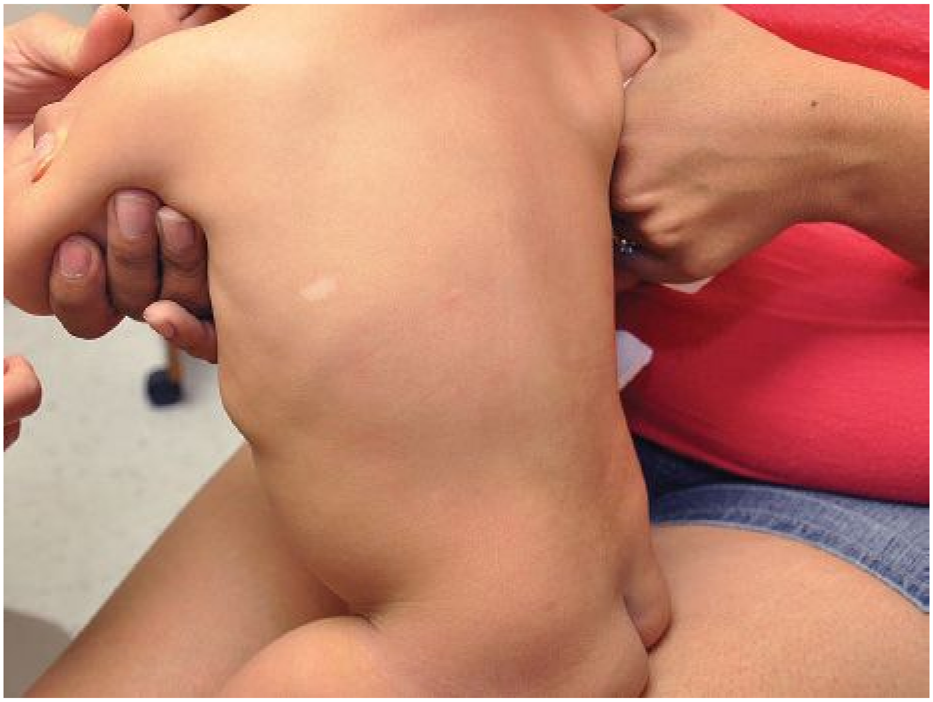

FIGURE 205-2 Hypomelanotic, or “ash leaf” lesion on the back of the same child as in Figure 205-1. (*Used with permission from Richard P. Usatine, MD*.)

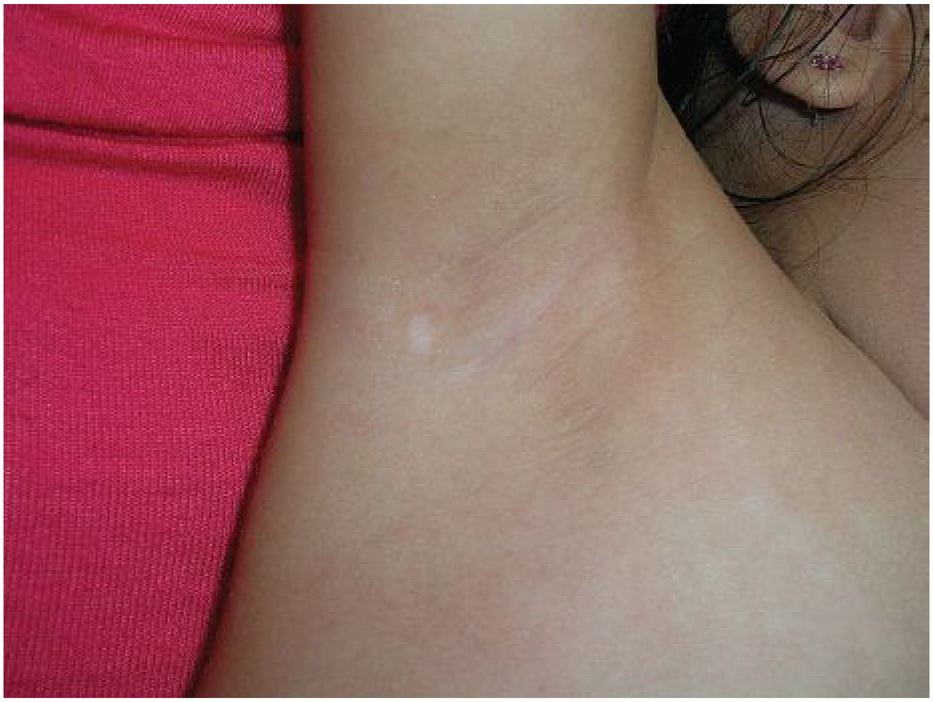

FIGURE 205-3 Hypomelanotic or “ash leaf” lesion in axilla of the child in Figure 205-1. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

Tuberous sclerosis (also called Tuberous sclerosis complex-TSC) is an inherited neurocutaneous and multisystemic disorder characterized by hamartomas (sclerotic tubers), which most notably affect the skin, brain, kidneys, heart and eyes.[1,2] TSC results in a wide spectrum of clinical manifestations and neurologic sequelae.

SYNONYMS

- Bourneviller Pringle Syndrome, Epiloia, Phakomatosis TS, Tuberose sclerosis, Tuberous Sclerosis-1, and Tuberous Sclerosis Complex (TSC).

EPIDEMIOLOGY

- TSC affects both sexes equally and all ethnic groups.
- The prevalence is estimated to be one per 6,000 to 10,000 individuals.[3]
- With one affected parent, the recurrence risk is 50 percent. When both parents appear to be unaffected, the recurrence risk is 1 in 22 after one affected offspring and 1 in 3 after two affected offspring.
- Only 7 to 37 percent of newly diagnosed cases have a family history of TSC.

ETIOLOGY AND PATHOPHYSIOLOGY

- TSC is caused by mutations on two genes, named TSC1 and TSC2. Only one of the genes needs to be affected for TSC to be present.
- TSC has an autosomal dominant mode of inheritance with almost complete penetrance, but a variable expressivity range in terms of the age of onset, severity of disease, and different signs and symptoms that result from a specific genotype.
- The variability is due to multiple causes. These include somatic mosaicism, differences between TSC1 and TSC2 genes, a variety of mutation types found in each gene, and the requirement for a secondary somatic mutation in the wild-type copy of the gene for the development of many pathologic features of TSC.
- Approximately 65 percent of cases are caused by a spontaneous mutation.
- Molecular genetic studies have identified two loci for TSC—TSC1 is located on the long arm of chromosome 9 (9q34) and TSC2 is located on the short arm of chromosome 16 (16p13.3). These loci encode for hamartin and tuberin, respectively. Hamartin and tuberin are thought to function together as a protein complex or as adjacent steps within the

same intracellular pathway, which may explain why the phenotypic expression of either mutation leads to almost identical disease.[2,4]

- Both TSC1 and TSC2 have tumor suppressor activity, which, when not activated, leads to uncontrolled cell cycle progression and the proliferation of hamartomas throughout the body.

RISK FACTORS

- Having an affected parent or sibling (autosomal dominant mode of inheritance).

DIAGNOSIS

CLINICAL FEATURES

- Dermatologic manifestations:
    - Hypomelanotic macules or “ash leaf” spots are found in more than 90 percent of patients with TSC, are evident within the first 2 years of life, and become more evident with age (**Figures 205-1** to **205-3**). In newborn infants and in fair-skinned individuals, these lesions often are difficult to visualize without the aid of an ultraviolet light (Wood’s lamp).
    - Facial angiofibromas (adenoma sebaceum) are comprised of vascular and connective tissue elements and are found in approximately 75 percent of patients with TSC. The lesions typically appear during the preschool years in the malar area as small pink to red dome-shaped papules in a “butterfly distribution” (**Figures 205-4** to **205-6**).

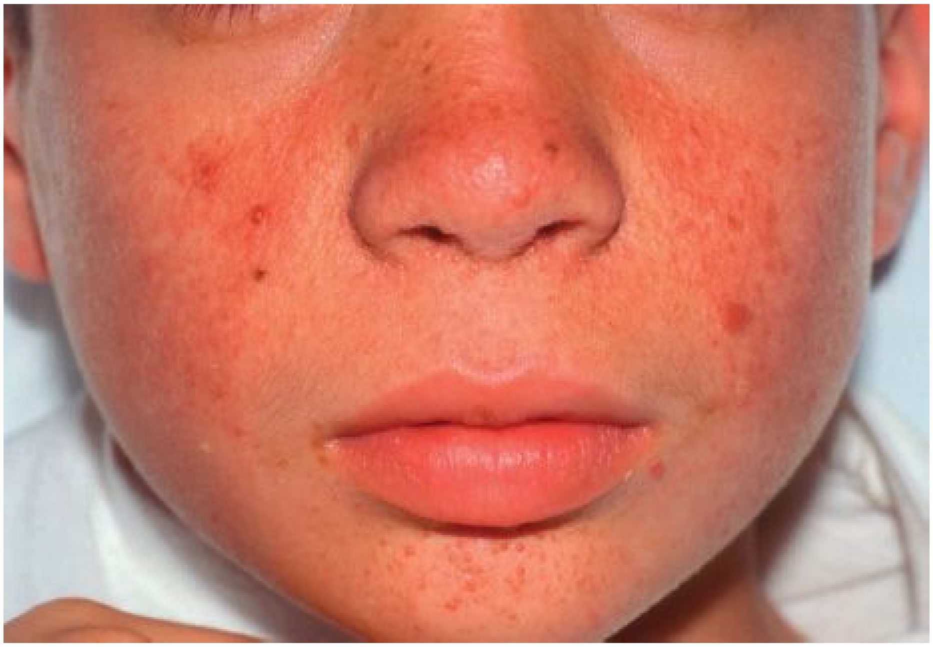

FIGURE 205-4 Facial angiofibromas (adenoma sebaceum) in a typical butterfly distribution in a child with tuberous sclerosis. (*Used with permission from Elumalai Appachi, MD*.)

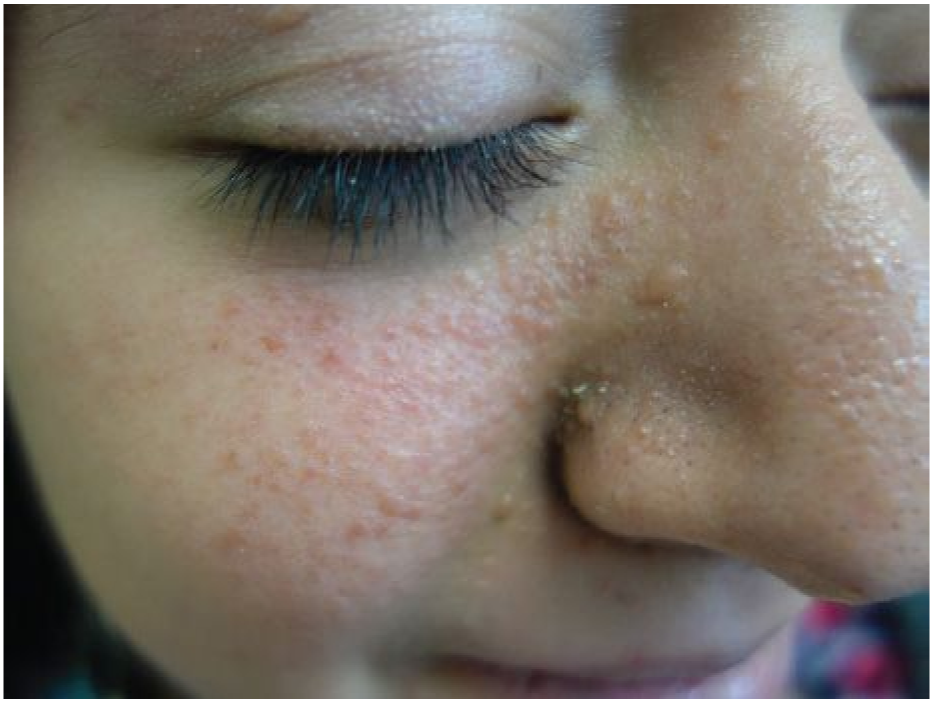

FIGURE 205-5 Angiofibromas on the nose and face of a teenager with tuberous sclerosis. These lesions can be easily confused with acne in adolescents. (*Used with permission from Emily Becker, MD*.)

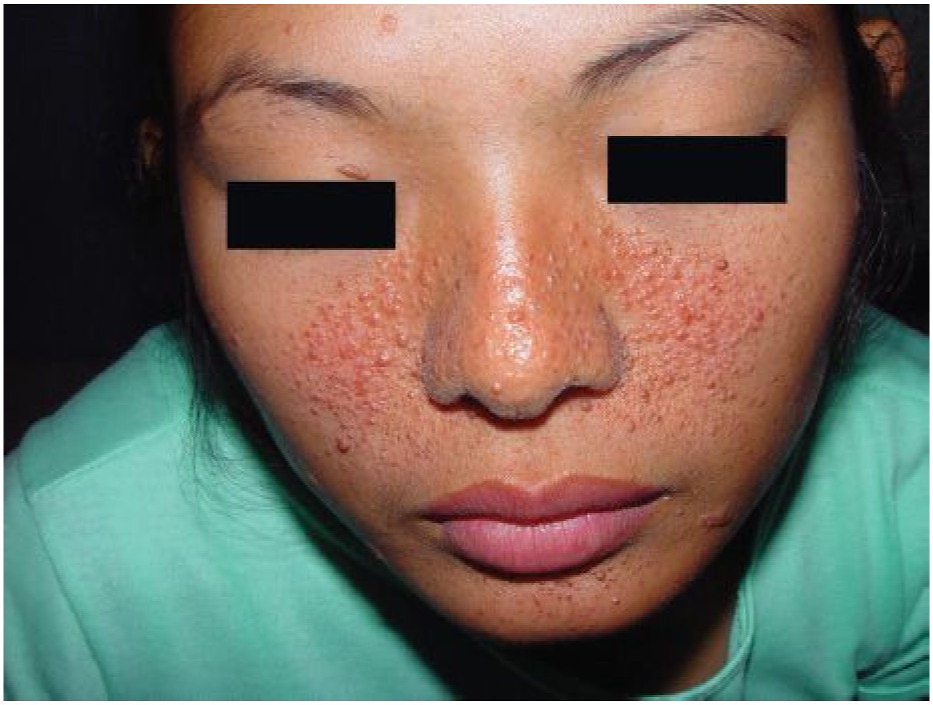

FIGURE 205-6 Angiofibromas on the nose and face of a teenager with tuberous sclerosis. This is also called adenoma sebaceum. (*Used with permission from Marisa Pongprutthipan, MD*)

- A shagreen or “leather” patch is identified in 20 to 30 percent of patients with TSC. They result from accumulation of collagen, and are typically is found in the lumbosacral area. The lesion presents as an irregularly shaped, grayish-green, or light brown, unevenly thickened plaque with a cobblestone or orange-peel appearance (**Figure 205-7**).

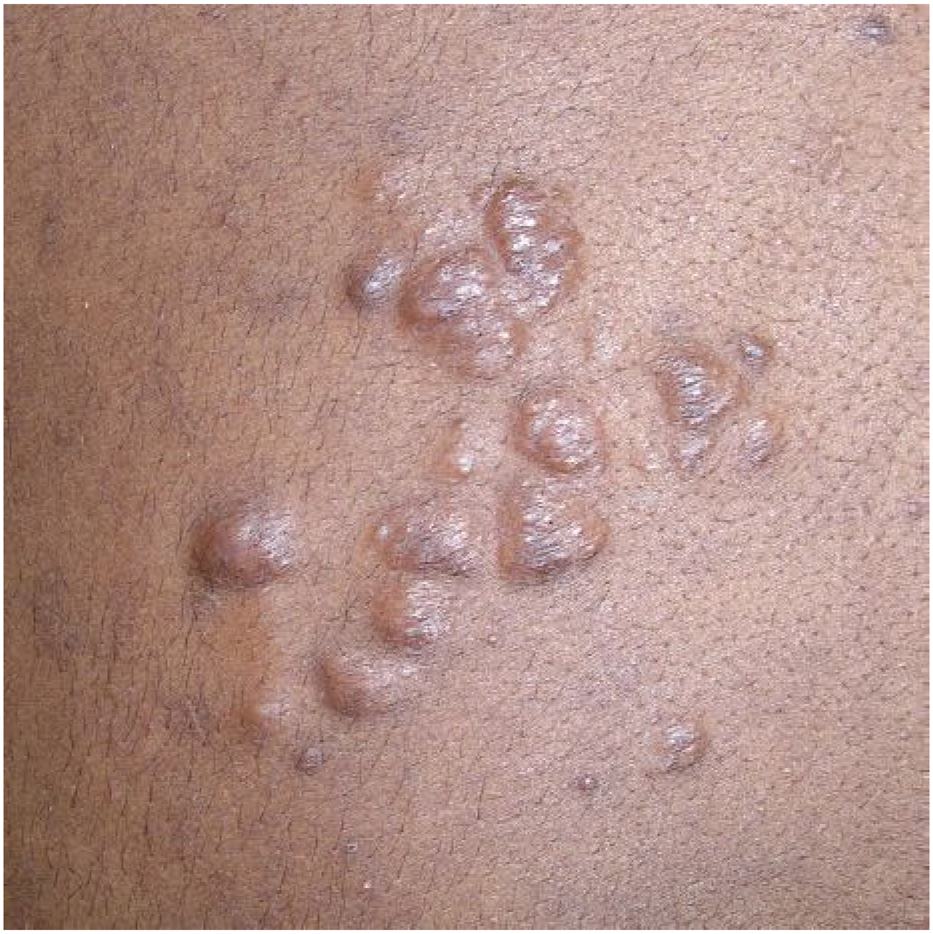

FIGURE 205-7 Shagreen patch (collagenoma) is a slightly elevated skin-colored connective tissue plaque found in tuberous sclerosis. These collagenomas are on the back of a young patient with tuberous sclerosis. (*Used with permission from Richard P. Usatine, MD.)*

- Periungual and ungual fibromas are smooth, firm, nodular, or fleshy lesions that are adjacent to or underneath the nails. These usually appear later in life and are not typically apparent in the pediatric age-group (**Figures 205-8** to **205-10**).

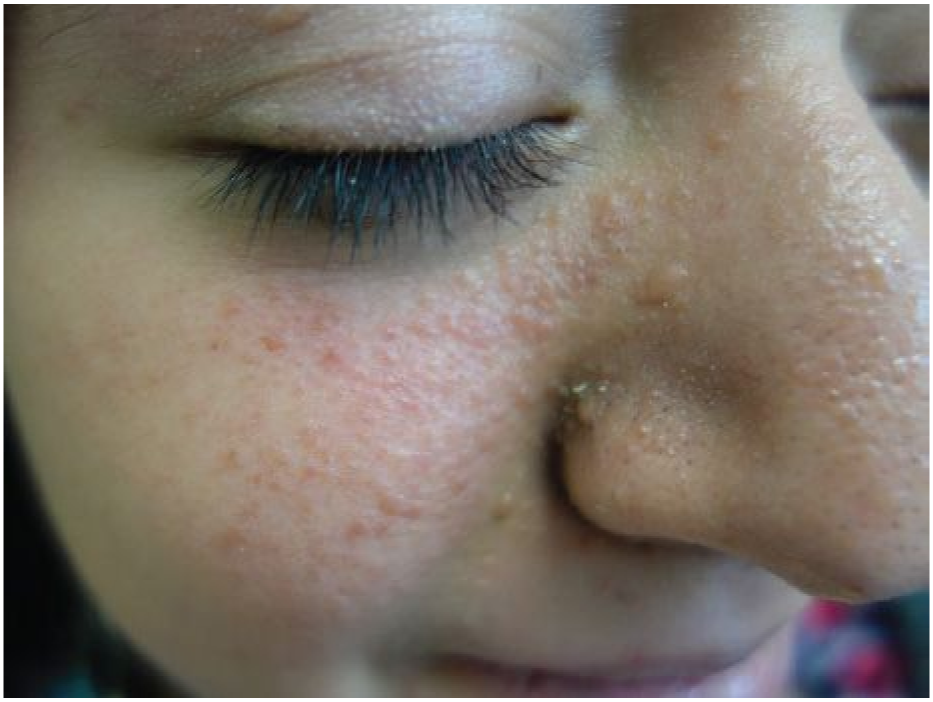

FIGURE 205-8 Periungual fibroma (Koenen tumor) in a patient with tuberous sclerosis. These appear later in life and are not typically seen in children. (*Used with permission from Richard P. Usatine, MD*.)

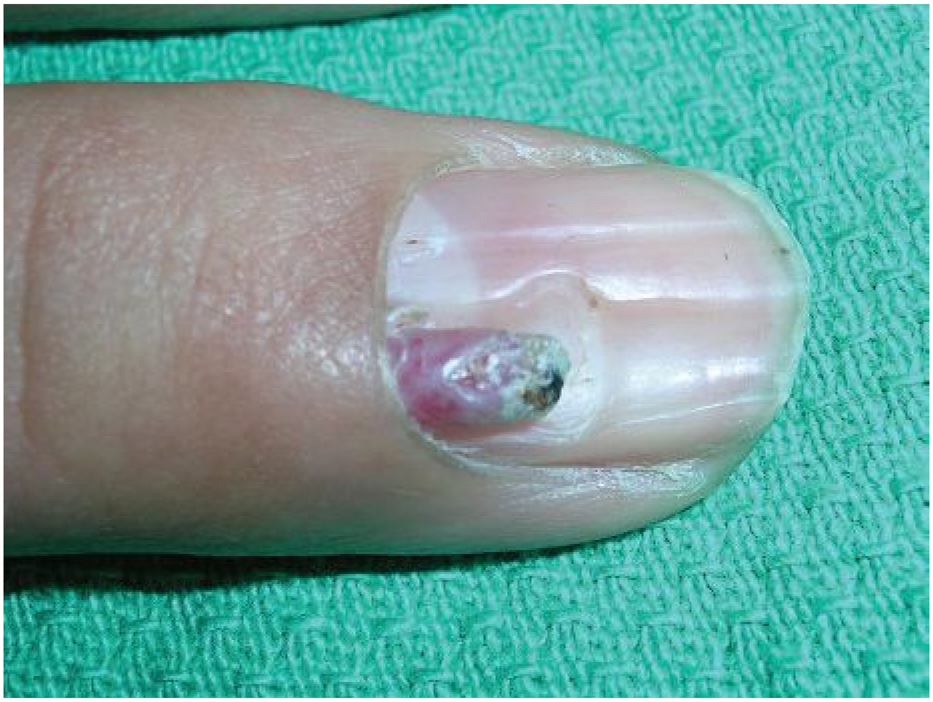

FIGURE 205-9 Periungual fibroma (Koenen tumor) in a young adult with tuberous sclerosis. (*Used with permission from Richard P. Usatine, MD.*)

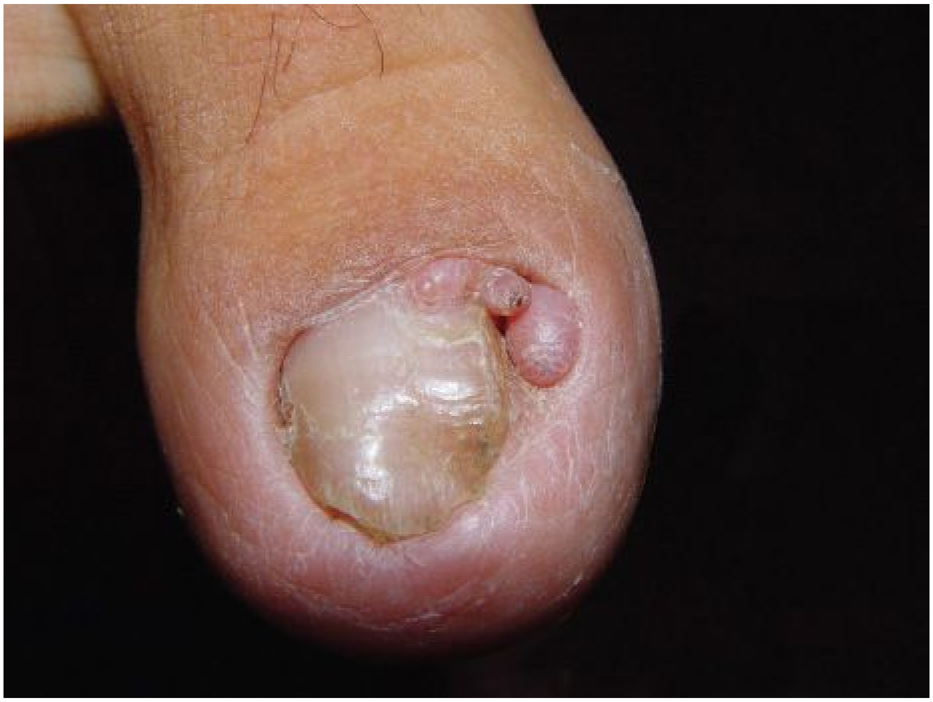

FIGURE 205-10 Periungual fibroma distorting the toe nail architecture of a teenager with tuberous sclerosis. (*Used with permission from Marisa Pongprutthipan, MD.*)

  - Café au lait spots are seen in up to 30 percent of patients with TSC. Most patients have fewer than six lesions whereas patients with neurofibromatosis usually have at least six (see Chapter 206, Neurofibromatosis).

- Neurologic manifestations:
  - There is a wide spectrum of neurological manifestations.
  - About half of persons with TSC will have normal intellect.
  - Neurologic complications, when present, are the most common causes of mortality and morbidity, and the most likely to affect the quality of life.
  - Seizures are the most common neurologic complication and are reported to occur in 75 to 90 percent of patients. These most commonly

present as infantile spasms, partial motor seizures, and generalized tonic clonic seizures.[3,4]

  - Autism, attention deficit, hyperactivity, and sleep problems are the most frequent behavioral disorders.
  - Intracranial abnormalities include tubers, subependymal nodules, and subependymal giant cell astrocytomas (**Figure 205-11**).[5]

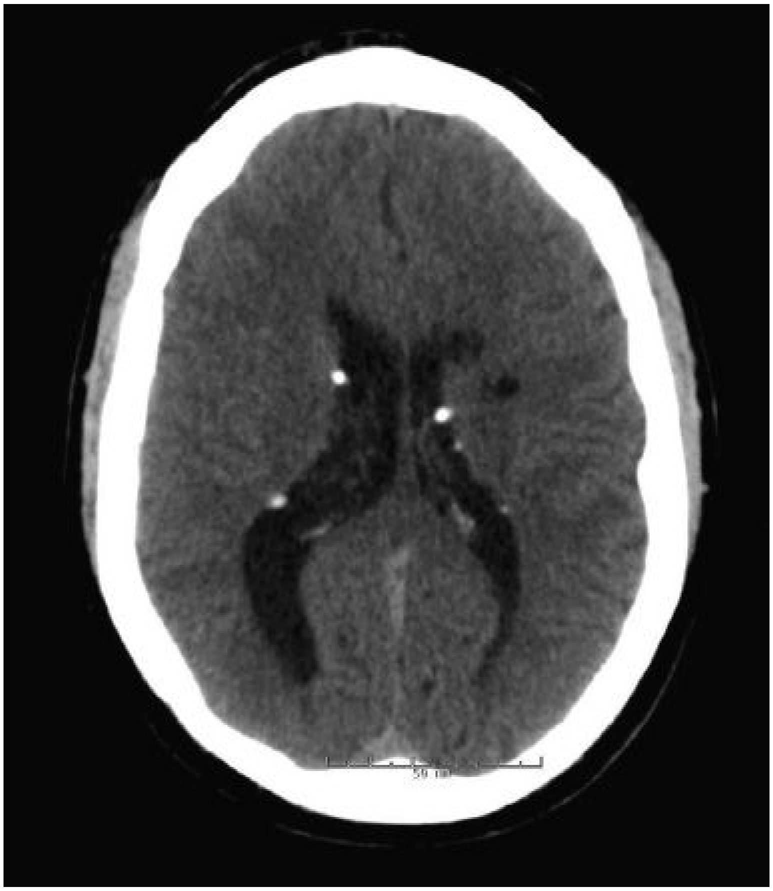

FIGURE 205-11 Bilateral subependymal calcified tubers on CT scan of a teenager with tuberous sclerosis. (*Used with permission from Elumalai Appachi, MD.*)

  - Patients with numerous cortical tubers tend to have more cognitive impairment and more difficulty with seizure control.
  - Subependymal giant cell astrocytomas develop in about 5 percent of patients and may lead to obstructive hydrocephalus.

- Renal manifestations:

  - Renal complications are the second most common cause of mortality.
  - The most common renal lesion is an angiomyolipoma, which occurs in approximately 75 to 80 percent of affected children and is usually present in older children and adults. These are benign vascular, smooth muscle, and adipose tissue tumors. The lesions are often multiple and bilateral, and increase in size and number with age.[6]
  - Renal cysts are the second most frequent renal manifestation (**Figure 205-12**). Cysts greater than 4 cm in diameter are more likely to be symptomatic. Presenting features may include flank pain, gross hematuria, or a tender mass.

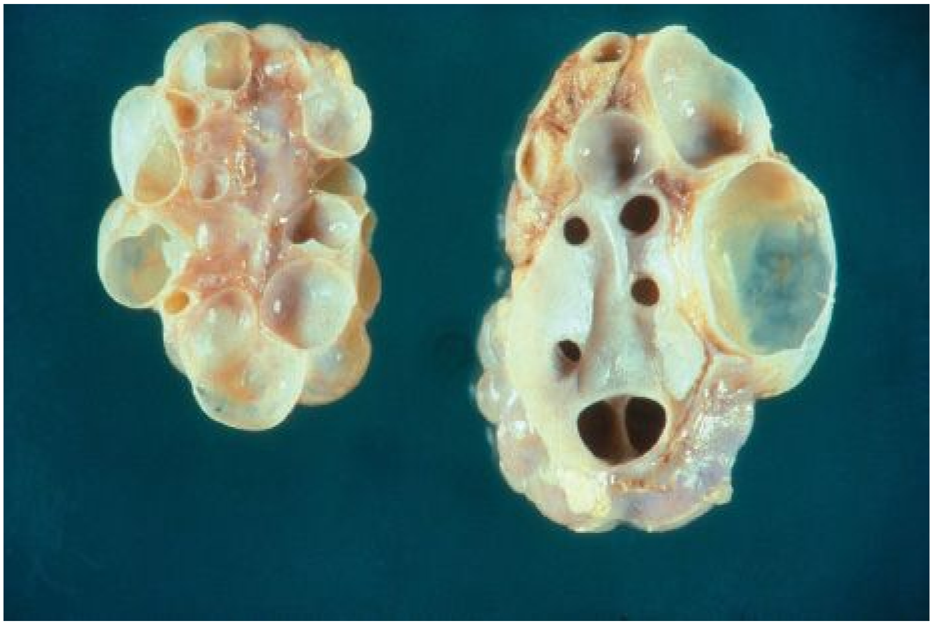

FIGURE 205-12 Multiple renal cysts found in both kidneys at autopsy from a teenager who succumbed to the complications of tuberous sclerosis. (*Used with permission from Elumalai Appachi, MD*.)

- Cardiac manifestations:
  - Cardiac rhabdomyomas are usually asymptomatic but can result in outflow obstruction, valvular dysfunction, arrhythmias (especially Wolff-Parkinson-White syndrome), and cerebral thromboembolism.
  - The most common presentation of cardiac dysfunction is heart failure soon after birth. The lesions often regress over the first few years of life.

- Ophthalmologic manifestations:
  - Retinal hamartomas occur in 40 to 50 percent of patients with TSC and are bilateral in a third of cases. While these are mostly asymptomatic, visual impairment as a result of a large macular lesion do occur in some patients.
- Respiratory manifestations:
  - Pulmonary involvement, as lymphangioleiomyomatosis, occurs in only approximately 1 percent of patients with TSC. This can manifest as spontaneous pneumothorax and progressive lung disease seen mainly in adult females.

DIAGNOSTIC CRITERIA

The diagnostic criteria for TSC are based upon specific clinical features.[7]

- Major clinical features of TSC:
  - Facial angiofibromas or forehead plaques (**Figures 205-4** to **205-6**).
  - Shagreen patch (connective tissue nevus; **Figure 205-7**).
  - Three or more hypomelanotic macules (**Figures 205-1** to **205-3**).
  - Nontraumatic ungual or periungual fibromas (**Figures 205-8** to **205-10**).
  - Lymphangioleiomyomatosis (also known as lymphangiomyomatosis).
  - Renal angiomyolipoma.
  - Cardiac rhabdomyoma.
  - Multiple retinal nodular hamartomas.
  - Glioneuronal hamartomas (i.e., cortical tubers).
  - Subependymal nodules (**Figure 205-11**).
  - Subependymal giant cell astrocytoma.
- Minor clinical features of TSC:
  - Confetti skin lesions (multiple 1 to 2 mm hypomelanotic macules).
  - Gingival fibromas.
  - Multiple randomly-distributed pits in dental enamel.
  - Hamartomatous rectal polyps.
  - Multiple renal cysts (**Figure 205-12**).

  - Nonrenal hamartomas.
  - Bone cysts.
  - Retinal achromic patch.
  - Cerebral white matter radial migration lines.
- According to these criteria, the diagnostic certainty of TSC for any individual depends upon the number of major and minor features:
  - *Definite*—TSC requires two major features (excluding women with only renal angiomyolipoma and pulmonary lymphangioleiomyomatosis) or one major and two minor features.
  - *Probable*—TSC requires one major plus one minor feature.
  - *Suspected*—TSC requires one major feature only, or two or more minor features but no major features.

LABORATORY TESTING

- Molecular genetic testing for disease-causing mutations in the TSC1 and TSC2 genes is clinically available.
- A positive test for a TSC1 or TSC2 mutation is most helpful in confirming the diagnosis in any individual with probable or possible TSC who does not meet the criteria for definite TSC by clinical evaluation.

IMAGING

- Calcification is frequently seen in subependymal nodules and giant cell astrocytomas and is best detected on a CT scan (**Figure 205-11**).
- MRI is more sensitive for the detection of cortical and subcortical tubers, areas of heteropia, and small subependymal nodules, especially when they not calcified.
- An electroencephalogram (EEG) should be performed if seizures are present.
- Cardiac echocardiogram and renal ultrasound should be done all the patients with TSC to identify abnormalities.

DIFFERENTIAL DIAGNOSIS

- TSC should be considered in any child with epilepsy and cognitive impairment. Clinical evaluation will usually reveal the diagnosis based on the diagnostic criteria previously outlined.
- Infants with Infantile Spasm (West Syndrome) should be evaluated for TSC.
- Periventricular calcifications can be associated with congenital CMV infection. These infants will not have the cutaneous manifestations noted in children with TSC, and may have other manifestations of congenital infection.
- Renal cysts of TSC can be confused with polycystic kidney disease. In these cases, the common presence of neurologic manifestations will point to the diagnosis of TSC.

MANAGEMENT

NONPHARMACOLOGIC

- Treatment should be supportive and organ specific, depending on the specific organ(s) involved and the spectrum of the manifestations.
- A multidisciplinary approach is highly recommended and should be aimed at improving the patient’s quality of life and outcome.
- Early intervention and special education is warranted when neurodevelopmental problems are evident.
- Control of seizures and cardiac dysrhythmias, when present, is paramount.

MEDICATIONS

- Seizures are managed with anticonvulsant medications. Specific recommendations depend on the specific seizure types.
- Vigabatrin has been shown to be effective for treating infantile spasms, and may help prevent more severe cases of cognitive dysfunction.[8] SOR Ⓑ
- Lamotrigine is effective in the treatment of generalized seizures.[9]

SURGICAL

- Neurosurgical intervention should be considered for intractable seizures, increased intracranial pressure, and giant cell astrocytomas. SOR Ⓒ
- Facial angiofibromas are potentially embarrassing cosmetic stigmata of TSC and can be treated with dermabrasion or laser surgery. SOR Ⓒ

REFERRAL

- A multidisciplinary approach to care is warranted; thus, consultations with a dermatologist, neurologist, nephrologist, cardiologist, and ophthalmologist should be strongly considered for patients who are diagnosed or suspected of having TSC.

PREVENTION AND SCREENING

- When a specific TSC mutation is identified, the family may elect to use preimplantation genetic diagnosis. This involves single cell analysis after biopsy of an embryo obtained through in vitro fertilization and subsequent implantation of embryos at low risk of carrying the mutation.
- Prenatal testing for TSC1 or TSC2 mutations of specimens obtained during pregnancy through either chorionic villus sampling or amniocentesis is also available.[9]

- Preimplantation or prenatal genetic testing with DNA analysis can be performed in families in which a specific mutation in the TSC1 or TSC2 gene has been identified in an affected family member.[10]
- Parents should be aware that TSC exhibits wide clinical variability within families and that establishing the diagnosis prenatally cannot predict the severity or outcome.
- When either parent is affected, fetal echocardiography should be performed in pregnancy. Echocardiography should be repeated in the neonatal period because it provides a better assessment than fetal echocardiography. An electrocardiogram should be performed to look for arrhythmias.
- When the diagnosis is made in a child with no family history of the disorder, both parents should be evaluated. This evaluation should include:
    - A thorough examination of the skin (in normal light and a Wood’s lamp exam).
    - Ophthalmic examination.
    - Cranial CT or MRI.
    - Renal ultrasound.
- The importance of determining whether a parent is affected lies in providing appropriate follow-up for the parent, that is, screening for renal disease, and in providing an appropriate risk estimate of having a subsequent child with TSC.

PROGNOSIS

- Life expectancy historically was reduced mainly because of intercurrent infection, uncontrolled seizures, or other complications. Diagnostic imaging and treatment has improved both the quality of life and life expectancy of patients with TSC.

FOLLOW-UP

- Close follow-up by a multidisciplinary team, based on the manifestations of the condition and the organ systems involved is important.
- Ongoing screening for central nervous system, renal, and pulmonary tumors is recommended.

206 NEUROFIBROMATOSIS

Heidi Chumley, MD

PATIENT STORY

A 12-year-old asymptomatic girl was noted to have six café-au-lait macules (**Figure 206-1A**) and axillary freckles (**Figure 206-1B**) during a general physical examination. No neurofibromas were noted at the time. Although neither parent had neurofibromatosis, that diagnosis was entertained. She was referred to an ophthalmologist and monitored closely for scoliosis. In time, she began to develop neurofibromas and was eventually diagnosed with sporadic neurofibromatosis type 1 (NF-1).

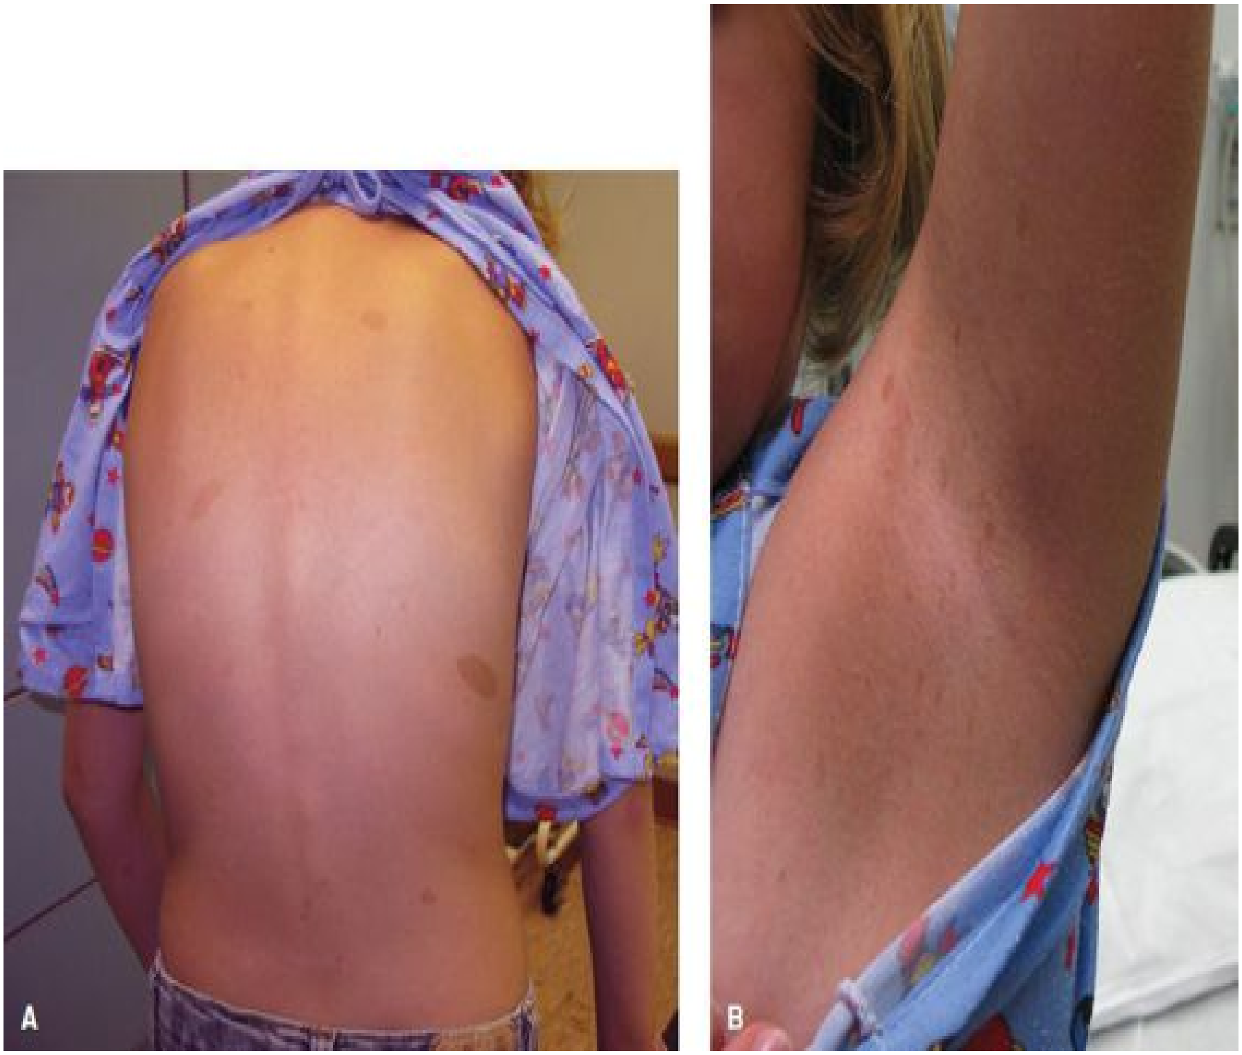

FIGURE 206-1 A. A 12-year-old girl presenting with over six café-au-lait macules (0.5 cm or larger) and **B**. axillary freckling (Crow sign). She does not have any neurofibromas visible but does meet criteria for neurofibromatosis. (*Used with permission from Emily Scott, MD*.)

INTRODUCTION

NF-1 is a common autosomal dominant disorder that predisposes to tumor formation. Café-au-lait spots are often the first clinical sign. Other clinical signs include neurofibromas, axillary or inguinal freckling, optic gliomas, Lisch nodules, and sphenoid bone dysplasia. Treatment at present is early recognition and monitoring for complications such as cognitive dysfunction, scoliosis or other orthopedic problems, tumor pressure on vital structures, or malignant transformation.

SYNONYMS

Café-au-lait spots and café-au-lait macules are synonyms.

EPIDEMIOLOGY

- NF-1 is relatively common—Birth incidence is 1 in 3000 and prevalence in the general population is 1 in 5000.[1]
- Autosomal-dominant inheritance; however, up to 50 percent of cases are sporadic.[1]
- Diagnosis is typically made during childhood.

ETIOLOGY AND PATHOPHYSIOLOGY

- Mutations in the NF-1 gene (on the long arm of chromosome 17) result in loss of function of neurofibromin, which helps keep protooncogene ras (which increases tumorigenesis) in an inactive form.
- Loss of neurofibromin results in increased protooncogene ras activity in neurocutaneous tissues, leading to tumorigenesis.[1]

RISK FACTORS

A first-degree relative with NF-1.

DIAGNOSIS

For a diagnosis of NF-1, patients need to have at least 2 of the following:[2]

- Two or more neurofibromas (**Figures 206-2** and **206-3**) or one or more plexiform neurofibromas (**Figures 206-4** and **206-5**).

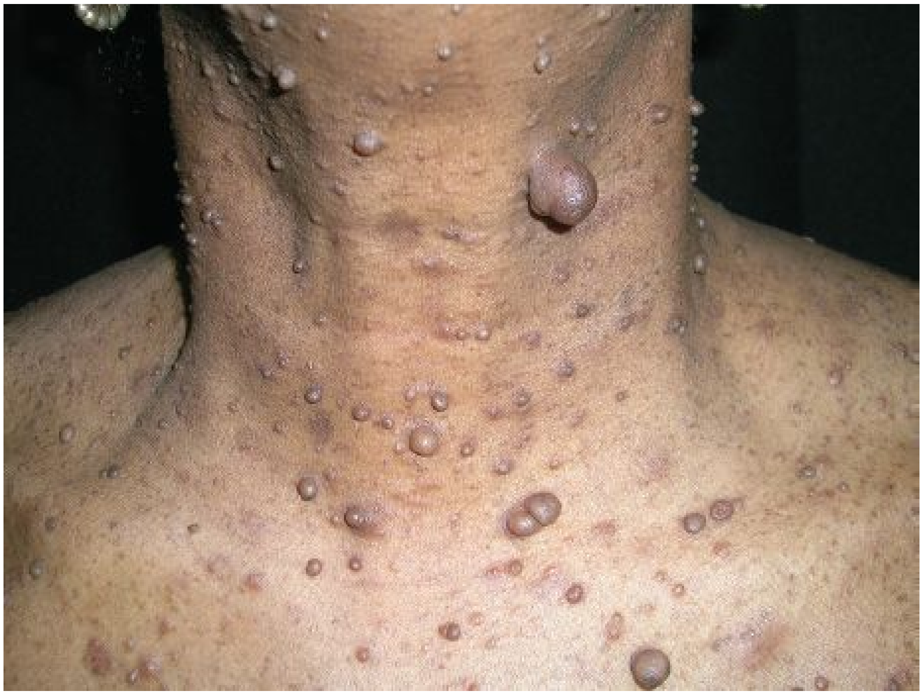

FIGURE 206-2 Close-up of neurofibromas on the neck and upper chest. These are soft and round. (*Used with permission from Richard P. Usatine, MD*.)

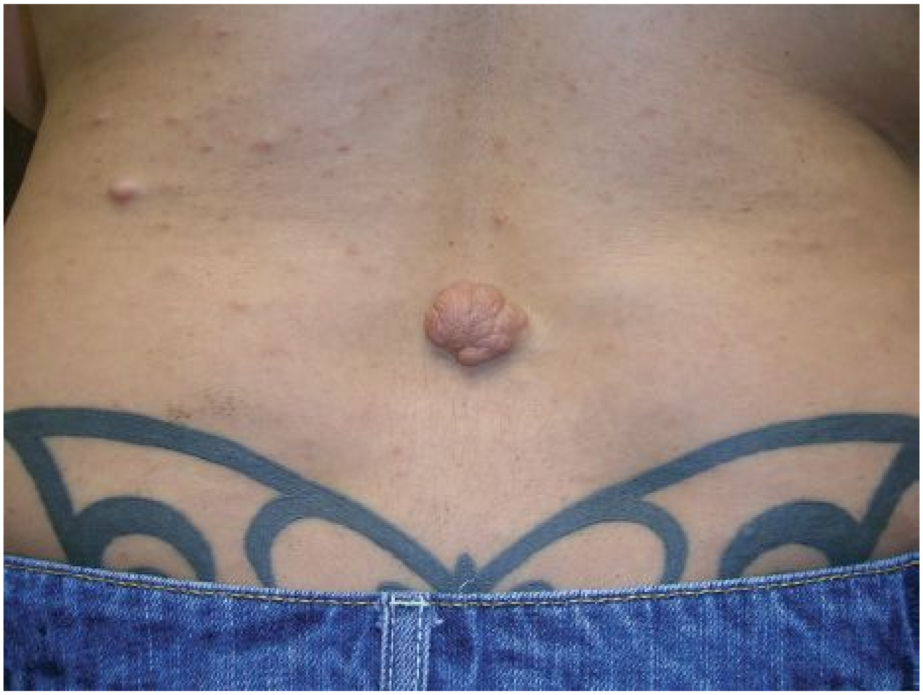

FIGURE 206-3 Large neurofibroma on the back of his teenage patient with neurofibromatosis. (*Used with permission from Richard P. Usatine, MD*.)

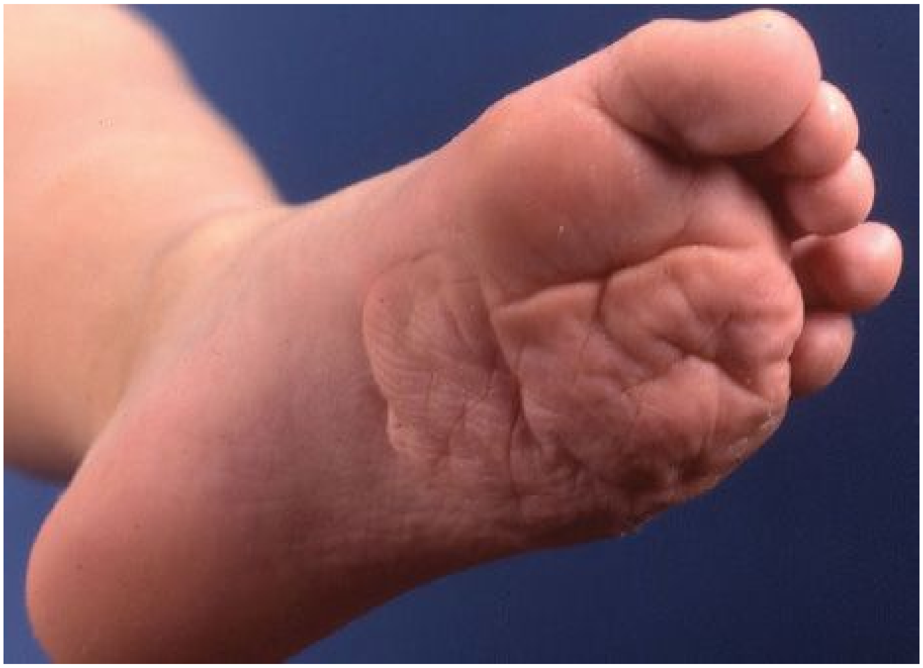

FIGURE 206-4 Neurofibromatosis (NF-1) in a child with a plexiform neuroma on the sole of the foot. This subcutaneous mass is soft and

asymptomatic. The child also has café-au-lait macules and multiple neurofibromas. (*Used with permission from Fitzpatrick dermatology Atlas*.)

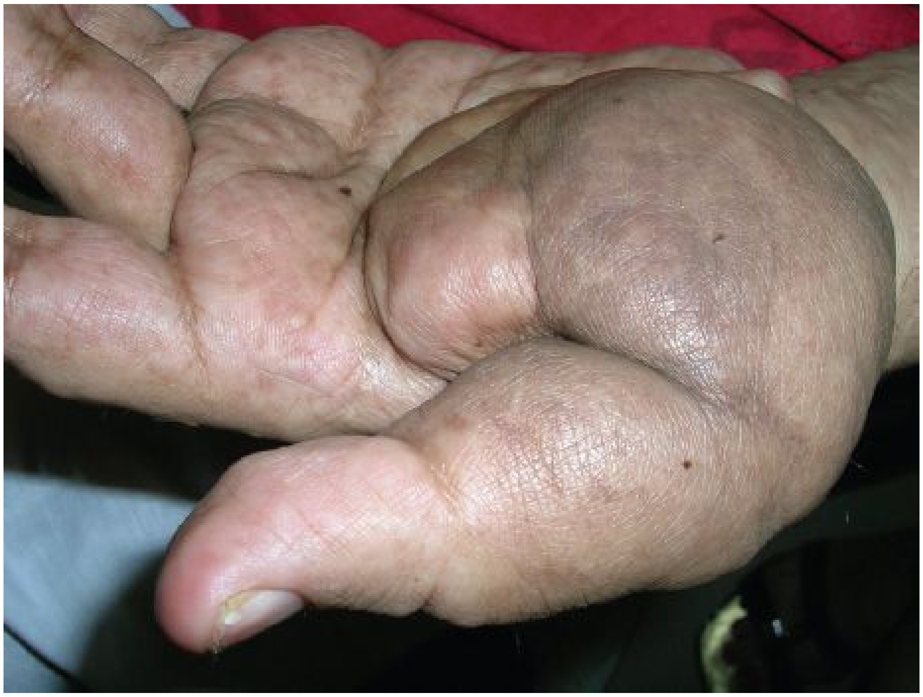

FIGURE 206-5 Plexiform neurofibroma on the thenar eminence feels like a bag of worms in this patient with neurofibromatosis. This is a benign tumor of the peripheral nerve sheath and is most often asymptomatic. (*Used with permission from Richard P. Usatine, MD*.)

- Six or more café-au-lait spots, 0.5 cm, or larger before puberty and 1.5 cm or larger after puberty (**Figures 206-6** to **206-9**).

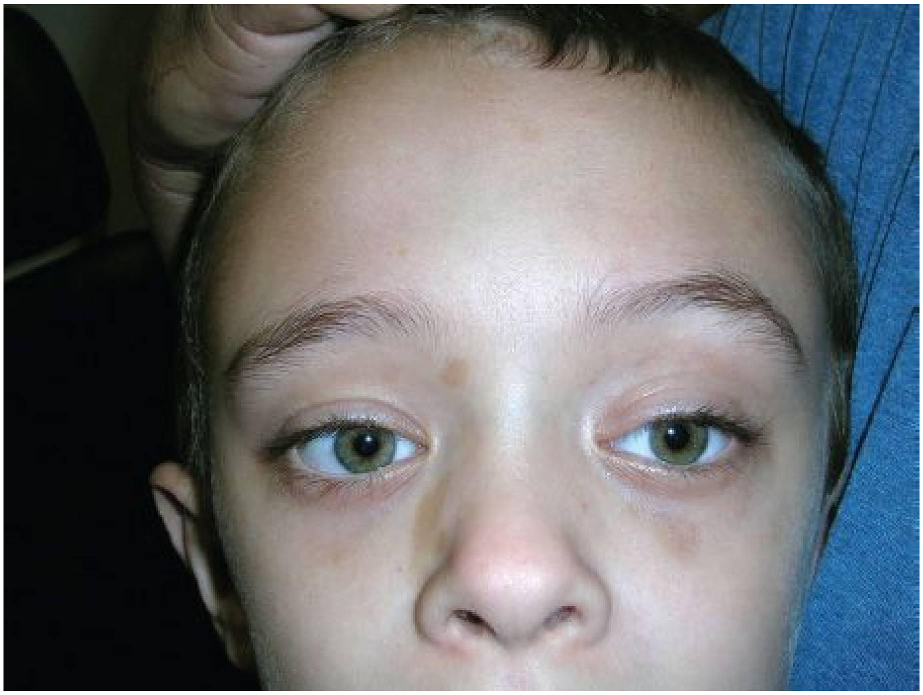

FIGURE 206-6 Neurofibromatosis in a 7-year-old boy with café-au-lait macules on the face. (*Used with permission from Richard P. Usatine, MD.*)

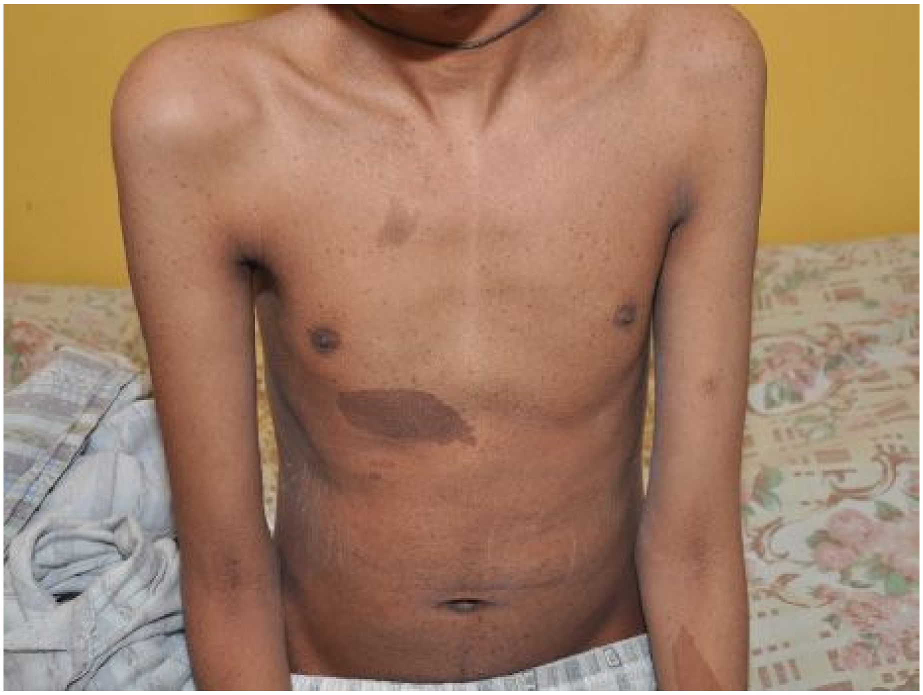

FIGURE 206-7 Neurofibromatosis with visible café-au-lait macule in a boy with leprosy in Africa. (*Used with permission from Richard P. Usatine, MD.*)

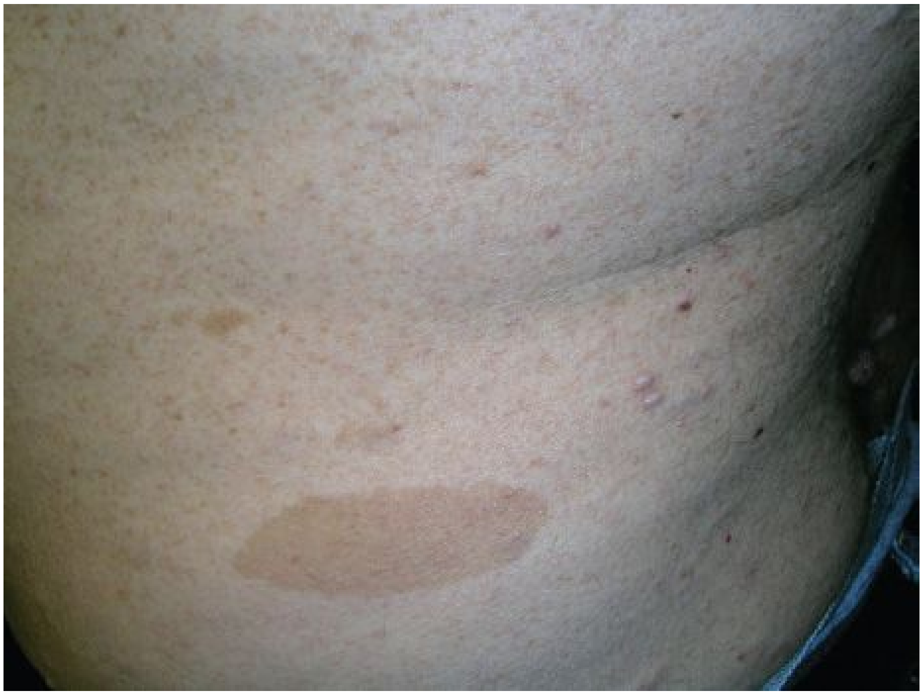

FIGURE 206-8 Neurofibromatosis with visible café-au-lait macule and small neurofibromas on the trunk. (*Used with permission from Richard P. Usatine, MD*.)

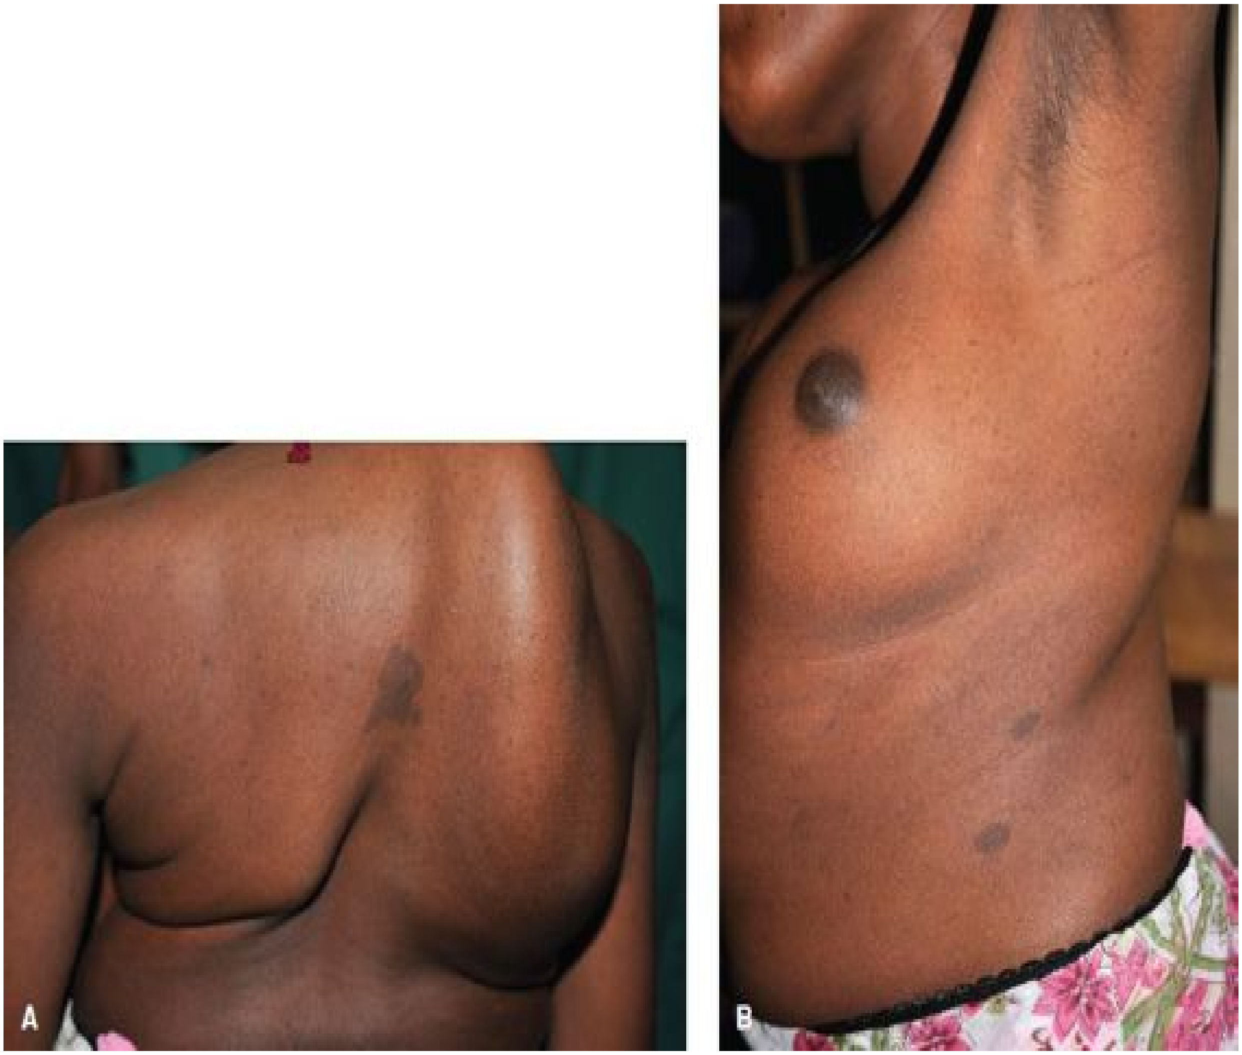

FIGURE 206-9 A. Neurofibromatosis in a teenage girl with severe scoliosis and a visible café-au-lait macule on the back. B. Axillary freckling (Crow sign) in the same teen with neurofibromatosis and scoliosis. (*Used with permission from Richard P. Usatine, MD*.)

- Axillary or inguinal freckling (**Figures 206-1** and **206-9**).
- Optic glioma.
- Two or more Lisch nodules (melanotic iris hamartomas; **Figure 206-10**).

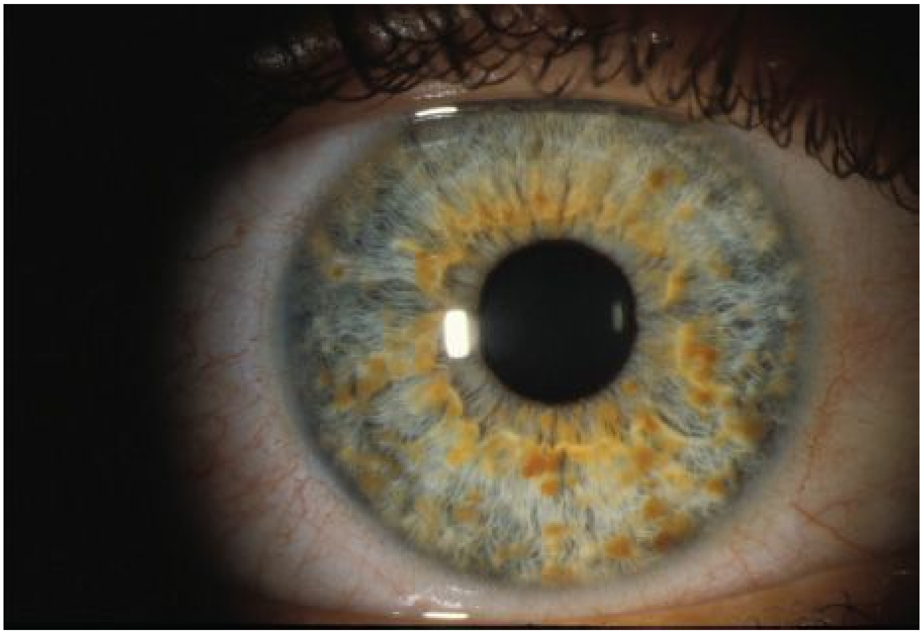

FIGURE 206-10 Lisch nodules (melanotic hamartomas of the iris) are clear yellow-to-brown, dome-shaped elevations that project from the surface of this blue iris. These hamartomas are the most common type of ocular involvement in neurofibromatosis type 1 and do not affect vision. (*Used with permission from Paul Comeau*.)

- Dysplasia of the sphenoid bone or dysplasia/thinning of long bone cortex.
- A first-degree relative with NF-1.

CLINICAL FEATURES

▸ History and physical

- Ninety-five percent have café-au-lait macules, mostly before the age of 1 year.
- Ninety percent have axillary or inguinal freckling (**Figures 206-1** and **206-9**).
- Eighty-one percent have cognitive dysfunction manifest as learning disorder, attention deficit hyperactivity disorder, or mild cognitive impairment.[3]
- Nerve sheath, intracranial, or spinal tumors.

- Cutaneous or subcutaneous neurofibromas (**Figures 206-2** to **206-3**).
- Other bony pathology, including dysplasia of the sphenoid or long bones, scoliosis, or short stature (**Figure 206-9**).
- Eye abnormalities, including Lisch nodules or early glaucoma (**Figure 206-10**).

LABORATORY TESTING

- Genetic testing for parents considering having other children.

IMAGING

- Although not typically used for diagnosis, imaging may be needed if tumor compression of vital structures is suspected.

DIFFERENTIAL DIAGNOSIS

NF-1 is the predominant cause of café-au-lait spots, which can also be seen in the following cases:

- Normal childhood—Thirteen percent to 27 percent of children younger than 10 years of age have at least 1 spot.
- Neurofibromatosis type 2 (NF-2)—Vestibular schwannomas, family history of NF-2, meningioma, glioma, schwannoma, juvenile posterior subcapsular lenticular opacities, or juvenile cortical cataracts.
- Tuberous sclerosis—Angiofibromas (skin-colored telangiectatic papules most commonly in the nasolabial folds, cheek, or chin; and hypopigmented ovoid or ash leaf-shaped macules (see Chapter 205, Tuberous Sclerosis).
- McCune-Albright syndrome—Fibrous dysplasia of bone and endocrine gland hyperactivity.

- Fanconi anemia—Decreased production of all blood cells, short stature, upper limb anomalies, genital changes, skeletal anomalies, eye/eyelid anomalies, kidney malformations, ear anomalies/deafness, and GI/cardiopulmonary malformations.
- Segmental NF—Cutaneous neurofibromas limited to specific dermatome(s); very rare.
- Bloom syndrome—Growth delay and short stature, increased risk of cancer, telangiectatic erythema on the face, cheilitis, narrow face, prominent nose, large ears, and long limbs.
- Ataxia telangiectasia—Progressive neurologic impairment, cerebellar ataxia, immunodeficiency, impaired organ maturation, ocular and cutaneous telangiectasia, and a predisposition to malignancy.
- Proteus syndrome—Very rare condition with hamartomatous and multisystem involvement. Joseph Merrick (also known as “the elephant man”) is now, in retrospect, thought by clinical experts to have had Proteus syndrome and not NF.

MANAGEMENT

Management focuses on early recognition and treatment of manifestations.

- Evaluate children twice a year. SOR C
- Screen for cognitive impairment and refer early for intervention. SOR C
- Screen for scoliosis and treat accordingly.
- Refer patients annually for ophthalmologic evaluation.
- Consider treatment or referral for treatment of café-au-lait spots if desired by the patient. Topical vitamin D_3 analogs (calcipotriene [Dovonex]) and laser therapy independently may improve the appearance of café-au-lait spots.[4,5] SOR B One small study suggests that intense pulsed light–radio frequency (IPL-RF) in combination with topical application of vitamin D_3 ointment may lighten small-pigmented lesions in patients with NF-1.[6]

SOR B Although calcipotriene is approved for use in psoriasis, it can be prescribed off-label to patients disturbed by their hyperpigmented macules.[4,6] SOR B

- Examine other undiagnosed first-degree relatives. SOR C
- Surgical excision of tumors is required for tumors pressing on vital structures (i.e., spinal cord impingement, and optic glioma) or when characteristics such as rapid enlargement are worrisome for malignant transformation.

PROGNOSIS

- Clinical manifestations are variable leading to difficulty in prognosis.
- There is a 10 percent lifetime risk of developing a malignant peripheral nerve sheath tumor.

FOLLOW-UP

- Primary care evaluation biannually for children, including monitoring of blood pressure.
- Ophthalmologic examination annually for children for early detection of optic gliomas and glaucoma. Neurofibromas and plexiform neuromas can occur on the eyelids. Neurofibromas on the eyelids usually are not a problem (**Figure 206-10**) but a plexiform neuroma can present with ptosis and need surgical intervention.
- Genetic counseling for parents of a child with NF-1 considering having other children.

207 STURGE-WEBER SYNDROME

Swathi Appachi, BS
Elumalai Appachi, MD, MRCP

PATIENT STORY

A 3-year-old girl is referred to a pediatric neurologist because of a history of developmental delay and focal seizures since birth that are no longer being well controlled with two antiseizure medications. On physical exam, the neurologist notes a large bilateral port-wine stain on the face (**Figure 207-1**). The neurologist suspects that the child has Sturge-Weber syndrome and orders brain imaging and an ophthalmologic exam. The MRI reveals leptomeningeal angiomas and the ophthalmologist diagnoses glaucoma. The diagnosis of Sturge-Weber syndrome is confirmed and education is provided to the parents on this condition. The child's anti-epileptic medications are maximized and her glaucoma is treated by the ophthalmologist.

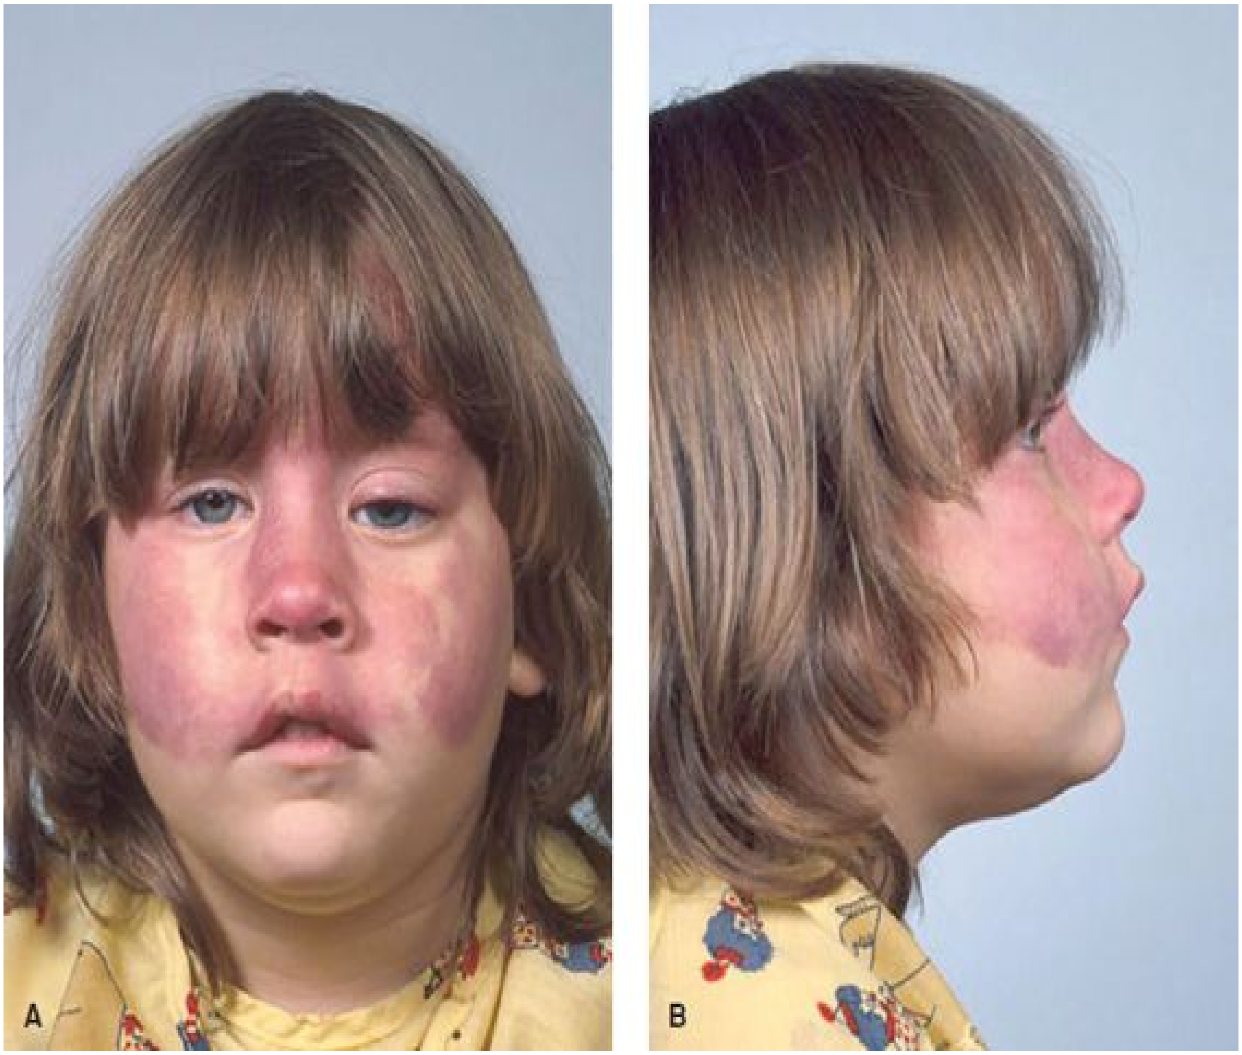

FIGURE 207-1 Port-wine stain on frontal (**A**) and right lateral (**B**) views in a young girl with Sturge-Weber syndrome. Although bilateral involvement is not common, it is associated with intracranial findings such as leptomeningeal angiomas. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

INTRODUCTION

Sturge-Weber syndrome (SWS) is a sporadic congenital neurocutaneous syndrome that is characterized by facial capillary malformation known as a port-wine stain, ocular abnormalities including glaucoma and choroidal hemangioma, and leptomeningeal angiomas. Seizures, developmental delay and glaucoma comprise the major clinical features. SWS is associated with mutations in the GNAQ gene.

SYNONYMS

Encephalotrigeminal angiomatosis and encephalofacial angiomatosis. Port-wine stains are also called nevus flammeus.

EPIDEMIOLOGY

- SWS occur sporadically at a rate of 1 per 20,000 to 50,000 newborns and in equal frequency in both genders.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- SWS is caused by somatic activating mutations in GNAQ gene, as confirmed by a whole-genome sequencing study that examined skin and brain tissue samples.[1]
- GNAQ encodes for G-alpha-q, a G-protein alpha subunit that acts as a mediator between G-protein coupled receptors and downstream signaling molecules.
- In fetal ectodermal tissue, this mutation is thought to cause inappropriate maturation of capillaries, thus leading to capillary malformations.[1] The port-wine stain is due to a dilation of capillaries and venous blood vessels in the dermis rather than a proliferation of the capillaries.[2]

DIAGNOSIS

CLINICAL FEATURES

- Physical manifestations of SWS can be divided into cutaneous, ocular, and neurologic. The diagnosis is usually made based on the presence of the facial capillary malformations and leptomeningeal angiomas.[2]
- Cutaneous:
  - The most obvious sign of SWS is the facial capillary malformation, known as a port-wine stain, due to its color (**Figures 207-1** to **207-3**).

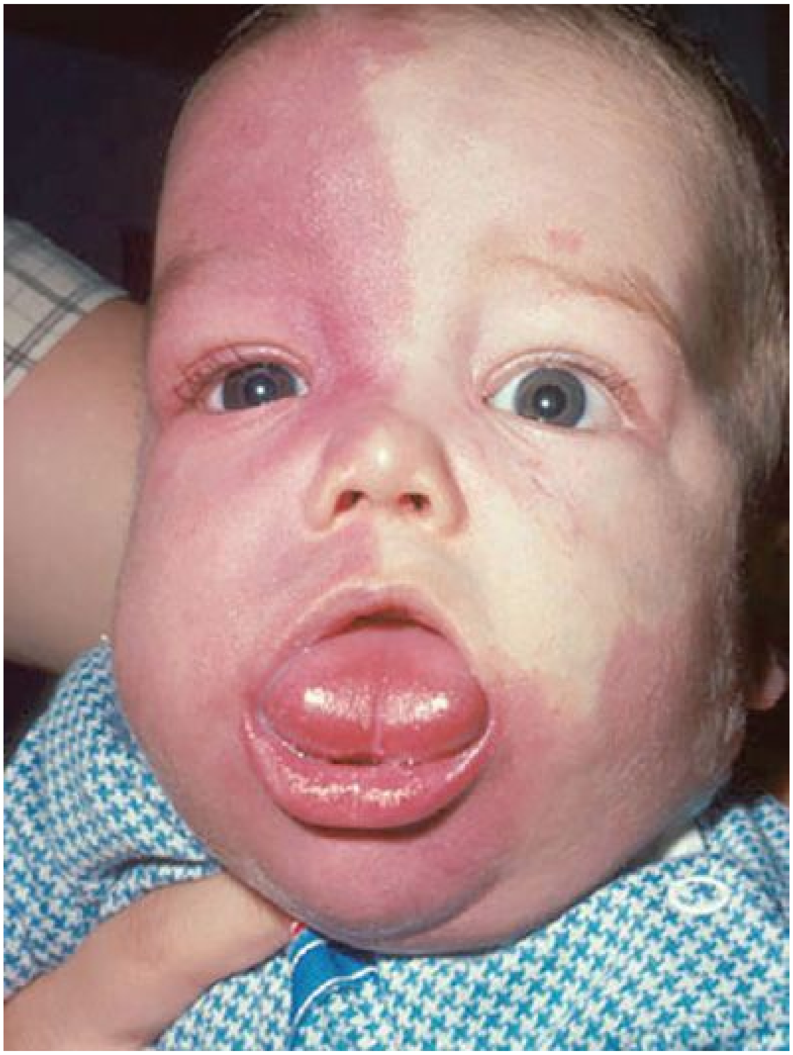

FIGURE 207-2 Port-wine stain in a young infant with seizures and developmental delay due to Sturge-Weber syndrome. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

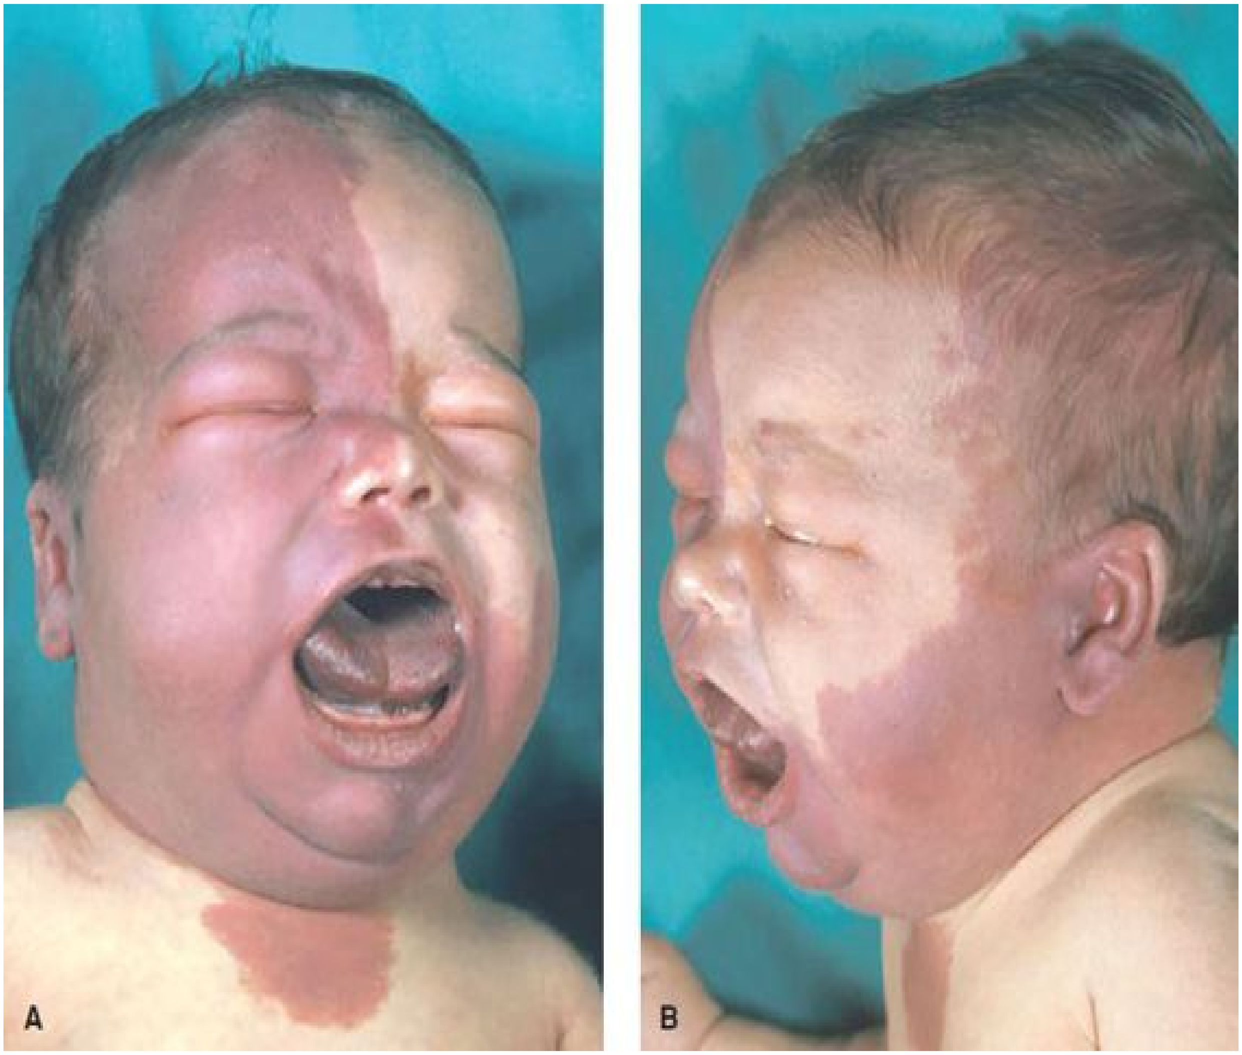

FIGURE 207-3 Bilateral port-wine stain on frontal (**A**) and lateral (**B**) views in a young child with Sturge-Weber syndrome. This is the same child as seen in **Figure 207-2** at an older age. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

  - Note that a capillary malformation is not the same as a cutaneous hemangioma even though these are often confused as the same entity. While there are ocular and CNS angiomas present in SWS, the port-wine stain is not a hemangioma.

  - It normally involves at least the distribution of the ophthalmic branch of the trigeminal nerve, overlying the forehead and the upper eyelid.
  - Although it usually does not cross the midline, those with bilateral port-wine stains are more likely to have cerebral involvement.[2,3]

- Neurological:
  - Leptomeningeal capillary-venous malformations, or angiomas can occur in children with SWS, usually ipsilaterally to the port-wine stain in the parietal or occipital areas (**Figure 207-4**). Underlying brain parenchyma may be atrophic and calcified.[2]

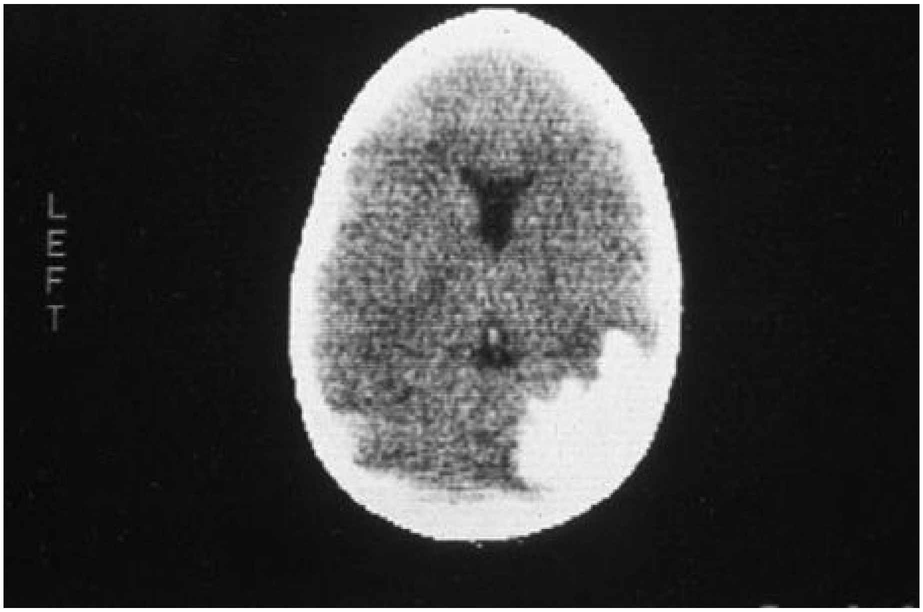

FIGURE 207-4 Leptomeningeal angioma on CT scan in a child with a port-wine stain, seizures, and developmental delay. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

  - Seizures are the usual presenting neurologic manifestation of this syndrome and can occur in 23 to 83 percent of patients. They can occur at any age but often manifest before 2 years of age. Seizures are typically focal motor seizures, but secondary generalization can occur. Infantile spasms are less common but can also occur. Seizures often present initially during a febrile episode. They can be more severe in patients with bilateral leptomeningeal angiomas.[2]
  - Developmental delay is present in approximately half of these patients. Degree of handicap is usually correlated with younger age at onset of

  seizures.
  - Recurrent headaches are also common in these patients.
  - Stroke-like episodes can occur, with hemiparesis or visual field defects.
- Ocular:
  - Glaucoma, the most common ocular manifestation of SWS, develops in 30 to 70 percent of patients with SWS in some studies, and is usually ipsilateral to the port-wine stain. It can occur early in childhood and has an insidious onset. For this reason, any newborn or child presenting with a port-wine stain in the V1 distribution of the trigeminal nerve should be referred for a complete ophthalmologic exam.[2]
  - Choroidal hemangioma occurs in many patients with SWS and is also usually ipsilateral to the port-wine stain (**Figure 207-5**). Over time, these lesions can cause retinal pigment epithelium degeneration, fibrous metaplasia, or cystic retinal degeneration, leading to vision loss. The presence of a choroid hemangioma almost always indicates presence of leptomeningeal hemangiomas.[2]

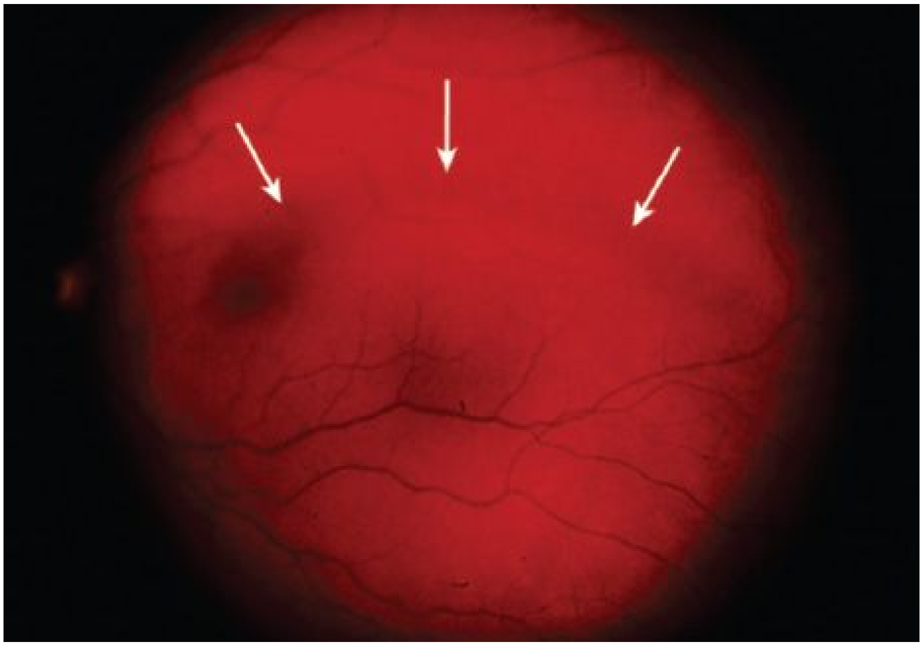

FIGURE 207-5 Choriodal hemangioma in a patient with Sturge-Weber syndrome. The arrows point to the superior border of the hemangioma. The posterior retina, including the fovea, is elevated. (*Used with permission from Lueder GT. Pediatric Practice Ophthalmology: Figure 32-19, and www.accesspediatrics.com*.)

IMAGING

- In addition to an ophthalmologic exam, any infant with a port-wine stain in the V1 distribution should have neuroimaging, specifically a brain MRI with gadolinium contrast.
  - If neonatal imaging is negative, repeat scans at 1 or 2 years of life or with onset of symptoms such as seizure or glaucoma.[4]
- Intracranial calcifications (Railroad or tramline calcifications) may be found on plain film or on CT scan (**Figure 207-6**). These represent calcification of the cortex.

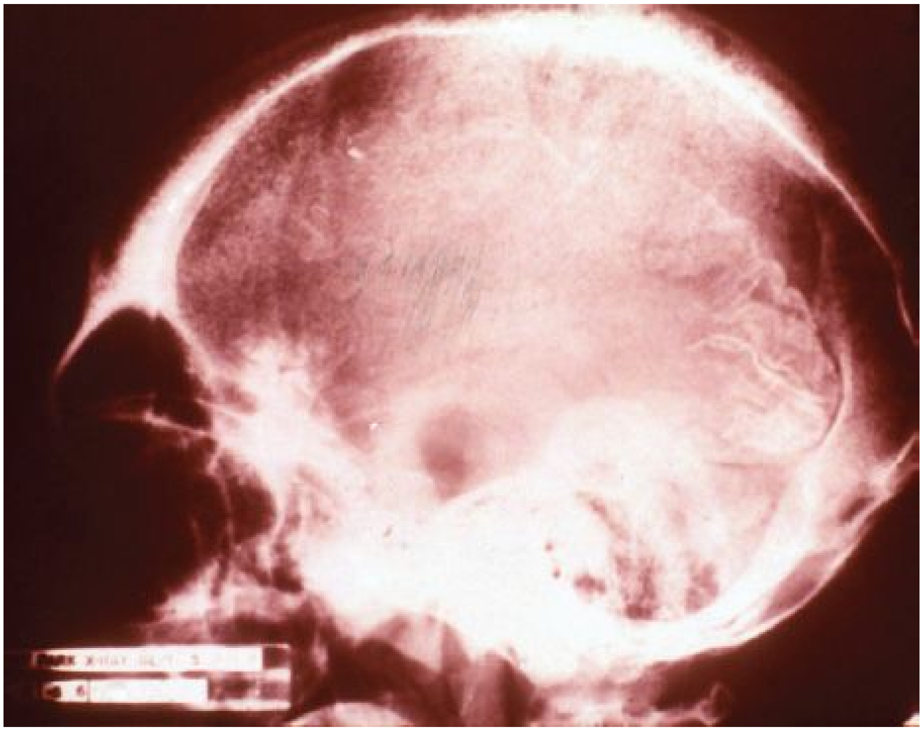

FIGURE 207-6 Intracranial calcifications on skull x-ray in a patient with Sturge-Weber syndrome. Note the tram track or railroad track pattern, signifying atrophic and calcified brain parenchyma, which is characteristic of this syndrome. (*Used with permission from Elumalai Appachi, MD*.)

- Leptomeningeal angiomas are common and cause seizures (**Figure 207-4**).

DIFFERENTIAL DIAGNOSIS

- The presence of a port-wine stain is not enough to diagnose SWS as only 8 to 20 percent of patients with this lesion have manifestations of neurological symptoms. Many children with facial port-wine stains do not have SWS (**Figures 207-7** and **207-8**).

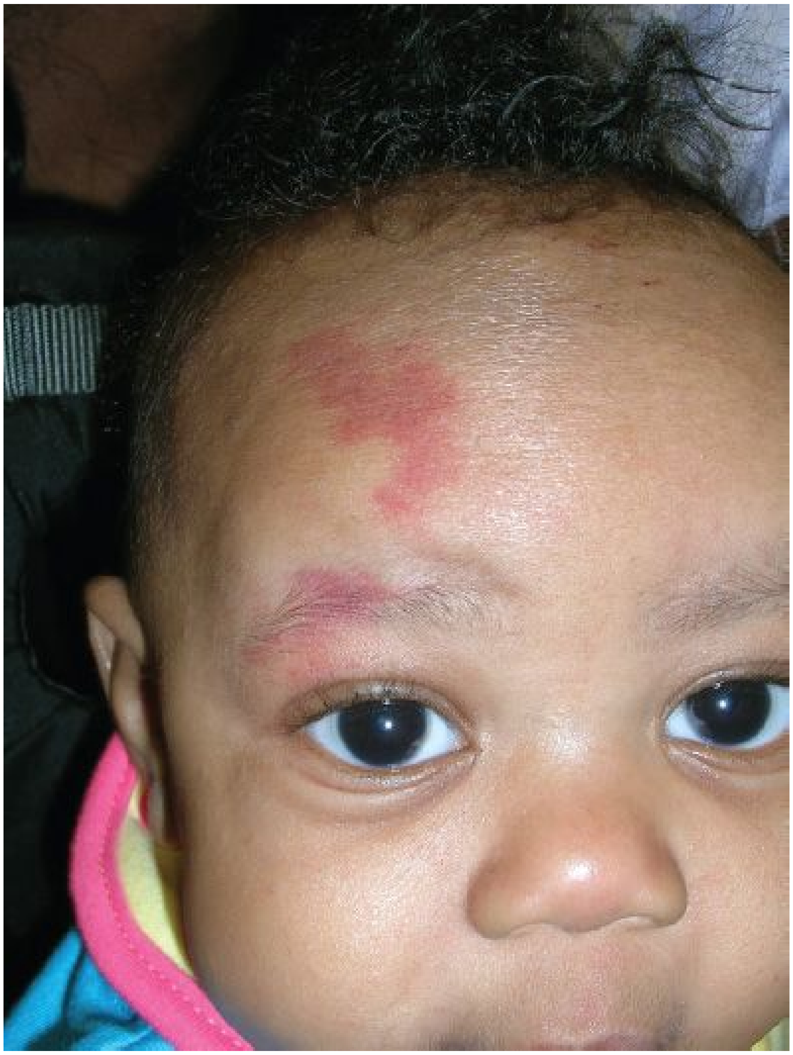

FIGURE 207-7 Port-wine stain in the V1 distribution in an infant without Sturge-Weber syndrome. The child has had no seizures and was developing normally. (*Used with permission from Richard P. Usatine MD*.)

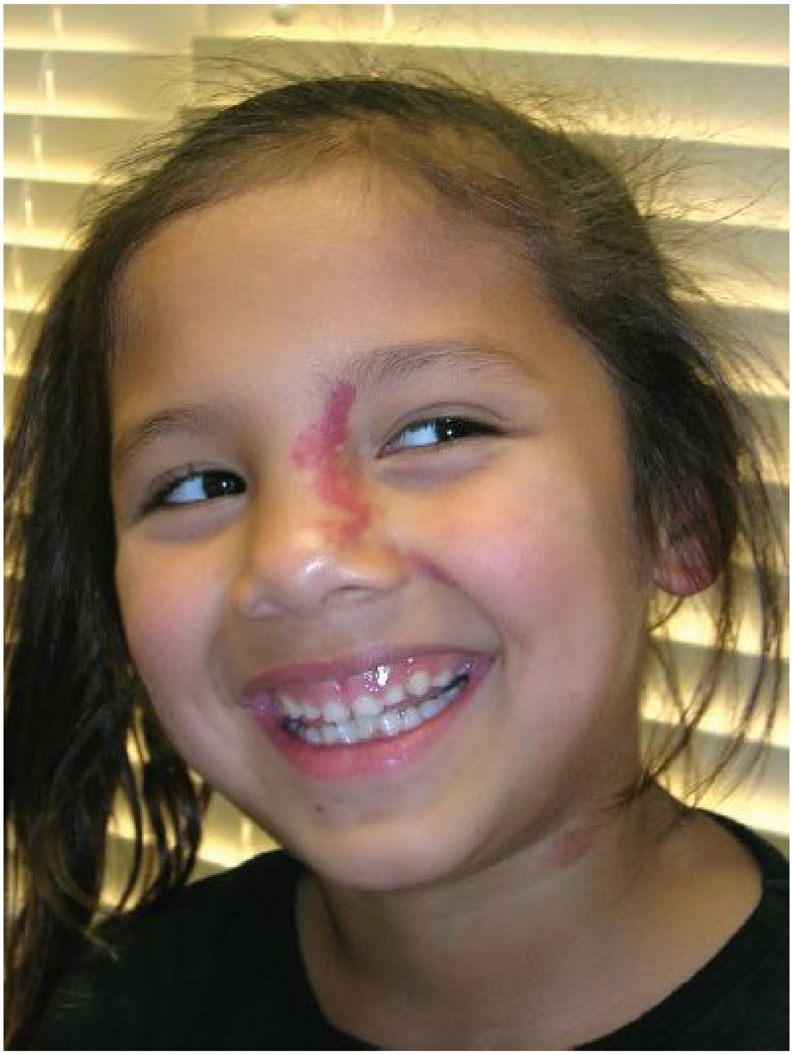

FIGURE 207-8 Port-wine stain on the face of a healthy young girl. She is doing well in school, has never had a seizure and has always had normal cognitive development. (*Used with permission from Richard P. Usatine MD*.)

- Facial hemangiomas that appear dermatomal are often confused with port-wine stains (**Figure 207-9**). Port-wine stains are usually flatter than hemangiomas and will not resolve over time as many hemangiomas do. Hemangiomas are benign vascular tumors that differ from capillary malformations (see Chapter 93, Childhood Hemangiomas and Vascular Malformations). Large facial hemangiomas may be seen with the PHACE syndrome (see Chapter 227, PHACE Syndrome).

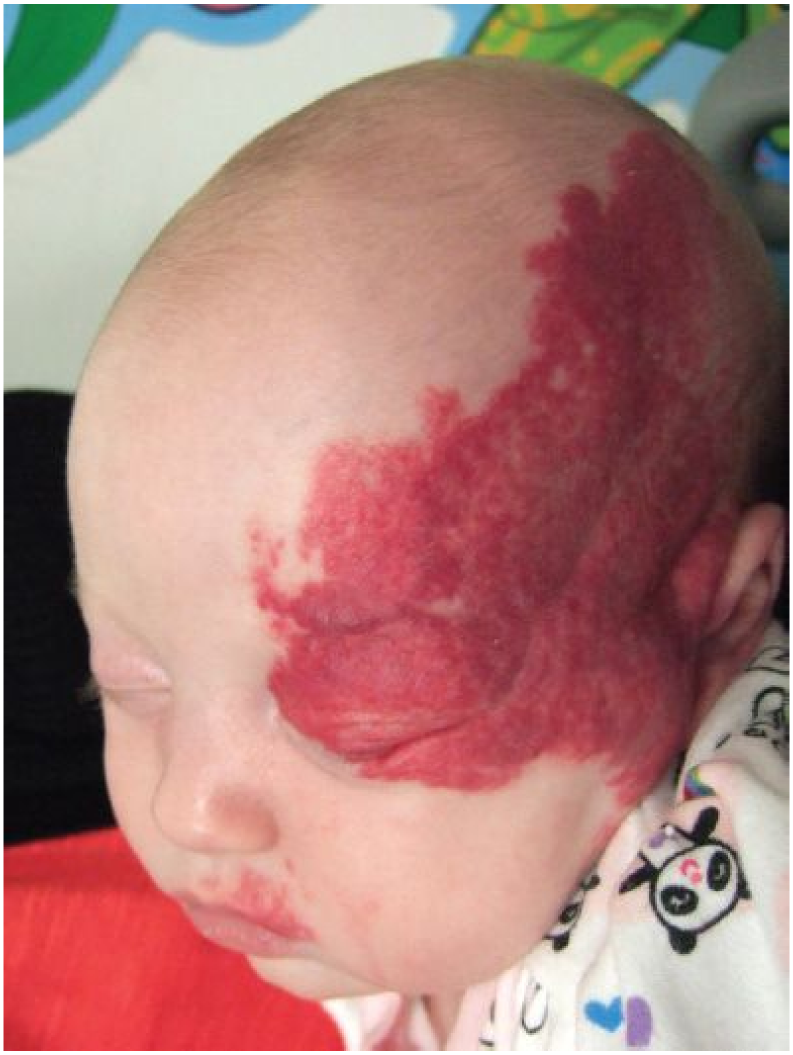

FIGURE 207-9 Large facial hemangioma in an infant without PHACE syndrome. Note that this is a hemangioma and not a port-wine stain. The hemangioma is not flat like a port-wine stain. This hemangioma resolved with propanolol and time. (*Used with permission from John Browning, MD*.)

- Patients with a port-wine stain, other extensive cutaneous capillary malformations, venous and lymphatic malformations, and limb hypertrophy have Klippel-Trenaunay syndrome.[3]

MANAGEMENT

- There is no cure for SWS. Management is aimed at controlling seizures and ocular manifestations such as glaucoma.

NONPHARMACOLOGIC

- A ketogenic diet has been shown in one study to be beneficial in stopping seizures refractory to pharmacological treatment.[3]

MEDICATIONS

- Managing epilepsy in patients with SWS is difficult and often requires more than one anti-epileptic drug (AED). However, management is crucial as increased seizure activity is thought to lead to neurocognitive deterioration.[3]
    - Patients should be aggressively started on an AED to prevent seizure activity from occurring and have an AED prescribed as abortive therapy.
    - If seizures are not controlled with a combination of 2 to 3 AEDs at their maximum doses, other routes of therapy, such as a ketogenic diet or surgery, should be considered.

SURGERY

- Surgery appears to be the treatment of choice for glaucoma in patients with SWS. Surgical treatments include cryocoagulation of the ciliary body, goniotomy, or trabeculotomy.[5,6]
- For refractory seizures, some small studies have shown that focal resection of the affected portion of the brain or hemispherectomy can achieve long-term seizure control. However, there is significant morbidity associated with these procedures, especially hemispherectomy (which is associated with hemiparesis and homonymous hemianopsia), and these should be discussed with the family.[3]
- The port-wine stain can be treated with pulsed dye laser.[2] This is a cosmetic procedure that is usually not covered by health insurance.

REFERRAL

- For any neonate with a port-wine stain, especially in the V1 distribution, an ophthalmologist should be consulted. Close monitoring of the child is necessary as onset of glaucoma can be insidious.[2]
- Similarly, in these children, a neurologist or epileptologist should be consulted for neuroimaging recommendations and possible management of seizures, especially if leptomeningeal angiomas are seen on imaging.
- In children with medically refractory seizures, a neurosurgeon should be consulted for surgical planning and decision-making.

PREVENTION AND SCREENING

- SWS cannot be prevented as it is sporadic.
- However, in any neonate or child with a port-wine stain on the face, a careful ophthalmologic exam with close follow-up is highly recommended.
- Neuroimaging is also necessary in children with a port-wine stain on the face, and should be repeated in 1 to 2 years if negative.

PROGNOSIS

- Prognosis depends directly on the severity and extent of the ocular manifestations and leptomeningeal angiomas.
- Screening for and surgical correction of glaucoma will be imperative for a good prognosis.
- Early onset of seizure activity and presence of leptomeningeal angiomas can cause developmental delay and neurocognitive decline. Thus careful control of seizure activity is necessary. However, cognitive deterioration can still occur as the patient ages.[3]

FOLLOW-UP

- Follow-up is contingent on the affected systems. An ophthalmologist and neurologist should be closely involved in care of the child with SWS.

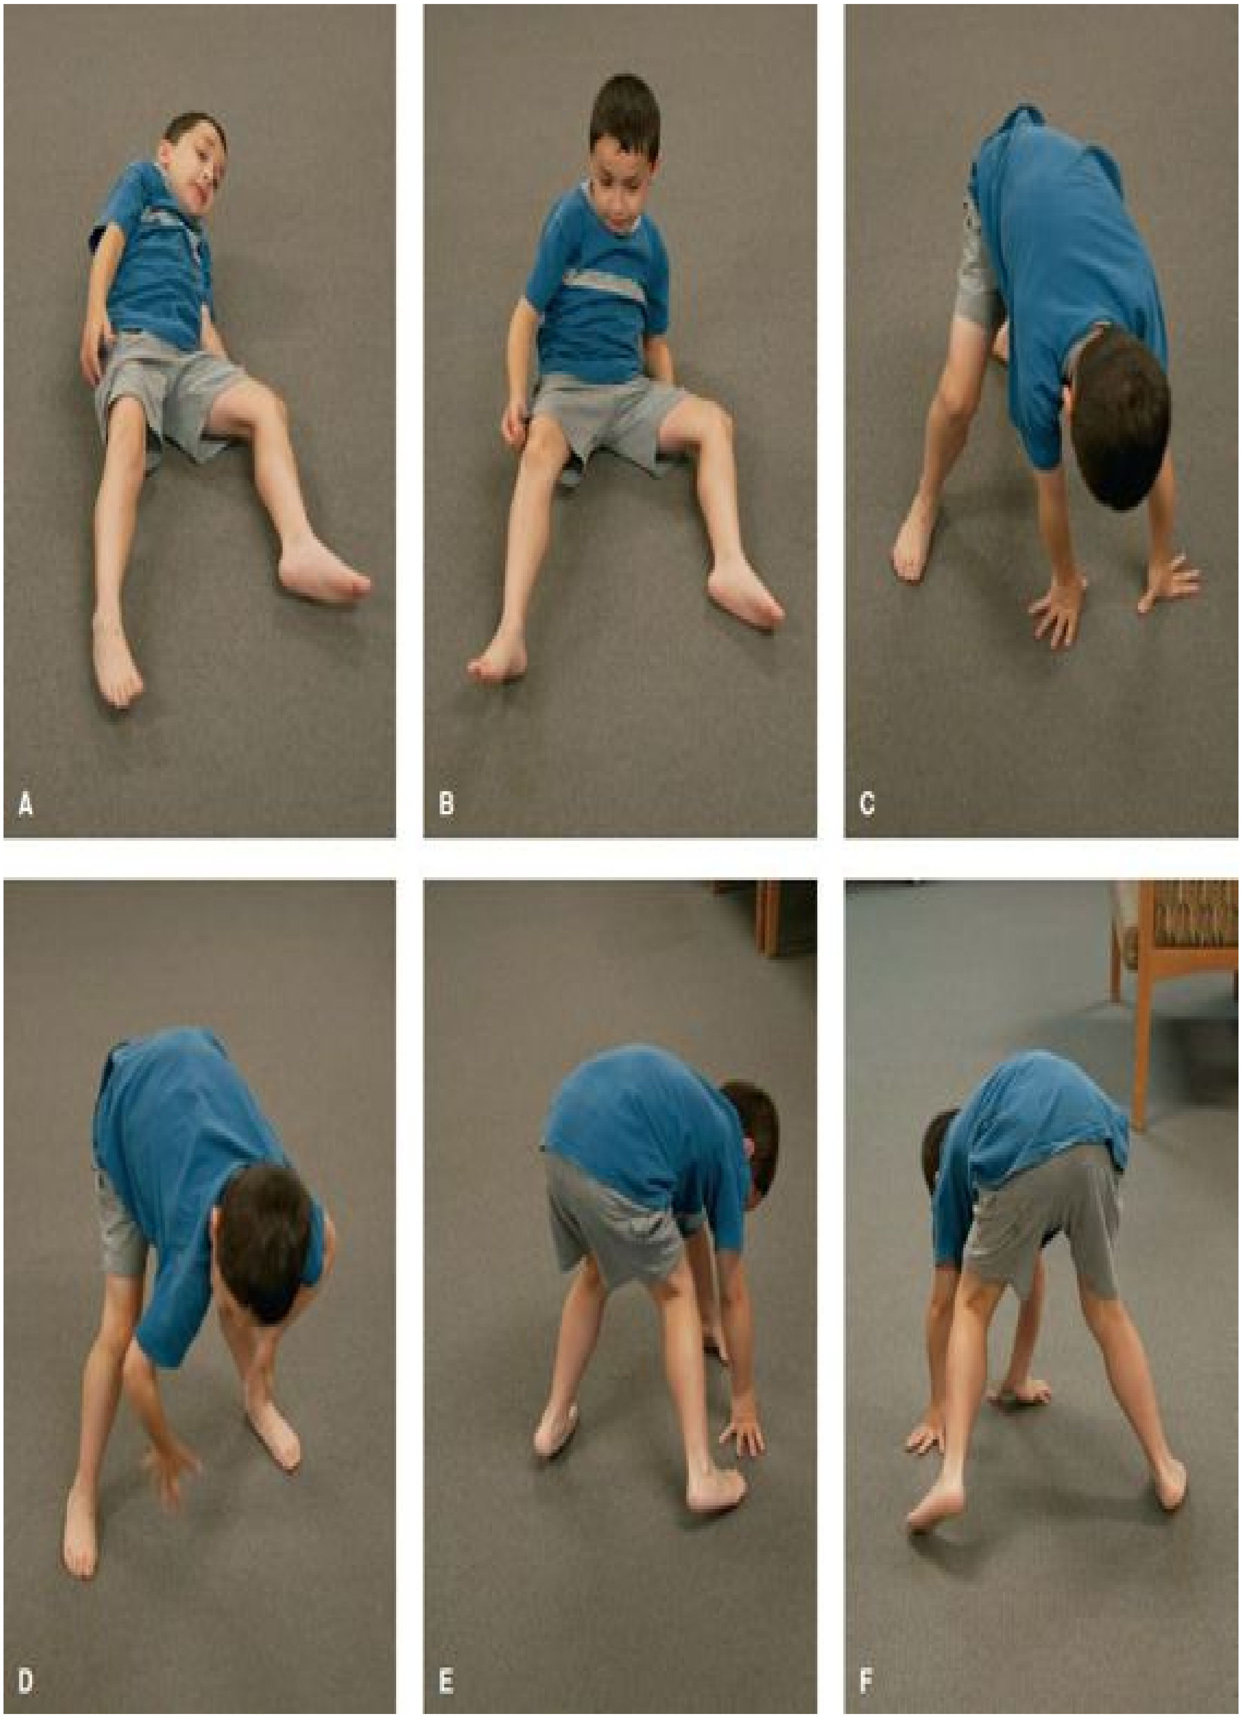
208 DUCHENNE MUSCULAR DYSTROPHY

Neil Friedman, MBChB

PATIENT STORY

A 9-year-old boy with a history of Duchenne muscular dystrophy (DMD) is being seen by his pediatrician for a routine maintenance exam. He initially presented at 3 years of age for evaluation of toe walking and excessive falling, and was diagnosed with DMD. He started walking independently between 12 to 14 months of age. He had always been slower than his peers and has difficulty keeping up with them. At the time of diagnosis, the family reported increasing difficulty going up steps which he can only do one step at a time. He also had difficulty getting up from the floor, needing to push on his knee or use furniture for assistance (Gower sign), which has continued and is pronounced at the current visit (**Figure 208-1**). He also tends to be clumsy with excessive falling and has an awkward appearing waddling gait, exacerbated by running.



A
B
C
D
E
F

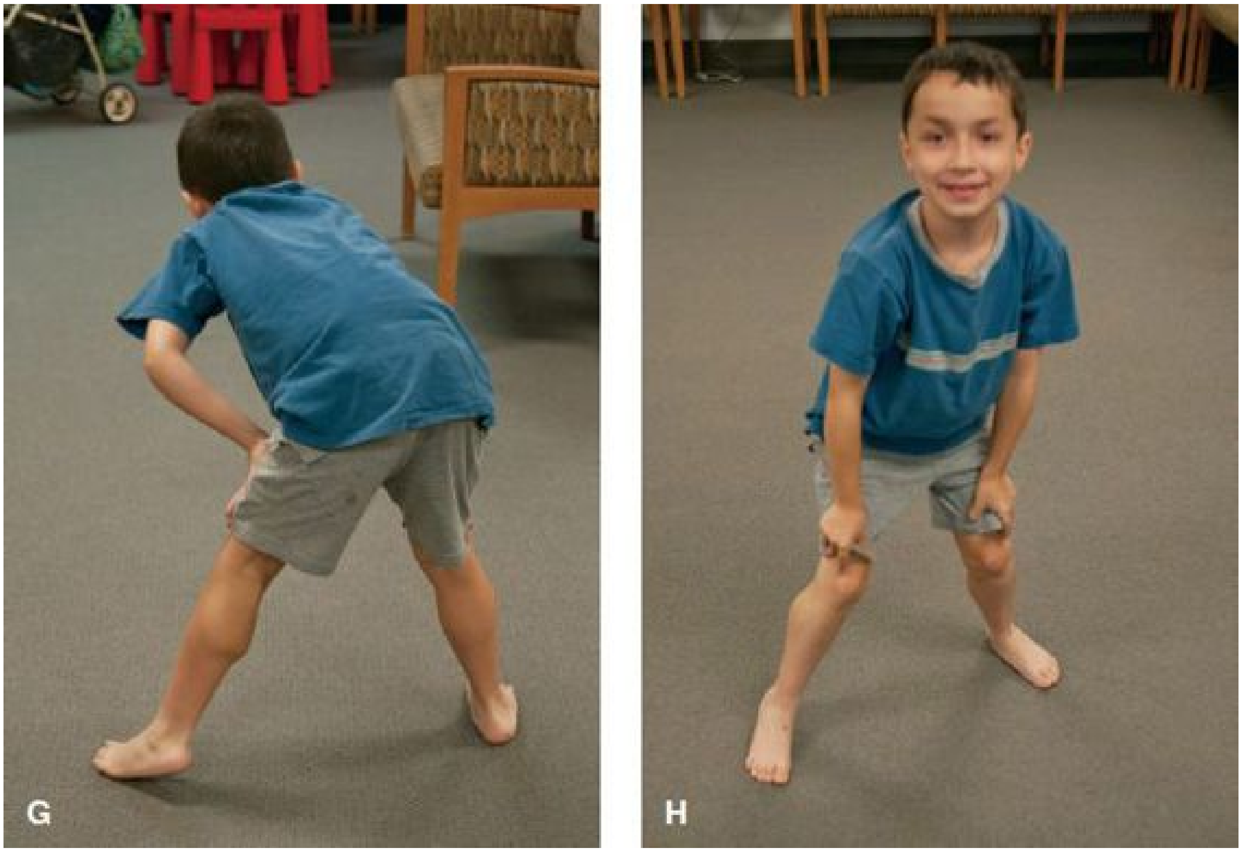


FIGURE 208-1 Gower sign. In order to stand up, the child gets into a prone crawl position with hands on the floor (**A-D**), extends and locks the legs in a widened stance (**E-F**), then using extended arms they shift their weight backwards and use their hands on their knees and thighs until they can achieve an upright position (**G-H**). (*Used with permission from Neil Friedman, MD.*)

INTRODUCTION

- Most common form of muscular dystrophy.
- Presents between 2 to 5 years of with progressive, symmetric proximal weakness manifesting as difficulty getting up from the floor, difficulty climbing stairs, a waddling gait, and excessive tripping and falling.
- Loss of ambulation typically between 7 to 13 years of age.

- Early demise in 2nd or 3rd decade secondary to cardiomyopathy and progressive respiratory failure due to weakness.
- Results from mutation of the *DMD* gene; dystrophin is the gene product.
- X-linked recessive inheritance—Primarily affects males but female carriers may manifest disease characteristics due to skewed inactivation of the X-chromosome (Lyon hypothesis).
- Variable phenotype depending on the nature of the gene mutation.
  - Absence of dystrophin results in the severe Duchenne muscular dystrophy (DMD) phenotype.
  - Preservation of some dystrophin results in the allelic, milder Becker muscular dystrophy (BMD) phenotype or a dilated cardiomyopathy (DCM) in which the heart is primarily affected with little or no skeletal muscle involvement (**Table 208-1**).

Table 208-1 Comparison of Duchenne and Becker Muscular Dystrophy

	Duchenne	Becker
Age of presentation	3-5 years	5–10 years, sometimes adolescence
Loss of ambulation	Before 13th birthday	Beyond 16th birthday
Death	Early 20's—from cardiopulmonary failure	Variable—long-term survival possible
CK	Massively elevated >10-100 x normal	Massively elevated >10–100 x normal
Cardiomyopathy	Late—end stage	Early, disproportionate to muscle weakness May be presenting feature
Dystrophin	Absent (<5%)	Reduced in quantity or quality (>10%)
Gene deletion	Large Deletions: about 2/3 of cases Small deletions, point mutations and duplications: about 1/3 of cases	Large Deletions: about 2/3 of cases Small deletions, point mutations and duplications: about 1/3 of cases

- 1851—Edward Meryon reported first clinical cases of DMD in the medical literature.
- 1868—The French neurologist Duchenne de Boulogne describes a series of children with the disease that would later bear his name.

- 1954—Walton and Nattrass developed first classification of muscular dystrophies based on clinical and inheritance factors.
- 1986—*DMD* gene identified by Luis Kunkel (positional cloning or “reverse genetics”).

SYNONYMS

- Dystophinopathies.
- Pseudo-hypertrophic muscular dystrophy.

EPIDEMIOLOGY[1]

- DMD is one of the more common genetic disorders affecting one in 3,500 live male births.
- BMD affects 1 in 30,000 to 35,000 live male births.
- Duchenne muscular dystrophy is the most frequent muscle disorder in childhood.

ETIOLOGY AND PATHOPHYSIOLOGY

- DMD is caused by an out-of-frame deletion, point mutation or duplication in the *DMD* gene leading to a complete absence of protein; whereas BMD results from an in-frame deletion or duplication in the *DMD* gene resulting in the expression of an altered size, but partially functional dystrophin protein.[2]
    - Deletions account for approximately 65 percent of cases of DMD and 85 percent of cases of BMD; the remainder due to point mutations or rarely duplications.

- *De novo* mutations occur in approximately 1/3 of cases, while 2/3 of cases are inherited from the mother.
- The *DMD* gene is the largest in the human genome (0.1% of the entire genome), encompassing 2.6 million base pairs of DNA and containing 79 exons.
- Dystrophin is a large, subsarcolemmal structural protein that has a major structural role in muscle as it links the internal actin cytoskeleton to the dystrophin-associated glycoproteins (DAG) in the sarcolemmal membrane (**Figure 208-2**).[3]

FIGURE 208-2 Dystrophin-associated glycoprotein complex. (*Reprinted by permission from Macmillan Publishers Ltd: Molecular Therapy (Mol Ther.2012 Feb;20(2):462-7), Copyright 2012.*)

- Absence of dystrophin disrupts the muscle ultra structure resulting in muscle injury, inflammatory changes and ultimately degeneration of the muscle fibers with resultant replacement of muscle fibers by connective tissue and fatty infiltration, which is irreversible.[4]

RISK FACTORS

- Family history of DMD since it is a genetically inherited disease.
  - X-linked recessive inheritance.
  - Mother is found to be a carrier in approximately 2/3 of cases; remaining cases due to spontaneous mutations.

DIAGNOSIS

CLINICAL FEATURES

- Progressive, symmetric proximal weakness initially affecting pelvic girdle muscles and later shoulder girdle muscles; with disease progression, neck muscles and distal muscles also become involved.
- Frequent calf hypertrophy (pseudohypertrophy; **Figure 208-3**).

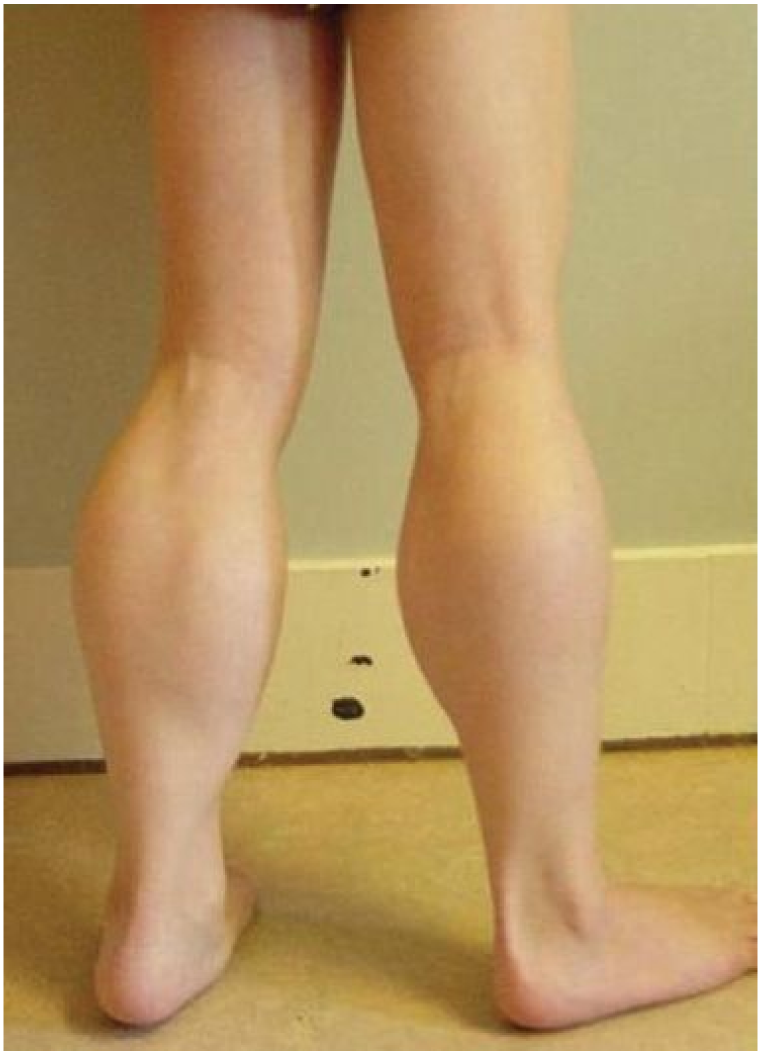

FIGURE 208-3 Calf hypertrophy in patient with Duchenne muscular dystrophy. (*Used with permission from Neil Friedman, MBChB*.)

- Gower sign (**Figure 208-1**)—While not pathognomonic for DMD, this is suggestive of proximal girdle muscle weakness.
- Waddling gait typically with toe walking.
- Hypo/areflexia.
- Contractures of Achilles tendons.
- Scoliosis usually later in the disease course.
- Becker muscular dystrophy is similar to DMD but has later onset and slower, more variable progression of symptoms.

DISTRIBUTION

- Initial proximal pelvic girdle weakness, which progresses over time to involve proximal shoulder girdle muscles, neck flexor and extensor muscles, and distal upper and lower extremity muscles.

LABORATORY TESTING

- Creatine kinase—Markedly elevated in all cases of DMD/BMD but is not discriminatory for DMD versus BMD or from other forms of neuromuscular disease.
- EMG/Neuroconductive studies—Rarely helpful but if performed will show a necrotizing myopathy. This is non-discriminatory for DMD versus BMD or from other forms of muscular dystrophy.
- Molecular diagnosis remains the testing of choice:
  - Initial screening includes either multiplex PCR of the exons most commonly deleted, which will pick up about 2/3 of cases but misses small deletions, point mutations and duplications; versus quantitative analysis of all exons using multiplex ligation-dependent probe amplification (MLPA) or oligonucleotide-based array comparative genomic hybridization (array-CGH).
  - If negative, reflex testing to full sequence analysis of genomic DNA.
- Muscle biopsy—Molecular testing has increasingly obviated the need for muscle biopsy, which shows dystrophic features including variation in muscle fiber size, increased internal nuclei, muscle replacement by fat and connective tissue, and whirling or splitting of muscle fibers.
  - Immunohistochemistry using antibodies directed against the dystrophin protein will be absent in DMD (rare revertent fibers may be seen) and show patchy and incomplete staining in BMD (**Figure 208-4**).

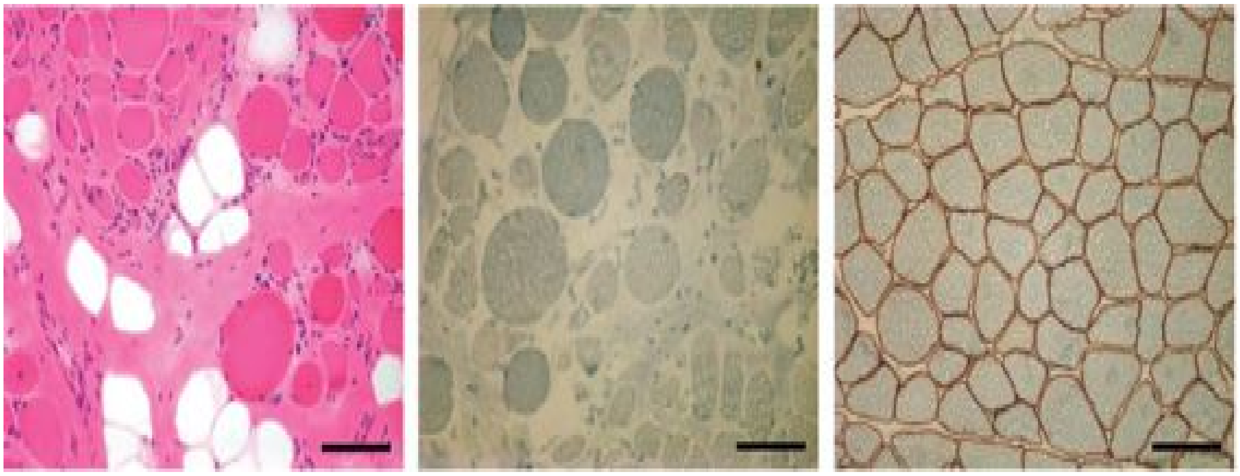

FIGURE 208-4 Duchenne muscular dystrophy. (Left) Hematoxylin and eosin stained section demonstrating dystrophic pattern of injury. There is a marked variation in fiber size and endomysial fibrosis and fat. Many large fibers are hyalinized consistent with early necrosis. Some have centrally located myocyte nuclei. Some small fibers are slightly basophilic and have plump nuclei consistent with fiber regeneration. (Center) Immunoperoxidase stain with antibody to dystrophin. There is no evidence of dystrophin expression. (Right) Positive control section demonstrating the normal pattern of dystrophin immunoreactivity. Scale bar = 100 µm. (*Used with permission from Susan M. Staugaitis, MD, PhD*.)

  - Western blot analysis allows for quantitative measurement of dystrophin that is essentially absent (<10%) in DMD and reduced in quality and quantity in BMD.

IMAGING

- Not usually indicated but ultrasound and/or MRI can show fatty replacement of muscle and fibrosis

DIFFERENTIAL DIAGNOSIS

- Other forms of muscular dystrophy including limb-girdle muscular dystrophies, Emery-Dreifuss muscular dystrophy, or fascioscapular humeral muscular dystrophy—Age of onset, pattern of weakness, and involvement of joint contractures can help to differentiate this group of disorders.
- Spinal muscular atrophy—The presence of tongue fasciculations (anterior horn cell involvement), pattern of muscle involvement, and early age of onset differentiate this from DMD.
- Dermatomyositis—An inflammatory myopathy that often presents with lower extremity proximal weakness. The short duration of symptoms, presence of muscle pain or discomfort, and presence of heliotrope rash, capillary telangiectasias of nail folds or Gottron papules differentiates this from DMD (see Chapter 174, Juvenile Dermatomyositis).

MANAGEMENT

NONPHARMACOLOGIC

- Supportive care:[5–7]
  - Respiratory: SOR A
  - Pulmonary function test monitoring.
  - Manual and mechanically assisted cough techniques as needed.
  - Obstructive sleep apnea and nocturnal ventilation resulting in early morning headache, fatigue, nausea is effectively treated with continuos positive airway pressure (CPAP).
  - Cardiac—Inevitable progression to dilated cardiomyopathy and heart failure in DMD. Early identification and treatment of heart failure and/or myocardial fibrosis with anti-failure medications can provide symptomatic relief and prolong life. SOR A
  - Orthopedic—Surgical releases of contractures as appropriate and repair of scoliosis to preserve lung function and facilitate sitting posture and care. SOR A

  - Bone health—Increased risk for osteopenia with loss of ambulation and/or use of corticosteroid therapy.
  - Measurement of serum concentrations of calcium and phosphorus, and activity of alkaline phosphatase.
  - 25-hydroxyvitamin D (25-OHD) level in springtime or biannually.
  - Magnesium and parathyroid hormone levels may be considered.
  - Urine (calcium, sodium, or creatinine).
  - Dual energy x-ray absorptiometry (DEXA) scanning.
    - At baseline (age ≥3 years) or at start of corticosteroid therapy.
    - Repeated annually in those at risk (history of fractures or chronic corticosteroid therapy) and those with DEXA Z score <-2.
  - Cognitive impairment and Learning difficulties—Frequent association with DMD and should be appropriately addressed when present, including individualized educational plans as needed; autism has also been reported in association with DMD in some instances and should be screened for in the appropriate clinical setting.
  - Non-specific strength treatment:
    - Physical and occupational therapy to promote mobility and prevent contractures.
    - Aquatherapy.

MEDICATIONS

- Drug therapy directed at disease pathogenesis:
  - Corticosteroids:[5,8,9] SOR A
    - Early corticosteroid therapy is the only medication currently available that can slow the progression of the muscle weakness but cannot cure the disease.
    - Appears beneficial in reducing the risk of scoliosis, and may help to stabilize pulmonary and cardiac function.
    - No generally accepted guidelines about the best time to initiate corticosteroid therapy.
    - The recommended starting dose for prednisone in ambulatory boys is 0.75 mg/kg daily given in the morning; alternative intermittent dosing regimes include 0.75 mg/kg daily for 10 days each month or high

dose weekend dosing of 5 mg/kg given each Friday and Saturday; the minimum effective dose that shows some benefit (albeit not to the maximum extent possible) is believed to be 0.3 mg/kg daily for prednisone.

- Experimental/Research Therapy:
  - Cell therapy to compensate for gene defect—Myoblast transplant.
  - Modify or regulate gene expression—Exon skipping strategies; mutation suppression.
  - Gene therapy—Gene transfer therapy via viral vectors.

REFERRAL

- Requires multi-specialty care including—Neurology, cardiology, pulmonology, orthopedic surgery, endocrinology, medical genetics, physical therapy, occupational therapy, nutrition, social worker, and/or case manager.
- Consider psychosocial support as indicated.

PREVENTION AND SCREENING

- Genetic counseling for affected individuals and family.
- Carrier testing is available for at-risk females.
- Prenatal testing and pre-implantation diagnosis of affected female carriers is possible, if the specific gene mutation is known.
- Currently study is underway to look at the feasibility of creatine kinase screening of the newborn blood screen to facilitate the diagnosis of DMC.

PROGNOSIS

- No cure currently exists for DMD or BMD.
- Life expectancy in DMD is typically the 2nd or 3rd decade with aggressive management and appropriate care.
- Long term survival possible in BMD but depends on disease severity.
- Cardiac involvement in BMD may be disproportionate to the muscle weakness and may occur early; may be amenable to heart transplantation.

FOLLOW-UP

- Chronic disease—Requires regular life-long medical care and follow up with multi-disciplinary team.

209 IRON DEFICIENCY ANEMIA

Margaret C. Thompson, MD, PhD

PATIENT STORY

A 24-month-old well appearing girl who is at the 50th percentile for height and 95th percentile for weight is being evaluated by her pediatrician. Her vital signs reveal a heart rate of 150 per minute, blood pressure 85/50 mm Hg, and respiratory rate of 15 per minute. She is noted to be an active toddler sucking on a bottle and upon questioning the mother reveals that the girl drinks 38 ounces of whole milk a day. She is not jaundiced or icteric but the pediatrician notes that she has conjunctival pallor (**Figure 209-1**). No hepatosplenomegaly is appreciated. Because of the conjunctival pallor and the dietary history, the pediatrician obtains a complete blood count, which shows a white blood cell count of 5100/mm3, hemoglobin 6.1 g/dL, and platelet count of 499,000/mm3. The lab reports microcytosis, hypochromia, mild anisocytosis, and polychromasia. There is no basophilic stippling. A diagnosis of iron deficiency anemia is made and the girl is treated with oral ferrous sulfate. The pediatrician suggests that the amount of milk intake should be limited to 20 ounces per day. One month later, her hemoglobin increased to 8 g/dl and she is continued on iron supplementation for 3 months after her hemoglobin is normal for age.

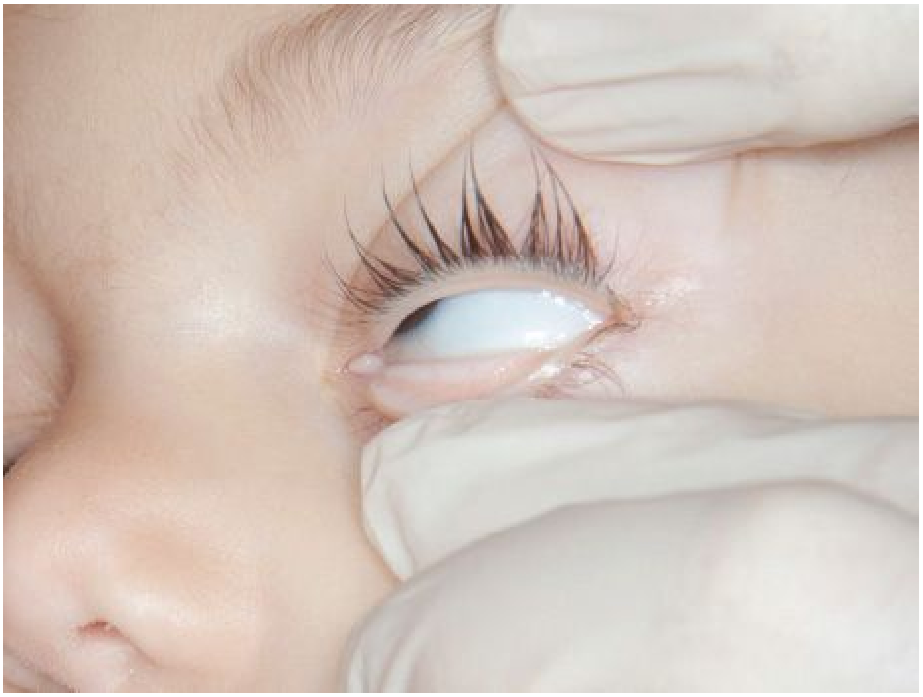

FIGURE 209-1 Conjunctival pallor in a toddler with severe anemia due to iron deficiency. (*Used with permission from Margaret C Thompson, MD PhD.*)

INTRODUCTION

Iron deficiency is the most common cause of anemia in the United State and worldwide.[1] Although iron deficiency has decreased with the use of iron supplements and with iron fortification of foods, especially infant formula, it remains a common problem.

EPIDEMIOLOGY

- Iron deficiency is rare before 9 months of age in full term infants.
- Iron stores are usually high in the full-term newborn and sufficient until 4 to 6 months of age. Children between 9 and 18 months of age are at

highest risk for developing iron deficiency due to rapid growth combined with insufficient intake.

- Iron deficiency anemia is present in 7 percent of toddlers aged 1 to 2 years and 9 percent of adolescent girls.[2]
- Risk factors include early introduction of cow's milk and consumption of more than 24 ounces of day of milk per day.
- Iron deficiency anemia is frequently seen in toddlers with excessive milk intake. The iron in milk is poorly absorbed. Further, the child may forego intake of other calorie sources because he or she is full from the milk. In addition, the child may develop mild blood loss from the gastrointestinal tract associated with the excessive milk.
- Preterm infants are at increased risk for iron deficiency anemia because of lower iron stores at birth and greater requirements due to faster growth rate.

ETIOLOGY AND PATHOPHYSIOLOGY

- Iron deficiency anemia occurs when iron is not available for the production of red blood cells. Most of the body's iron is found in the hemoglobin of circulating red blood cells.
- The remaining iron is stored in ferritin. Ferritin is an intracellular protein found in all cells but primarily in the bone marrow, liver, and spleen. The liver's stores of ferritin are the primary physiologic source of reserve iron in the body. A small amount of iron (0.1%) is found circulating and bound to transferrin.
- As red blood cells are destroyed and taken out of circulation, the iron is efficiently scavenged by macrophages and reused for production of new red cells. Only a small amount of iron is lost each day and is usually replaced by dietary absorption.
- When loss exceeds exogenous replacement (food or iron supplement), iron stores decrease and iron deficiency anemia may occur. This may occur in the following settings:

- Blood loss.
    - Gastrointestinal loss as in Crohn disease, excessive milk intake, peptic ulcers, varices, or hookworm infection.
    - Uterine blood loss with menses.
    - Urinary loss.
- Inadequate dietary intake.
- Impaired absorption.
    - Celiac disease.
    - Crohn disease.
    - After surgery involving the duodenum.
    - Proton Pump Inhibitors and H2 blockers.
    - Regional Enteritis.
    - Consumption of foods such as calcium, phytate, and tannins.

RISK FACTORS

- Socioeconomic risk factors include low income, minority ethnicity, and poor maternal iron status.[3,4]
- Early introduction of cow’s milk into the diet of an infant (below the age of one year).
- Consumption of more than 24 ounces of milk per day.
- Pagophagia (craving and chewing ice) and pica (ingestion of non-food substances).

DIAGNOSIS

CLINICAL FEATURES

- Symptoms of iron deficiency anemia are the same as in all forms of anemia and depend on severity of the anemia as well as the rapidity of onset.

- These symptoms include fatigue, decreased stamina, tachycardia, and shortness of breath with exertion.
- Physical signs include pallor, mucosal pallor (conjunctiva and gums; **Figures 209-1** and **209-2**), and blue sclerae.

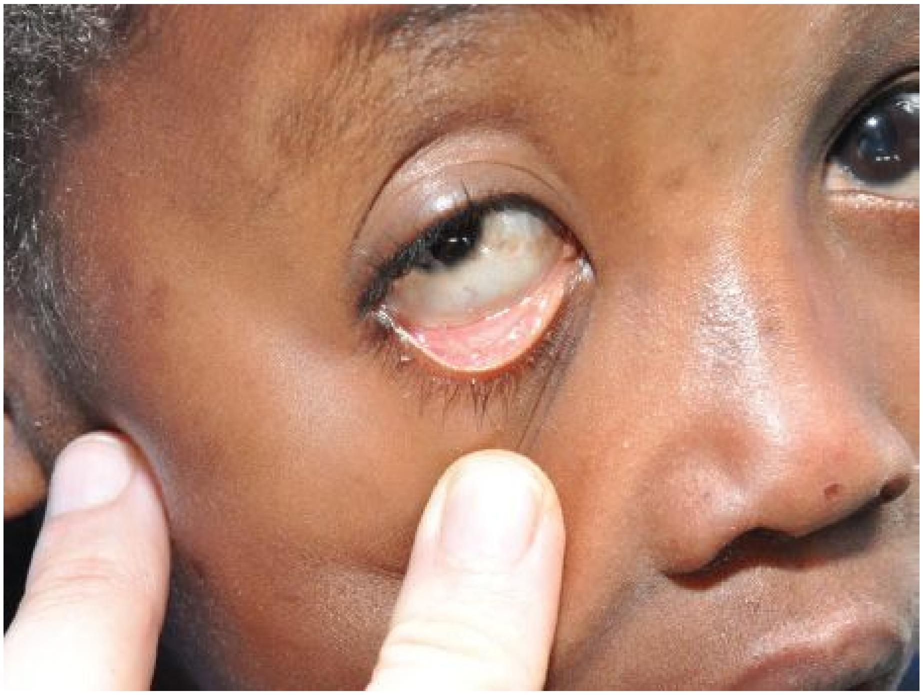

FIGURE 209-2 Conjunctival pallor in an African child with iron deficiency anemia. This child lives in extreme poverty in rural Africa with limited access to iron in her diet. (*Used with permission from Richard P. Usatine, MD.*)

- Spooning of the fingernails (koilonychias; **Figure 209-3**) and atrophy of the papillae of the tongue are rare findings in children.

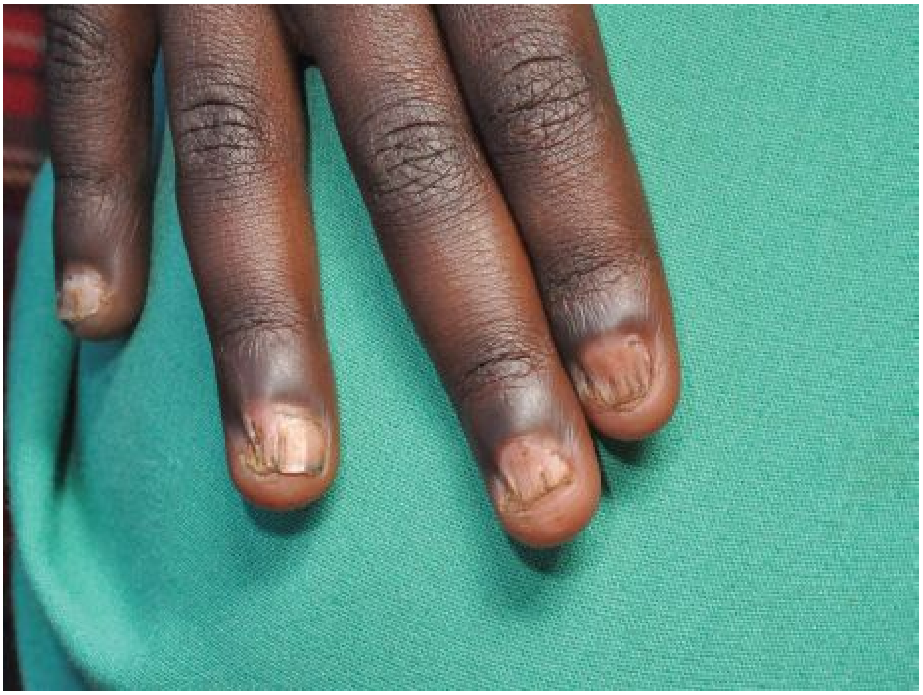

FIGURE 209-3 Koilonychia (spoon-shaped nails) in the same African child with iron deficiency anemia as in **Figure 209-2**. Children in her village may only have one to 2 meals per day and are lucky if they receive meat once a year in their diet. (*Used with permission from Richard P. Usatine, MD.*)

LABORATORY TESTING

- Iron deficiency anemia is characterized by microcytic, hypochromic red blood cells on peripheral smear (**Figure 209-4**). This is reflected by a low mean corpuscular volume (MCV) and low mean corpuscular hemoglobin (MCH).

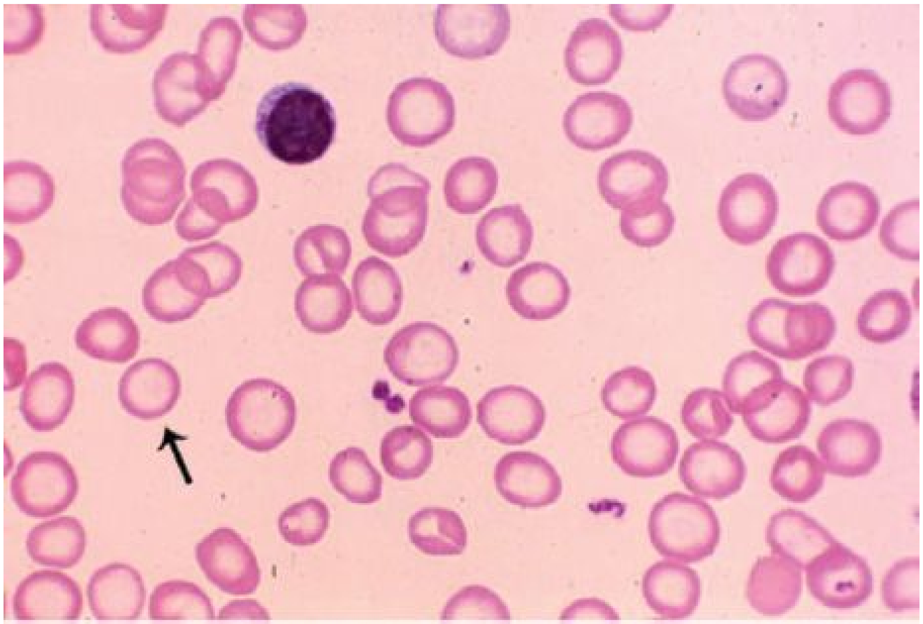

FIGURE 209-4 Microcytic, hypochromic red blood cells, which are characteristic of iron deficiency anemia, on peripheral smear. (*Used with permission from Lichtman MA, Shafer MS, Felgar RE, Wang N. Lichtman's Atlas of Hematology.* http://www.accessmedicine.com.)

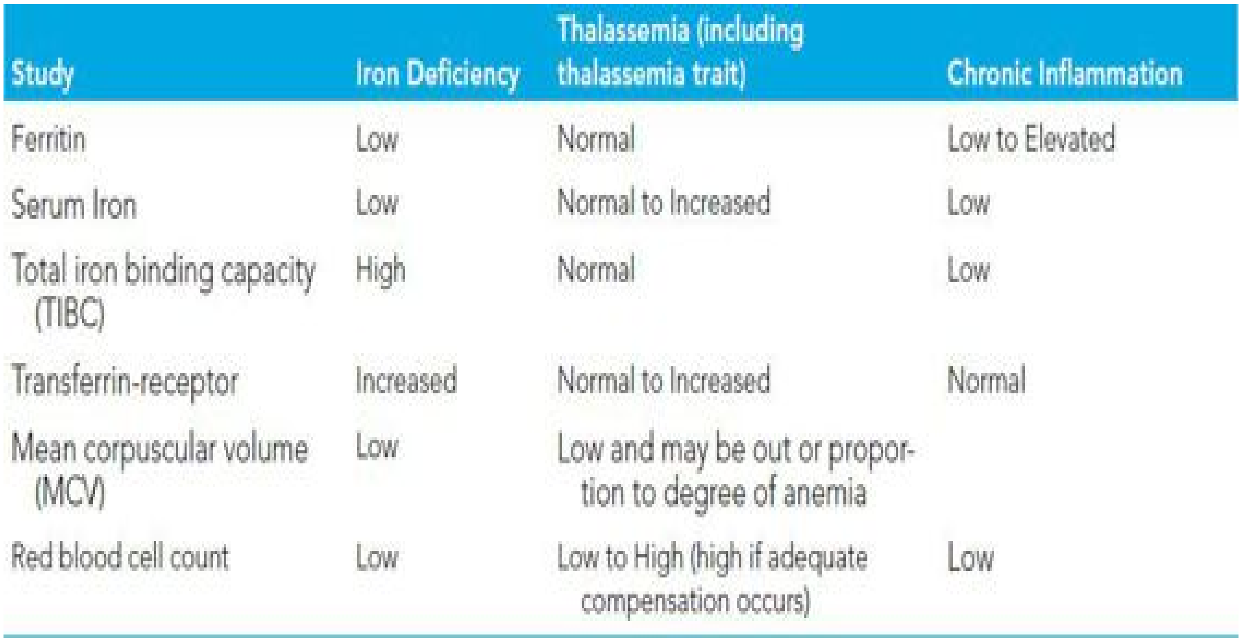
- It also results in an uneven red blood cell size (anisocytosis), which is reflected by an increased red blood cell distribution width (RDW).
- The reticulocyte count is low or inappropriately normal for the degree of anemia.
- Serum ferritin reflects iron stores in the reticuloendothelial system and the liver. A low serum ferritin is the most specific laboratory test for iron deficiency anemia. Ferritin, however, is an acute phase reactant and may be increased in the settings of infection or chronic inflammation. As a result, its sensitivity is decreased, and a normal ferritin does not completely rule out iron deficiency anemia.
- Serum iron concentrations are generally low and serum total iron binding capacity (TIBC) is increased.
- Serum transferrin receptor, which reflects erythropoietic activity, is another nonspecific marker of the iron status and is elevated in iron deficiency, and can be used to help distinguish iron deficiency from anemia of chronic inflammation.[5]

- Initially, as iron stores decrease, iron deficiency erythropoiesis occurs. In this state, a very mild decrease in hemoglobin may be observed without a decrease in MCV. This decrease in hemoglobin is generally asymptomatic. With continued decrease in iron availability, true iron deficiency anemia occurs, with concomitant abnormalities in the MCV and hemoglobin.
- It may help to order a urinalysis to look for urinary blood loss if the cause of iron deficiency is not readily available based on history and physical examination. If there are concerns for chronic illness, a comprehensive metabolic profile may show signs of liver or renal disease. If gastrointestinal blood loss is a concern, stool heme studies may be added to the workup.

DIFFERENTIAL DIAGNOSIS

- Thalassemia syndromes and anemia of chronic disease (anemia of inflammation) also cause a microcytic anemia. These can be distinguished from iron deficiency based on family and dietary history, current medical condition of the patient, and laboratory studies (**Table 209-1**).

TABLE 209-1 Laboratory Differentiation of the Causes of Microcytic Anemia



Study	Iron Deficiency	Thalassemia (including thalassemia trait)	Chronic Inflammation
Ferritin	Low	Normal	Low to Elevated
Serum Iron	Low	Normal to Increased	Low
Total iron binding capacity (TIBC)	High	Normal	Low
Transferrin-receptor	Increased	Normal to Increased	Normal
Mean corpuscular volume (MCV)	Low	Low and may be out or proportion to degree of anemia	
Red blood cell count	Low	Low to High (high if adequate compensation occurs)	Low

- Congenital and acquired sideroblastic anemias are rare causes of microcytic anemia. The acquired form can be due to lead toxicity or isoniazid toxicity.
- Other rare causes of microcytic anemia include congenital absence of transferrin, copper deficiency, and lymphoid hamartoma syndrome (Castleman disease).

MANAGEMENT

NONPHARMACOLOGIC

- Sources of ongoing blood loss should be identified.
- Nutritional counseling may be beneficial in individuals with inadequate dietary intake of iron.
- Milk should be limited to 20 to 24 ounces per day in milk-associated iron deficiency anemia.
- Transfusion of red blood cells for iron-deficiency anemia is indicated only in the most severe cases such as extremely low serum hemoglobin, heart failure, or when ongoing blood losses exceed (or equal) bone marrow production after appropriate iron therapy.

MEDICATIONS

- Iron may be given orally, intravenously, or intramuscularly. Regardless of the route, an increase in peripheral reticulocytes is generally seen within 3 or 4 days.
- Oral iron salts are inexpensive and almost always sufficient to correct the anemia.
- There are many pharmacologic forms of iron available for oral therapy. For all forms, the dose is 3 to 6 mg/kg of elemental iron divided into 3 or 4 doses daily. This should be continued for at least 3 months after the

hemoglobin has normalized. Iron supplements should be taken with vitamin C to increase absorption. Some experts recommend giving the iron between meals and with vitamin C juice, to increase absorption.[6] SOR C

- Adverse effects of iron therapy, such as gastrointestinal upset and constipation are unusual in children. Temporary staining of the teeth can occur but is temporary and can be avoided by rinsing the mouth after the medication is given.
- Iron replacement may be given parenterally in patients who have impaired absorption, when there are concerns of adherence, and when rapid replacement therapy is required.[7] Three commonly used parenteral forms of iron are:
  - Iron dextran may be given intravenously and is also the only form of iron that may be given intramuscularly. The benefit of iron dextran is that a larger dose may be given at a time, and thus a patient may be able to receive a full replacement dose in a single infusion. Iron dextran, however, is associated with a significantly greater risk of allergic reaction including anaphylaxis. Intramuscular injection has become less common and requires experience with the Z-track method of administration. It is associated with pain, staining of the skin and inconsistent absorption of the iron.
- Sodium Ferric gluconate is a parenteral form, which is associated with a very low risk of allergic reaction. The maximum dose that may be given with this form is less than with iron dextran, and as a result, full replacement frequently requires several doses given weekly. Pediatric dosing is not fully established, but based on its use in hemodialysis patients is 0.12 mL/kg or 1.5 mg/kg of elemental iron with a single dose not to exceed 125 mg.
- Iron Sucrose is a parenteral form which also has associated with a low risk of allergic reaction. Pediatric dosing is not fully established but based on use in hemodialysis patients is 0.05 mg/kg, with a maximum 200 mg per infusion.

REFERRAL

- Depending on the degree of anemia, referral to a hematologist may be appropriate.
- Referral to gastroenterology or gynecology should be made, as needed to identify potential sources of blood loss.

PREVENTION AND SCREENING

- The committee on Nutrition of the American Academy of Pediatrics[8] has made the following recommendations for the prevention of iron deficiency anemia in term infants:
    - Breast milk should be given for at least 6 months, if possible. Iron supplementation (1 mg/kg/day) should be provided for infants who are exclusively breast-fed, starting at 4 months of age and continuing until appropriate iron containing complementary foods have been introduced.
    - Iron fortified formula, rather than cow’s milk, should be given to infants who are weaned from breast milk before 12 months of age.
    - An iron-supplemented formula for the first year of life should be provided for infants who are not breast-fed.
    - Iron enriched cereals and other foods rich in iron should be introduced gradually to infants starting at 4 to 6 months of age.
    - All preterm infants who are fed human milk should receive an iron supplement of 2 mg/kg per day by one month of age and continued until the infant is weaned to iron fortified formula or begins eating complementary foods that supply the 2 mg/kg of iron.
- Universal screening for anemia, by determination of hemoglobin concentration and assessment of risk factors for iron deficiency, should be performed at 12 months of age.
- Consumption of more than 20 ounces of whole cow’s milk per day in toddlers should be avoided.

PROGNOSIS

- The prognosis for complete resolution of iron deficiency anemia is excellent in otherwise healthy children.
- Effects of ongoing anemia include cardiomegaly, impaired growth and development in infants, poor school performance in older children, and decreased physical endurance.[9,10]

FOLLOW-UP

- A complete blood count of hemoglobin should be obtained after 4 weeks of treatment to assess response.
- An increase in hemoglobin of at least 1 g/dL after one month is diagnostic of iron deficiency.
- If the response is adequate, the complete blood count should be retested every 2 to 3 months until the hemoglobin is normal for age.
- Once the hemoglobin is normal, iron supplementation should be continued for 3 more months to replenish iron stores.

PATIENT EDUCATION

- Appropriate dietary education should be provided to parents and caregivers regarding the appropriate modalities of nutrition that will avoid iron deficiency in the first year of life.
- Families should be counseled regarding limiting milk and juice intake in the toddler years.

210 IMMUNE THROMBOCYTOPENIA PURPURA

Margaret C. Thompson, MD, PhD

PATIENT STORY

A 22-month-old boy is brought to his pediatrician by his parents because he has developed several dark purple bruises on his back and spine (**Figure 210-1**). He has additional bruises over both legs (**Figure 210-2**) along with smaller bruises over his neck and cheeks. He developed these over the past 2 to 3 days, and his mother reports that 3 weeks prior to this presentation, he had an illness characterized by vomiting, nausea, and diarrhea. The pediatrician suspects immune thrombocytopenic purpura (ITP) and orders a CBC, which shows a normal white blood cell count, differential count, and hemoglobin, but a platelet count of 7,000 microL. His liver function studies, prothrombin time (PT), and partial thromboplastin time (PTT) are all normal. A diagnosis of ITP is made and the child is admitted to the hospital, where his activity is restricted and he is treated with intravenous immunoglobulin. His platelet count increases rapidly over 3 days and he is discharged home with close follow-up.

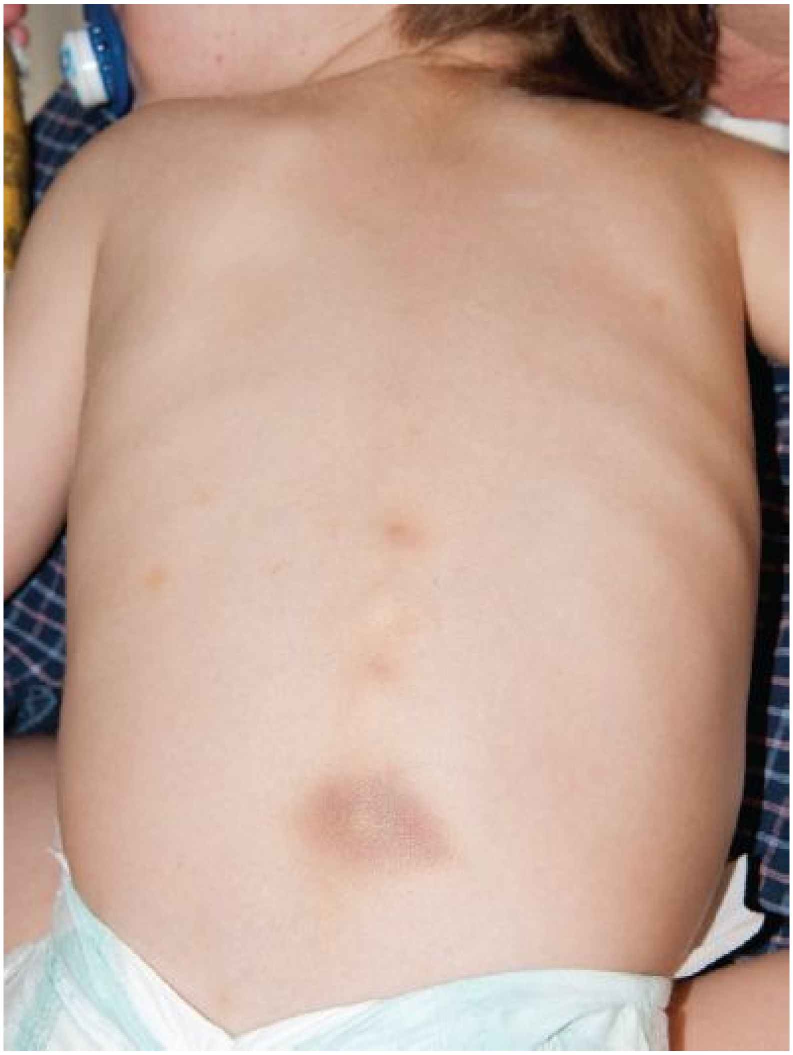

FIGURE 210-1 Purpuric and ecchymotic lesion over the back, and petechial lesions on the face of a child with immune thrombocytopenic purpura. (*Used with permission from Margaret C Thompson, MD, PhD.*)

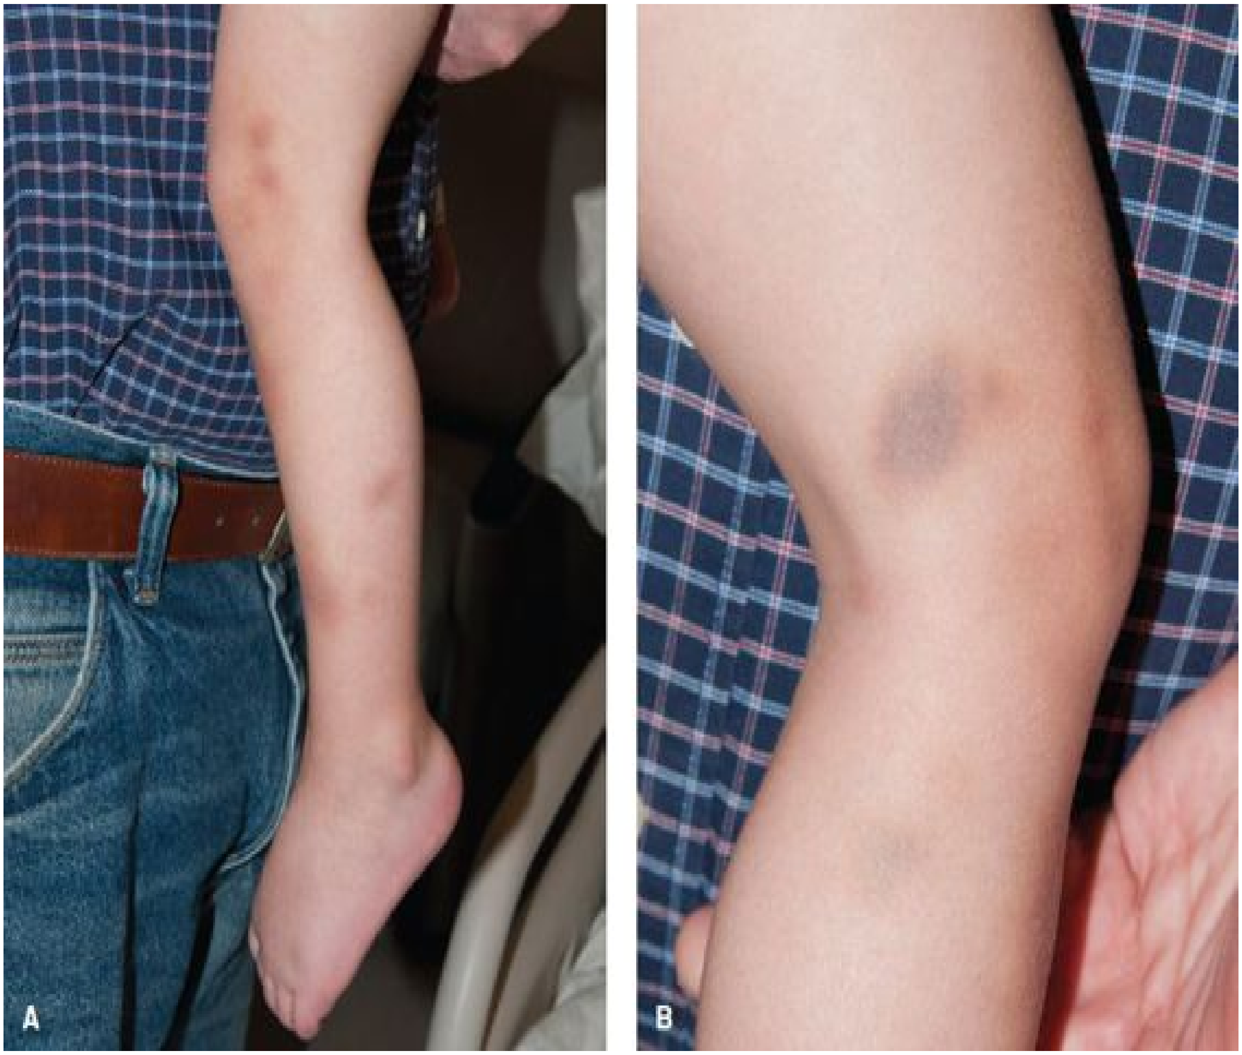

FIGURE 210-2 **A.** Large purpuric lesions on the legs of the child in **Figure 210-1**. B. Close-up of an ecchymotic lesion on the same child. (*Used with permission from Margaret C Thompson, MD, PhD.*)

INTRODUCTION

Immune thrombocytopenia purpura (ITP), formerly called idiopathic thrombocytopenic purpura, is an acquired disorder in which there is increased destruction of platelets causing thrombocytopenia (platelet count <100,000 microL). ITP may be divided into acute and chronic forms. Acute

ITP is defined as having duration less than 6 months while chronic ITP is defined as lasting more than 6 months.

SYNONYMS

Idiopathic Thrombocytopenic Purpura.

EPIDEMIOLOGY

- The incidence of symptomatic disease is estimated to be 3 to 8 per 100,000 per year.[1–3]
- Acute ITP is the most common bleeding disorder in children.
- It is seen most frequently in children between the ages of 2 and 10 years with a peak occurring between 2 and 5 years of age.[2]
- It affects males more frequently among children younger than 8 years and equally among males and females beyond that age.[2]
- More common in winter and spring.
- In approximately 2/3 of cases, ITP in children occurs within 6 weeks of a recent viral illness.[4]
- Chronic ITP is defined as persistent thrombocytopenia that persists for longer than 6 months from the initial presentation. This occurs in 10 to 20 percent of children with ITP.
- Chronic ITP occurs more frequently in adolescents (and adults) than in young children. It affects females more than males and may be associated with underlying autoimmune disorders such as collagen-vascular diseases.

ETIOLOGY AND PATHOPHYSIOLOGY

- ITP is an immune mediated process whereby the body produces antibodies that attach to the glycoproteins expressed on platelet membranes.[5]
- The spleen and reticuloendothelial system then destroy the antibody coated platelets.
- There appears to be some differences between acute and chronic ITP with respect to pathophysiologic mechanisms. It is believed that acute ITP occurs when antibodies produced in response to a viral or bacterial infection cross-react with platelet antigens. On the other hand, chronic ITP may be the result of an underlying defect in immune regulation. There is also evidence of decreased thrombopoietin level in chronic ITP patients and megakaryocytes from patients with chronic ITP may demonstrate decreased growth in vitro.
- ITP may rarely follow measles-mumps-rubella (MMR) vaccination. Although mild thrombocytopenia after such vaccination is not uncommon, the incidence of clinically significant thrombocytopenia (<50,000 microL) is between 1:30,000 and 1:40,000 vaccinations. The onset is within 6 weeks of vaccination and the majority of cases resolve within 1 month and in 93 percent of the children, the thrombocytopenia resolves within 6 months.[6,7]
- Vaccination is not associated with a relapse of ITP in children with a history of non-vaccine associated ITP but revaccination may be associated with relapse in children with vaccination associated disease.
- ITP is felt to be unlikely after other early childhood vaccines.

DIAGNOSIS

The diagnosis is suggested by the finding of isolated thrombocytopenia in an otherwise healthy child. A history of a recent viral illness, especially in children under the age of 10 years, is common.

CLINICAL FEATURES

- Acute presentation of bruising, bleeding, and/or a petechial rash in an otherwise healthy child is the most common presentation.
- Mucosal bleeding, especially in the nares and gums, may be present.
- Physical examination reveals signs of bleeding, including petechiae, purpura and ecchymoses (**Figures 210-1** to **210-4**).

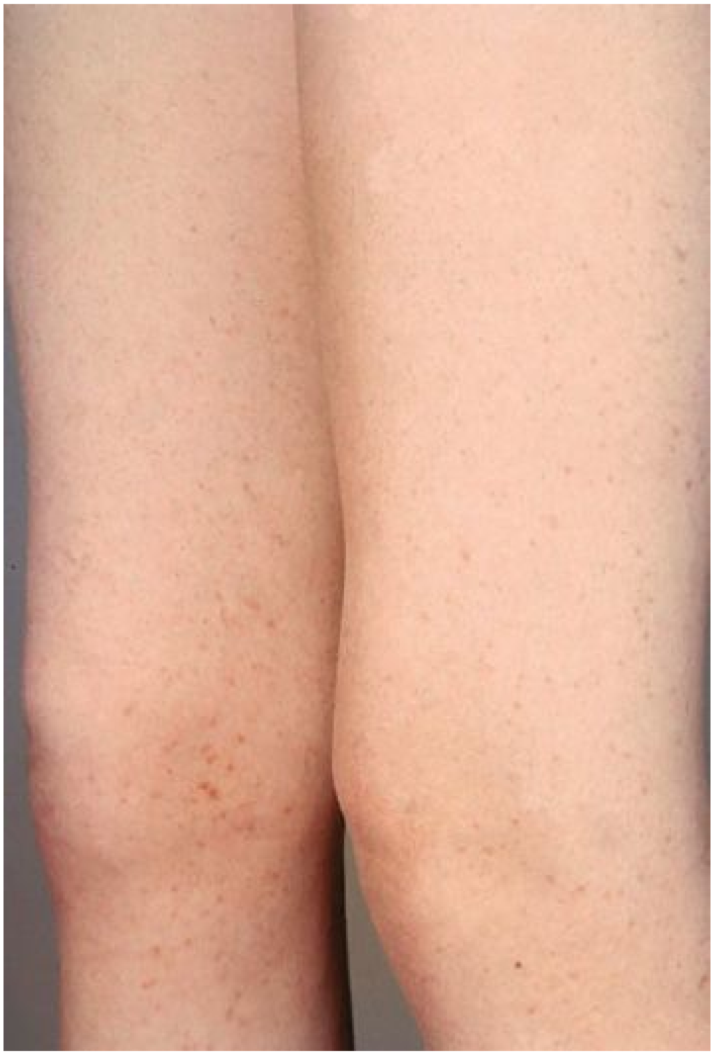

FIGURE 210-3 Numerous petechial lesions on the lower extremities of a young child with immune thrombocytopenic purpura. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files.*)

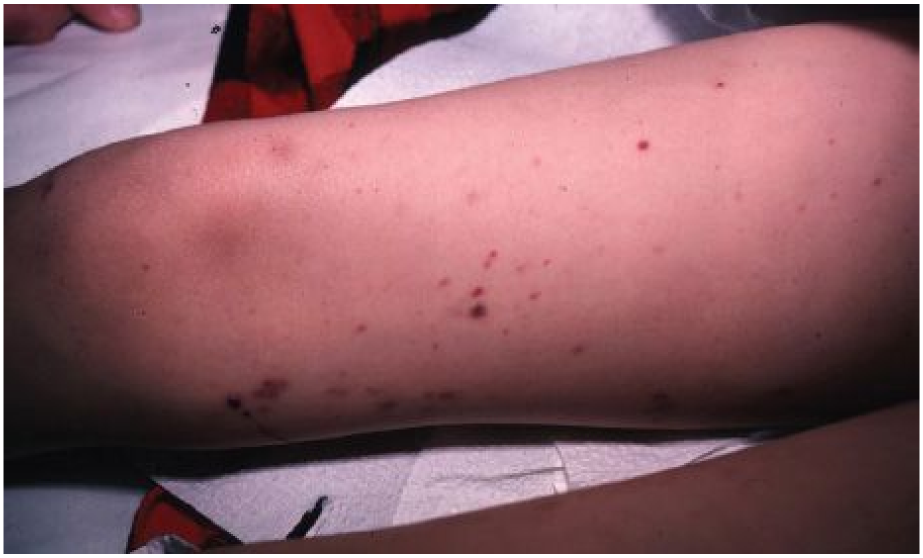

FIGURE 210-4 Petechial and purpuric lesions in a child with immune thrombocytopenic purpura following chickenpox infection. The platelet count dropped to 10,000 and the child was also bleeding from her gums. (*Used with permission from Richard P. Usatine, MD.*)

- Mucosal bleeding involving the nares, gingiva, gastrointestinal, genitourinary, or vaginal tract may be present.
- Increased menstrual flow may be present.
- Amount of bleeding is usually related to the degree of thrombocytopenia.
- Except for signs of cutaneous and mucosal bleeding, the child usually appears well. Lymphadenopathy, hepatomegaly and splenomegaly are not present, although the spleen tip may be palpated in a minority of cases.
- Serious gastrointestinal or intracranial bleeding occurs in about 1 to 3 percent of patients. These are usually associated with platelet counts of less than 20,000/microL.
- Intracranial hemorrhage is the most serious consequence of ITP and occurs in 0.1 to 1.0 percent of patients.[2,8]

LABORATORY FEATURES

- A platelet count of less than 100,000 microL is used to make diagnosis but counts of less than 20,000 microL are frequently present at the time of clinical presentation.

- The white blood cell line is normal and anemia is not present unless there is significant hemorrhage.
- Peripheral blood smear may show scattered large platelets without hypogranulation and morphologically normal red and white blood cells.
- Bone marrow (not required for diagnosis) will show normal trilineage hematopoiesis with normal or increased megakaryocytes.
- Anti-platelet antibodies may be sought on testing but the sensitivity is poor and is not required for diagnosis.
- The mean platelet volume (MPV) may be elevated but this is neither a sensitive nor specific finding.
- The prothrombin time and partial thromboplastin time are normal.

DIFFERENTIAL DIAGNOSIS

- Thrombocytopenia may be the result of decreased production or increased destruction.
- Causes of decreased production include:
    - Infection—Mainly caused by viruses.
    - Bone marrow failure—Such as with aplastic anemia.
    - Bone marrow infiltration—Such as a neoplastic process such as leukemia.
    - Medications.
    - Nutritional deficiencies—Such as B12 and folic acid.
    - Liver failure that results in decreased thrombopoietin synthesis.
    - Genetic disorders that cause impaired thrombopoiesis—Such as Thrombocytopenia-Absent Radius (TAR) syndrome, giant platelet disorder, Bernard Soulier syndrome, congenital amegakaryocytic thrombocytopenia, and Wiskott-Aldrich syndrome.
    - Most causes of decreased production of platelets also result in decreased production of at least one other cell line and this helps to differentiate

these disorders from ITP.

- Causes of increased destruction include:
  - Neonatal alloimmune thrombocytopenia (NAIT)—Occurs in neonates.
  - Drug induced (e.g., anti-epileptic agents).
  - Platelet consumption such as Hemolytic uremic syndrome (HUS), Disseminated intravascular coagulation (DIC), Thrombotic Thrombocytopenic Purpura (TTP), Kasabach-Merrit syndrome, thrombosis—These entities result in more systemic manifestations than seen with ITP.
  - Mechanical destruction.
  - Platelet sequestration associated with hypersplenism as in sickle cell, chronic liver disease, and type 2B and platelet-type von Willebrand disease.

TREATMENT AND MANAGEMENT

- The natural history of ITP is spontaneous remission, which occurs in 80 percent of children.
- Although thrombocytopenia is frequently severe at the time of diagnosis, platelet counts usually improve within 6 weeks.
- Restriction of activity, especially contact sports is recommended for all children with ITP.
- Medications with antiplatelet activity should also be avoided.
- While the goal of therapy is to increase platelets so that the risk of hemorrhage is decreased while waiting for spontaneous remission, it is unclear whether intervention actually prevents clinically-significant bleeding, including intracranial hemorrhage.
- There are no randomized studies comparing treatment to observation in the management of ITP. Thus, management is highly physician dependent.
- Given the natural history, many pediatric hematologists will observe non-bleeding patients with close follow-up.

- Some pediatric hematologists will initiate treatment for platelet counts less than 20,000 microL or 10,000 microL.
- The American Society of Hematology recommends treatment in any child with ITP and either severe bleeding or platelet count of less than 10,000 microL.[9]

MEDICATIONS

- Although improvement and spontaneous resolution usually occurs regardless of treatment, there is some evidence that the duration of symptomatic thrombocytopenia is shortened by pharmacologic therapy, such as corticosteroids, intravenous immune globulin (IVIG), or intravenous anti-Rho(D) immune globulin.[10–16] SOR Ⓒ
- If pharmacologic management is felt necessary, the following treatments are commonly used:
  - Corticosteroids—Oral prednisone therapy can be administered and weaned over several weeks as the platelet count allows. Because of the risk of pretreating a patient with a missed diagnosis of acute leukemia, many pediatric hematologists will not use corticosteroids as a first line treatment or will perform a bone marrow evaluation prior to initiating steroids. However, current guidelines recommend performing a bone marrow examination only if the history, physical examination, complete blood count, and smear evaluation are not consistent with ITP or there are any findings suggestive of an alternative diagnosis. SOR Ⓒ
  - IVIG—One to two doses of IVIG may be used as first line treatment particularly in the setting of severe acute bleeding. The response is usually within 24 hours with a continued rise over the new few days. The response may be transient lasting only a few weeks or may be sufficient as a one-time treatment. Adverse effects include headache, nausea, and aseptic meningitis, which may mimic acute intracranial hemorrhage. SOR Ⓒ
  - Winrho or Anti D antibody—Use of this treatment is limited to patients who are Rh-positive and have a spleen. Administration of Winrho causes a hemolytic anemia competitively sparing some platelets. As a result, a patient receiving Winrho usually sees a drop in hemoglobin.

  While this is usually mild, it can be severe. Winrho should not be used in patients with evidence of hemolytic anemia, such as in patients with Evan’s syndrome, or in patients with preexisting anemia.
  - Platelet transfusion is used only in the case of acute significant bleeding. The transfused platelets are quickly destroyed with the patient’s own platelets and any benefit is usually short lived.

SURGERY

- Splenectomy is reserved for patients who are refractory to other treatments, whose thrombocytopenia lasts over a year, and whose baseline platelet count is at a level where there is significant bleeding risk or the child’s quality of life is impaired.
- Immunization against encapsulated organisms, including *Haemophilus influenzae* type b, *Streptococcus pneumoniae*, and *Neisseria meningitidis*, should be completed prior to splenectomy.

REFERRAL

- Consultation with a hematologist is important in the diagnosis and management of ITP and in determining the need for admission, treatment, and follow-up.

PROGNOSIS

- Spontaneous remission occurs in about 90 percent of patients.
- Progression to chronic ITP occurs in about 10 percent of patients.
- Although approximately 20 percent of children present with mucous membrane bleeding, petechiae and bruising at the time of diagnosis, only 2.9 percent of patients will have severe hemorrhage.
- The most serious complication of ITP is intracranial hemorrhage and the incidence is very low (0.1 to 1%) with the greatest risk felt to be in

patients with platelet counts less than 10,000 microL.

FOLLOW-UP

- Close monitoring for acute bleeding is critical in the management of ITP.
- Close follow-up of platelet counts is important in monitoring spontaneous resolution, response to therapy, and risk of severe bleeding.

PATIENT EDUCATION

- The risk of bleeding and measures to limit the risk of bleeding should be discussed at length with the family.
- Discussion of the activities in which the child can participate will depend on the platelet count and risk of bleeding.

211 SICKLE CELL DISEASE

Arunkumar Modi, MD, MPH
Margaret C. Thompson, MD, PhD

PATIENT STORY

A 4-year-old boy with known sickle cell disease is brought to the emergency department with worsening pain in his thighs, lower back, abdomen, and chest. He developed pain in both thighs 2 days ago, and was treated with ibuprofen without improvement. His chest pain began today and he refused to walk or eat. In the emergency department, he was tachypneic and had an oxygen saturation by pulse oximetry of 84 percent on room air, which increased to 95 percent on 2 liters oxygen by nasal canula. A chest x-ray showed bilateral infiltrates (**Figure 211-1**). He was diagnosed with acute chest syndrome and admitted to the pediatric intensive care unit, where he was treated with intravenous fluids, pain medications, and antibiotics, and made a full recovery.

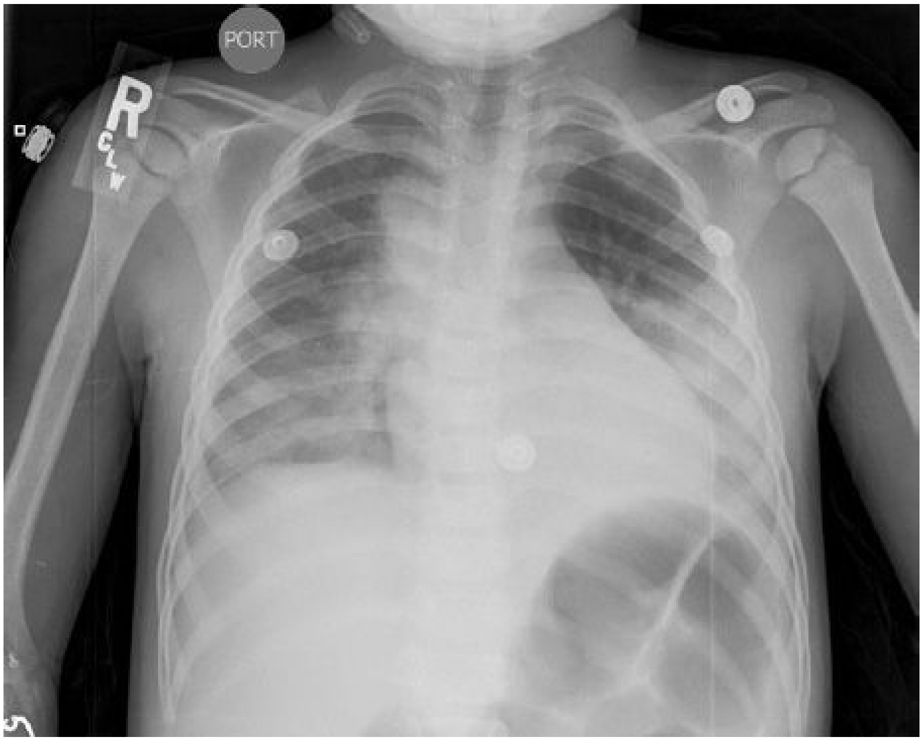

FIGURE 211-1 Acute chest syndrome on chest x-ray in a young child with sickle cell disease. (*Used with permission from Arunkumar Modi, MD, MPH.*)

INTRODUCTION

Sickle cell diseases (SCD) are a group of genetic disorders in which the affected individual has at least one copy of the genes that encode b-globin chains affected by the sickle cell mutation. This mutation causes sickling of red blood cells with resultant hypoxia and acidosis leading to a chronic progressive multisystem disorder. Sickle cell trait (SCT) is a condition in which affected individuals have one normal copy of the b chain gene and one sickle mutated copy. These individuals are generally unaffected. Hemoglobin SS disease (SCD-SS) is a condition in which affected individuals are homozygous for the sickle mutated β chain gene.[1]

SYNONYMS

- Sickle cell disease (SCD), Sickle cell anemia, Hemoglobin SS disease (SCD-SS).
- Hemoglobin SC disease (SCD-SC) and Hemoglobin *S* β-*thalassemia* (SCD-S-β Thalassemia) are types of sickle cell disease with different mutations than SCD-SS.

EPIDEMIOLOGY

- SCD affects 90,000 to 100,000 Americans.
- SCD occurs in approximately 1 out of every 500 Black or African-American births.
- SCD occurs in approximately 1 out of every 36,000 Hispanic-American births.
- SCT occurs in approximately 1 in 12 Blacks or African-Americans.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Sickle cell disease is caused by a hemoglobin structural defect that results from the substitution of valine for glutamic acid at the 6th position on the gene coding for b globin.
- The mutation causes sickling in deoxygenated cells and leads to red cell membrane rigidity, increased red blood cell adhesion to the vascular endothelium, venous occlusion, and a decreased red cell life span of 10 to 20 days.
- The point mutation in Hemoglobin C disease results from a hemoglobin structural defect that results from the substitution of lysine for glutamic

acid at the 6th position on the gene coding for b globin.

- This mutation results in persistent cellular potassium loss and cellular dehydration, causing increased blood viscosity and subsequent vaso-occlusion.
- The clinical problems associated with sickle cell diseases are a consequence of hypoxia and acidosis, which are caused by tissue ischemia that results from vaso-occlusion by irreversibly sickled red blood cells.

RISK FACTORS

- Hemoglobin S occurs frequently in areas previously exposed to falciparum malaria. This includes western coastal Africa, central Africa, India, Saudi Arabia, and the Mediterranean. It is also seen in South America.
- Hemoglobin C occurs more frequently in individuals of western African descent.
- In the US, SCD is found most commonly among African Americans.

DIAGNOSIS

CLINICAL FEATURES

Sickle cell diseases are chronic progressive multisystem disorders.[3] The acute clinical manifestations may be grouped into three categories:

- Vaso-occlusive events.
    - Vaso-occlusive crisis commonly affects bone, lung, liver, and spleen.
    - Bone infarction or ischemia of periarticular tissues is the most common form of acute pain crisis.
    - Diffuse or localized pain and tenderness, along with swelling and limited range of motion, is common.

- Dactylitis (hand-foot syndrome) is a painful swelling of the metacarpals, metatarsals and phalanges and usually occurs in children under 2 years of age (**Figures 211-2** and **211-3**).

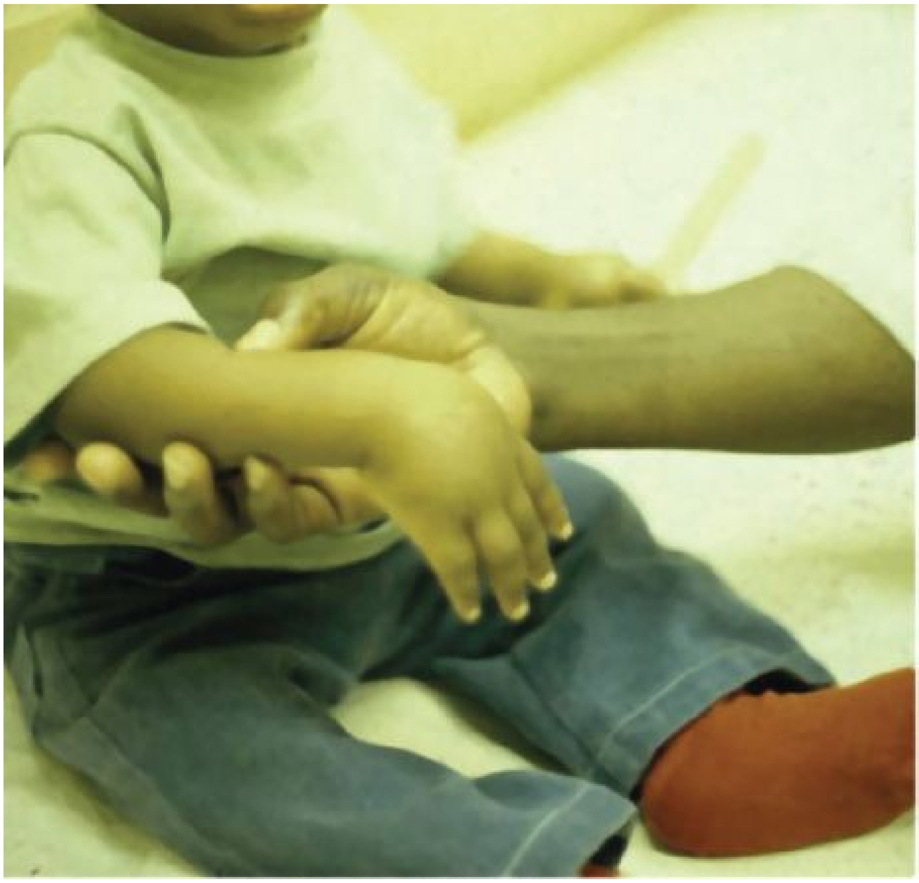

FIGURE 211-2 Dactylitis, characterized by painful swelling of the hands and fingers, in a toddler with sickle cell disease. (*Used with permission from http://www.accessemergencymedicine.com*.)

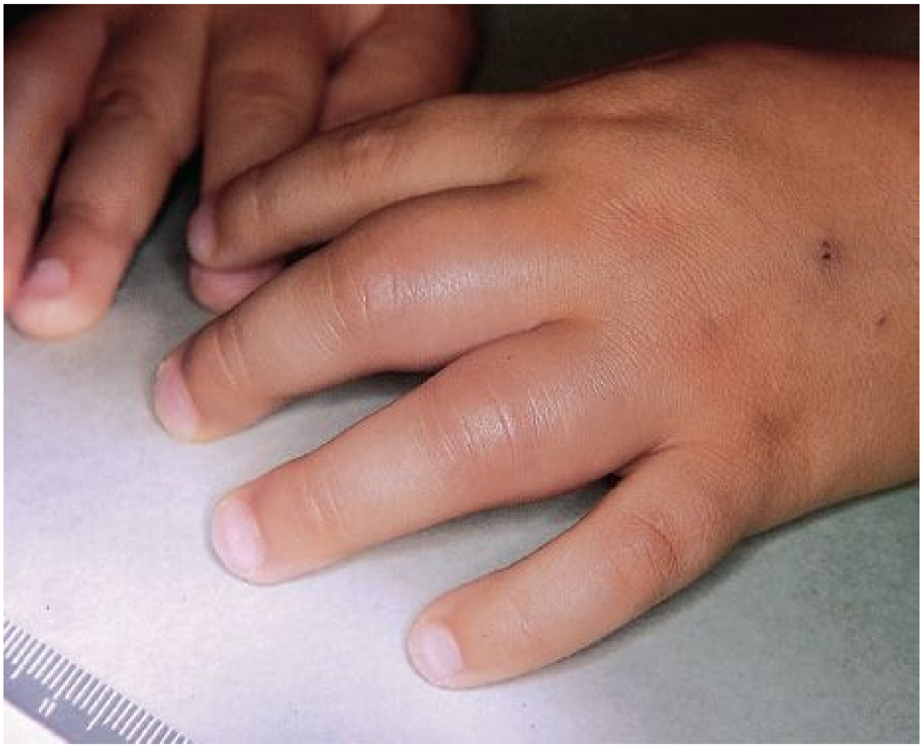

FIGURE 211-3 Acute sickle dactylitis caused by a vaso-occlusive crisis in a young child with sickle cell disease. (*Reproduced with permission from Knoop et al., The Atlas of Emergency Medicine, 3rd edition, McGraw-Hill, 2010, Figure 14-67.*)

  - Cerebrovascular events include occlusive stroke in large vessels and aneurysms in small vessels.
  - Acute chest syndrome is defined as a new infiltrate on chest x-ray associated with one or more new symptoms including fever, cough, sputum production, dyspnea, or hypoxia and may be the result of sickling in the lungs with or without infection (**Figure 211-1**).[4]
  - Priapism is a painful and persistent erection secondary to sickling in the corpora cavernosa.
- Hemolytic events.
  - Hemolytic crises occur when the patient experiences an increase in their baseline level of hemolysis.
  - Aplastic crisis occurs when there is temporary suppression of the markedly increased production of reticulocytes in the marrow. It can be associated with many viral and bacterial infections, but is most frequently associated with parvovirus B19 infection (**Figure 211-4**).

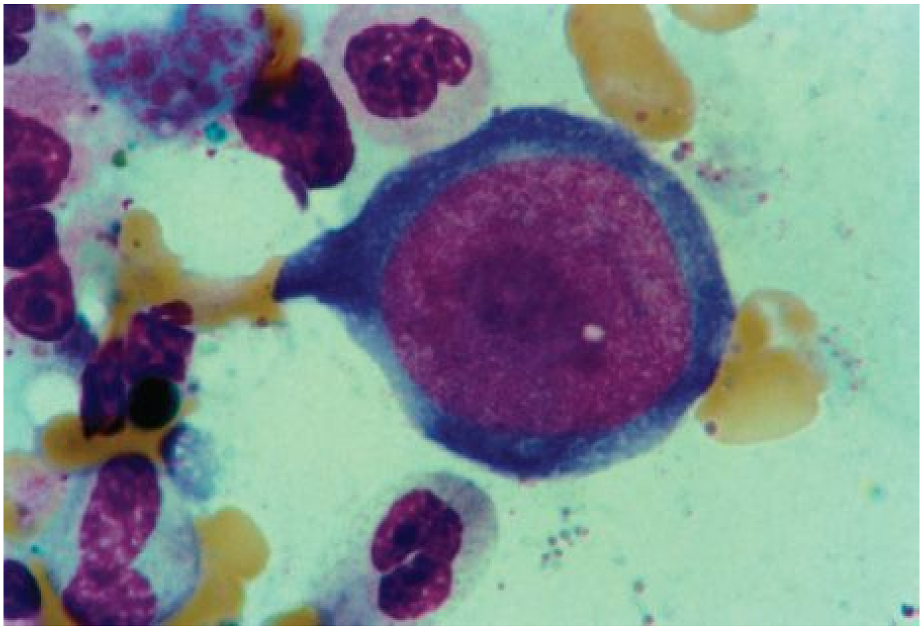

FIGURE 211-4 Giant pronormoblast seen on peripheral smear of a patient with aplastic crisis due to parvovirus B19. This represents an early erythroid cell that has been infected with this virus, which has a predilection to infect erythroid progenitor cells. (*Used with permission from Camille Sabella, MD.*)

  - Cholecystitis occurs due to gallstones and results from persistent hemolytic anemia.
  - Splenic sequestration is the acute pooling of blood within the spleen with a resultant precipitous drop in the hemoglobin level and/or platelet count.
- Infectious Events.
  - Patients with SCD are at increased risk for infection as a result of functional asplenia. They are particularly susceptible to infection with encapsulated organisms, such as *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Neisseria meningitides*.
  - Overwhelming sepsis from pneumococcal infection was especially common prior to universal antimicrobial prophylaxis in young children and a major cause of early death in young children with SCD.[5]
  - Osteomyelitis most often occurs at the site of necrotic segments of bone, and is most frequently caused by *Salmonella* and *Staphylococcus aureus*.

- Chronic complications of sickle cell diseases are the result of persistent ischemic damage and include pulmonary, cardiac, renal, central nervous system, orthopedic, urinary, and ophthalmologic complications.
- Decreased growth, frontal bossing of the forehead (**Figure 211-5**), signs of chronic anemia (**Figure 211-6**), and delayed puberty are possible manifestations of long standing sickle cell disease.

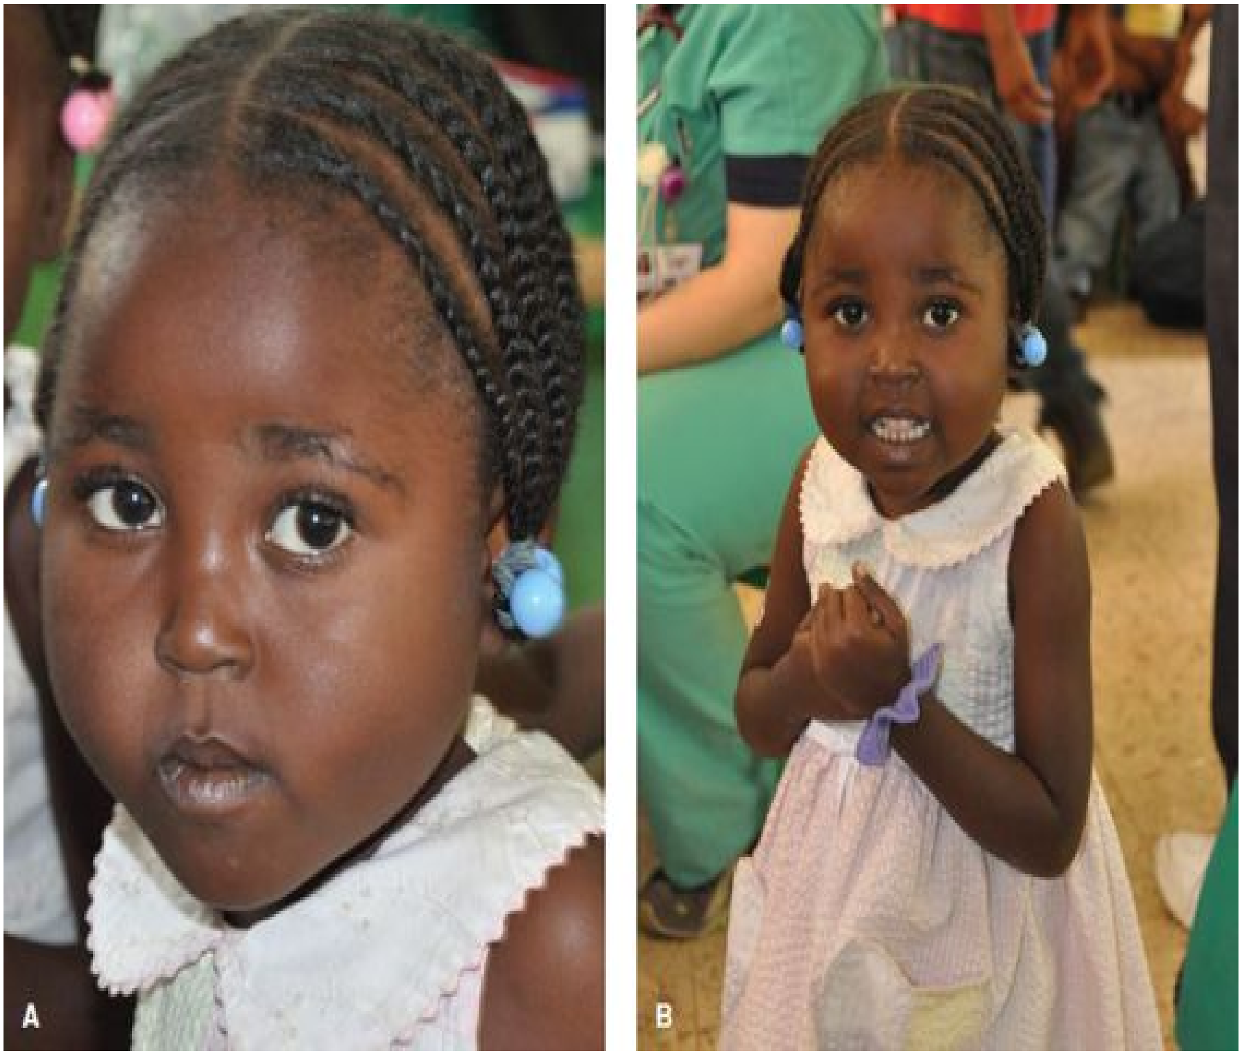

FIGURE 211-5 Frontal bossing (**A**) and stunted growth (**B**) in a young child from Haiti with untreated sickle cell disease. (*Used with permission from Richard P. Usatine, MD.*)

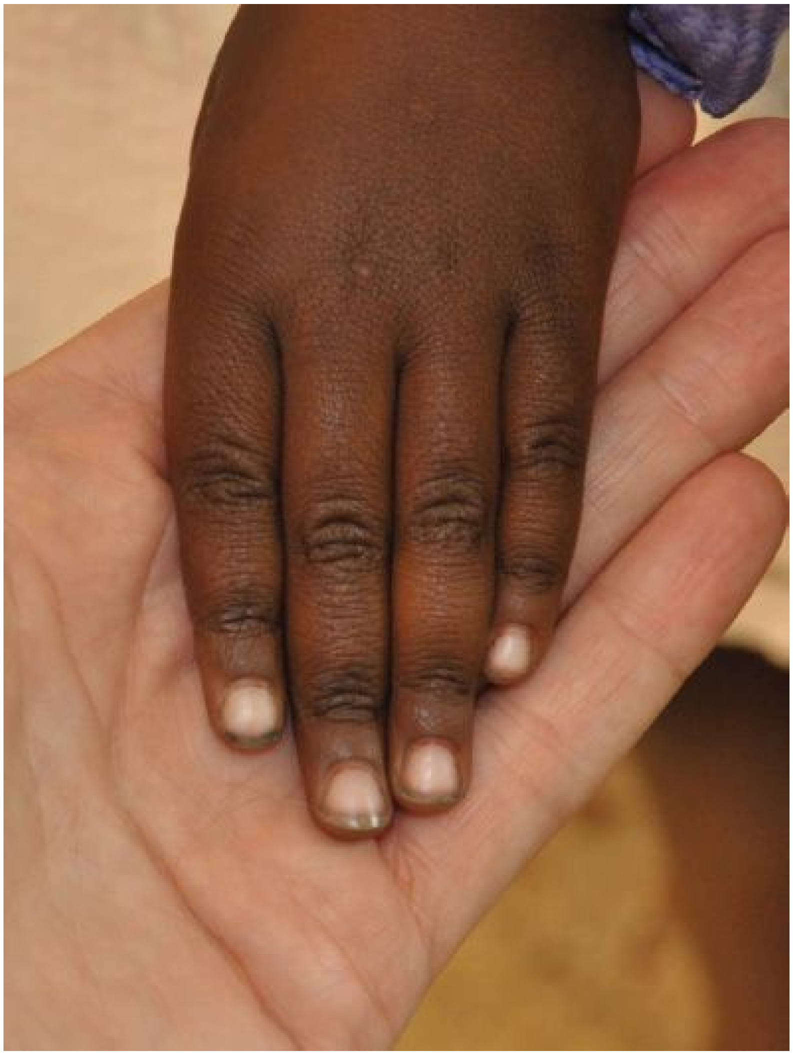

FIGURE 211-6 White nail beds in the same patient as in Figure 211-5. (*Used with permission from Richard P. Usatine, MD.*)

- Patients who have received chronic red cell transfusions are at risk for organ damage from iron overload.

LABORATORY TESTING

- The diagnosis of SCD is confirmed by hemoglobin electrophoresis.
- As of May 1, 2006, in the US, all states provide universal newborn screening for sickle cell disease.[6]

- Thus, most patients in the US are diagnosed at birth by newborn screening, which shows the presence of hemoglobin S.
- Neonatal screening for sickle cell disease reports the level of expression of the different hemoglobins. In individuals without sickle cell, at birth, there is more fetal hemoglobin (Hb F) than adult hemoglobin (Hb A) and the screening would report “FA.” Individuals with sickle cell disease syndromes show hemoglobin S, hemoglobin F, and depending on the syndrome possibly hemoglobin A or hemoglobin C.[3]
- A simple peripheral smear of blood will demonstrate drepanocytes, which are the sickled red blood cells (**Figure 211-7**). Microcytosis and target cells are also seen in patients with SCD-Sb Thalassemia.

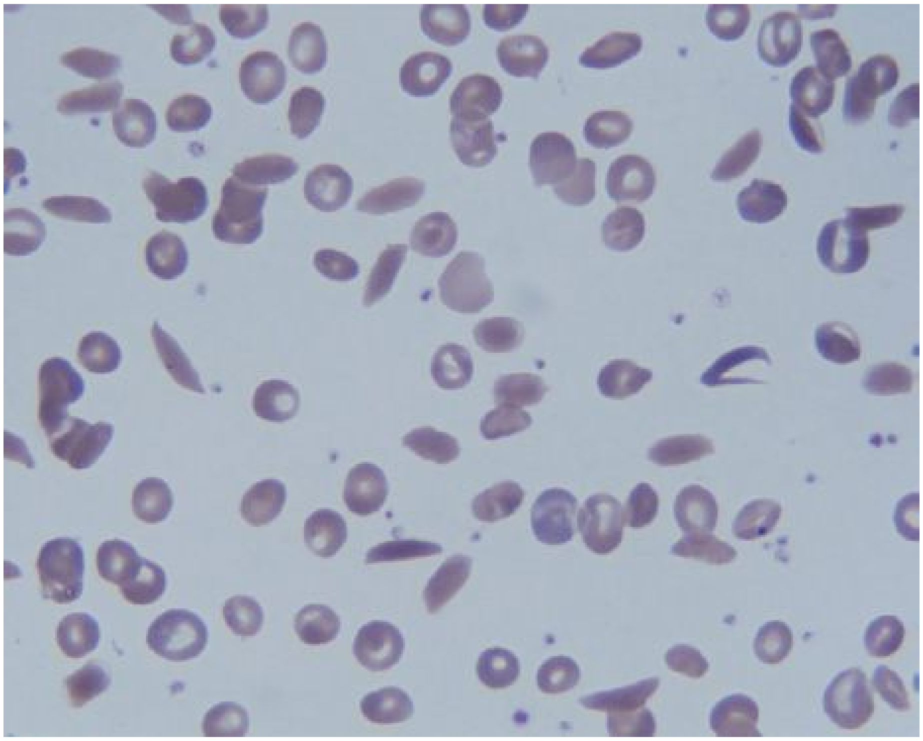

FIGURE 211-7 Numerous crescent shaped and sickled cells on a blood smear from a patient with sickle cell disease. (*Used with permission from Gary Ferenchick MD.*)

IMAGING

- Plain bone x-rays are helpful in detecting bony infarcts or osteomyelitis (**Figure 211-8**). Differentiating infarct from osteomyelitis can be difficult.

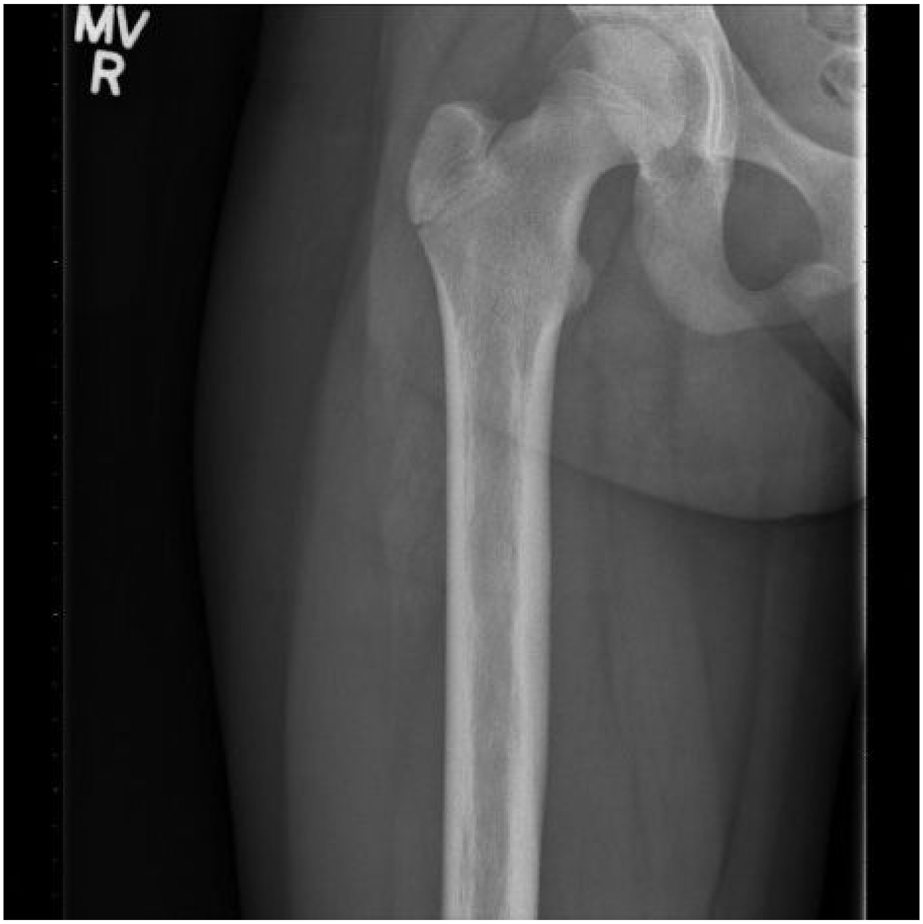

FIGURE 211-8 Femoral bone infarcts on plain x-ray in a 14-year-old girl with sickle cell disease. Note the “bone within bone” appearance present in the proximal and mid-femoral shaft. (*Used with permission from Margaret C. Thompson, MD, PhD.*)

- Chest x-ray is used to diagnose acute chest syndrome (**Figure 211-1**).
- Transcranial Doppler Studies (TCD) is used to measure vascular velocities and may be helpful in evaluating the risk for cerebral stroke. This study should be done annually.[1,1]
- MRI of bone should be performed when there is concern for avascular necrosis or osteomyelitis (**Figure 211-9**).

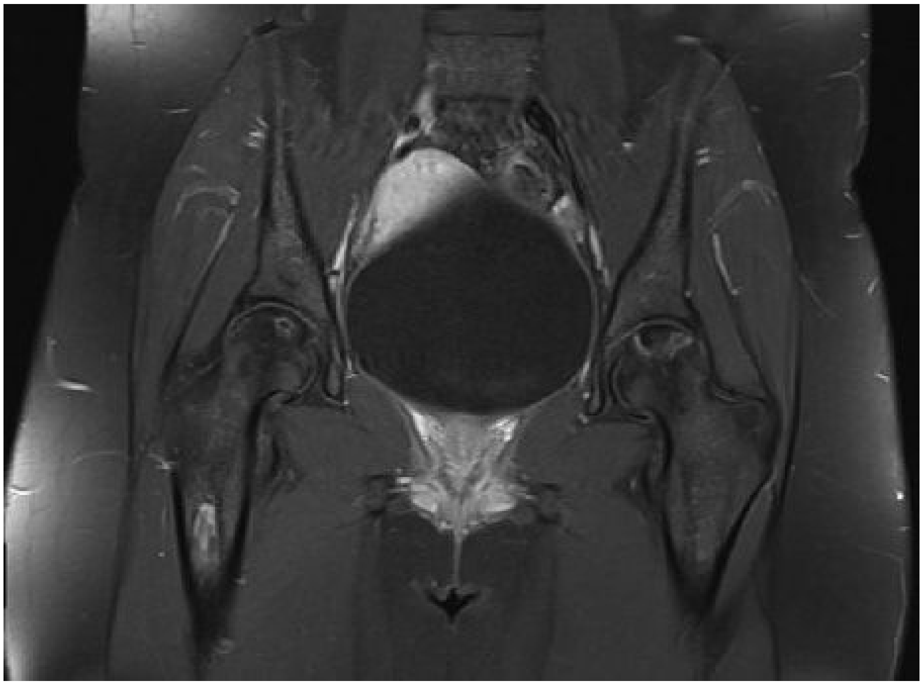

FIGURE 211-9 Bilateral femoral head osteonecrosis on MRI in a teenager with sickle cell disease. (*Used with permission from Arunkumar Modi, MD, MPH.*)

- Echocardiogram is used for monitoring cardiac complications related to chronic anemia.

DIFFERENTIAL DIAGNOSIS

- In addition to SCT and SCD-SS disease, there are three conditions with varying degrees of clinical severity associated with sickle mutated b-chain genes.
    - Two of these conditions involve a combination of sickle cell disease and b thalassemia. In these disorders, one copy of the b-chain gene contains the sickle cell mutation while the other copy contains a qualitative defect resulting in normal but decreased (or absent) b chains from that gene. These disorders are *Hemoglobin S* b-*thalassemia plus* (SCD-Sb$^+$) where there is some normal Hemoglobin A produced in addition to the

  Hemoglobin S and *Hemoglobin S* b-*thalassemia null* (SCD-Sb^0) where there is no normal Hemoglobin A.
  - *Hemoglobin SC* (SCD-SC) disease is a condition in which affected individuals have one sickle mutated copy of the b chain gene and one copy with a mutation with Hemoglobin C.

- The clinical manifestations of these disorders may be quite variable. In general, the higher the percentage of hemoglobin S, the more clinically severe the disease. Thus, SCD-SS and SCD-Sb^0 tend to be clinically most severe while SCD-SC and SCD-Sb+ tend to be less severe.

MANAGEMENT

- The only cure for SCD is hematopoietic stem cell transplant, which has been used successfully in patients with SCD. However, because of significant complications and limitations associated with this intervention, it is currently not the standard of care for all patients.[3]
- The screening of newborns for SCD has led to early diagnosis. Early medical intervention and education and care in specialty clinics have decreased morbidity and mortality in individuals with SCD.
- Routine health maintenance, with an emphasis on nutrition, education of families, infection prophylaxis, rapid response to signs of infection, and anticipatory guidance has significantly increased the lifespan of individuals with SCD.
- Individuals with sickle cell disease should receive care at a comprehensive sickle cell clinic under the guidance of a hematologist.[3]

NONPHARMACOLOGIC

- All patients with SCD should be vaccinated against *Haemophilus influenzae* type b, meningococcal, and 23-valent pneumococcal polysaccharide vaccines, in addition to routine age-appropriate vaccinations. They should also receive annual influenza vaccine.[1,7, 8] SOR Ⓐ

- Simple blood transfusions and exchange transfusions may be required intermittently, especially for acute chest syndrome, stroke, splenic sequestration, and prior to anesthesia.[3] SOR Ⓑ
- Chronic simple transfusions, chronic exchange transfusions and apheresis are used in high-risk sickle cell patients to prevent or decrease the risk of long-term morbidity. SOR Ⓒ
- Patients on regular transfusion protocol are increased risk for acquiring transfusion related iron overload and the development of allo-antibodies.
- Patients with SCD should maintain good hydration and may require cautious hydration when admitted to the hospital.

MEDICATIONS

- Amoxicillin or penicillin prophylaxis prevents pneumococcal sepsis in young children with SCD and should be given to all patients starting at 2 months of age and continued until 5 years of age.[9–11] SOR Ⓐ
- Folic acid supplementation is needed to meet the demands of increased red cell production.[3] SOR Ⓑ
- Hydroxyurea increases the production of hemoglobin F and is beneficial in preventing complications of SCD.[12–14] SOR Ⓐ
- Patients with fever should be evaluated and treated empirically with intravenous antibiotics until infection has been ruled out.[3]
- Patients with acute pain crises and dactylitis may require non-steroidal anti-inflammatory agents and opioids. When possible, they should be treated at home, but frequently require admission for intravenous administration.

SURGERY

- Surgical intervention may be necessary for treatment of complication, such as avascular necrosis and cholecystitis.

REFERRAL

- Referral to a center specializing in blood disorders is recommended for all patients with SCD at the time of diagnosis.

PREVENTION AND SCREENING

- All infants are screened at birth for sickle cell disease.[6]
- Screening for complications should be followed as per national sickle cell guidelines.[3]

PROGNOSIS

- The median age at death for SCD-SS has improved greatly and is approximately 42 years for males and 48 years for females. For SCD-SC, median age at death for males is 60 years and for females is 68 years. Symptomatic patients are more likely to die early. Hemoglobin F percentage is a positive predictor for survival.[15]

FOLLOW-UP

Patients with SCD should be seen at least once per year by a hematologist and once a year by their primary care physicians.

PATIENT EDUCATION

- Families and patients should be counseled regarding the importance of follow-up care and seeking immediate care whenever there are signs of infection.

Margaret C. Thompson, MD, PhD

PATIENT STORY

A 3-year-old girl presents to the emergency department with decreased appetite, fatigue, and irritability for 1 month. She has periorbital ecchymoses (raccoon eyes) without a history of trauma (**Figure 212-1**). A CT scan is ordered to look for a neuroblastoma. The CT scan of her orbit shows bony erosions and periosteal reaction of her orbits. An MRI scan of her abdomen reveals a primary adrenal tumor. A biopsy is performed of the adrenal tumor confirming the diagnosis of neuroblastoma. She responds well to several courses of chemotherapy.

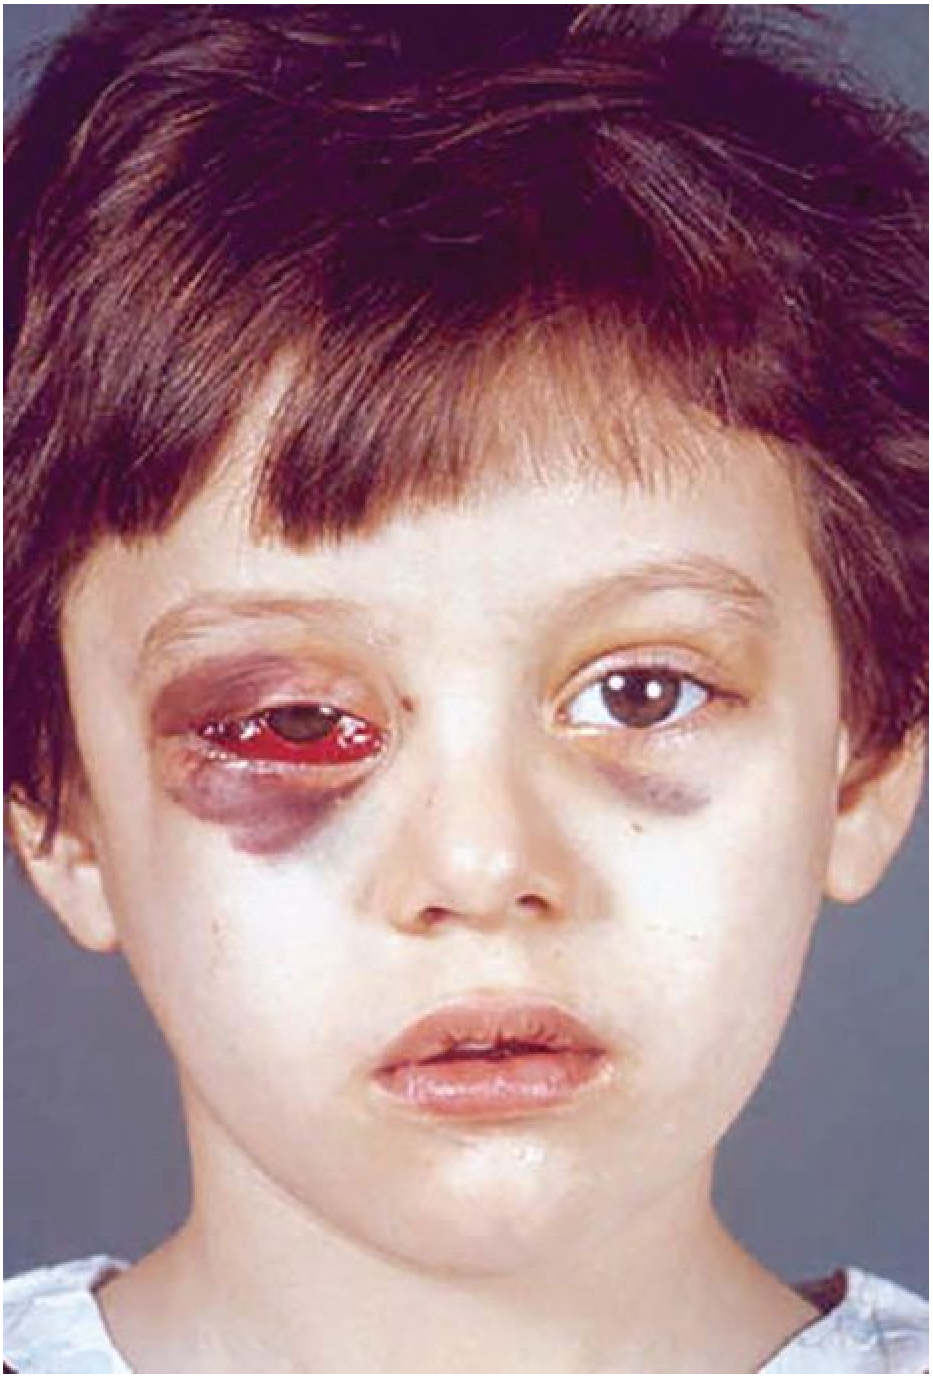

FIGURE 212-1 Neuroblastoma presenting with periorbital ecchymoses (raccoon eyes) in a 3-year-old girl. In this case, the eye tumor is metastatic disease from a primary neuroblastoma of the adrenal gland. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files.*)

INTRODUCTION

Neuroblastoma is a malignant embryonal childhood tumor of the sympathetic nervous system derived from primordial neural crest cells.

EPIDEMIOLOGY

- Neuroblastoma is the most common malignant extracranial solid tumor of childhood and accounts for 8 to 10 percent of childhood cancers in children under 15 year of age.
- There are between 600 to 650 cases each year in the US.
- Occurs in approximately 14/100,000 live births.
- Occurs in approximately 0.8 to 1/100,000 children under age 15 per year.
- It is the most common cancer of infancy (<12 months; 58/1,000,000 infants per year).
- Median age at diagnosis is 17 to 22 months. Ninety percent of cases are diagnosed by 5 years of age. It is rare after the age of 10 years.
- Accounts for approximately 15 percent of all pediatric cancer fatalities.
- More common in Caucasians.
- Occurs slightly more frequently in boys that girls (1.2:1).

ETIOLOGY AND PATHOPHYSIOLOGY

- Neuroblastic tumors arise from the primitive sympathetic ganglion cells and include neuroblastomas, ganglioneuroblastomas, and gangliomas. They may arise anywhere along the sympathetic ganglia and in the adrenal medulla. The etiology of neuroblastoma in most cases remains unknown, but certain recurrent molecular abnormalities have been found including amplification of the oncogene MYCN in approximately 20 percent of tumors, deletion of 1p36 and 11q, and in patients under 18 months of age.[2]

- Familial neuroblastoma accounts for 1 to 2 percent of all cases and demonstrates an autosomal dominant pattern of inheritance with incomplete penetrance. It is associated with an earlier presentation, and bilateral adrenal or multifocal disease. It has been linked to mutations in the *Phox2B* and *ALK* genes.[4]
- Mutations in Phox2B mutations are also associated with Haddad's syndrome, a rare congenital neurocristopathy that includes Hirschsprung disease, congenital central hypoventilation, and sympathetic ganglia tumors.
- Neuroblastoma may be detected in utero on prenatal ultrasound and often regresses or differentiates without intervention.

RISK FACTORS

- Epidemiologic studies have failed to show identifiable environmental etiologic risk factors.[1]
- The consistent rates of neuroblastoma suggest a major role of genetic factors.[4]

DIAGNOSIS

Clinical presentation depends on the site of the primary tumor, the extent of disease as well as the presence of a paraneoplastic syndrome. Approximately 65 percent of patients have metastatic disease at the time of diagnosis.

CLINICAL FEATURES

- Children with adrenal primary tumors may present with an asymptomatic palpable abdominal mass along with constipation, hypertension due to renal artery compression, and early satiety.
- Patients with neuroblastoma originating along the lower sympathetic chain may present with evidence of cord compression such as urinary incontinence and decreased lower extremity movement.
- Patients with a thoracic primary tumor may present with superior vena cava syndrome, and those with a tumor originating in the superior cervical ganglion with Horner's syndrome (**Figure 212-2**).

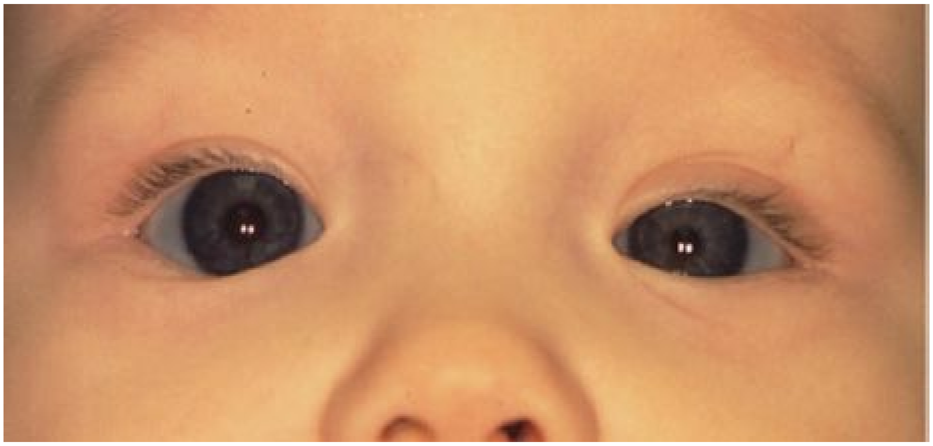

FIGURE 212-2 Horner syndrome in a patient with neuroblastoma. Note the smaller pupil and ptosis of the left eye. (*Used with permission from Access Pediatrics, Lueder, Pediatric Practice Ophthalmology, Figure 18-1, McGraw Hill.*)

- Evidence of metastatic disease depends on the location and may include periorbital ecchymoses (raccoon eyes; **Figures 212-1** and **212-3**) and bone pain with bone metastasis, hepatomegaly, and "blueberry muffin" spots. Extensive bone marrow involvement may result in signs and symptoms of anemia and thrombocytopenia (**Figure 212-4**).

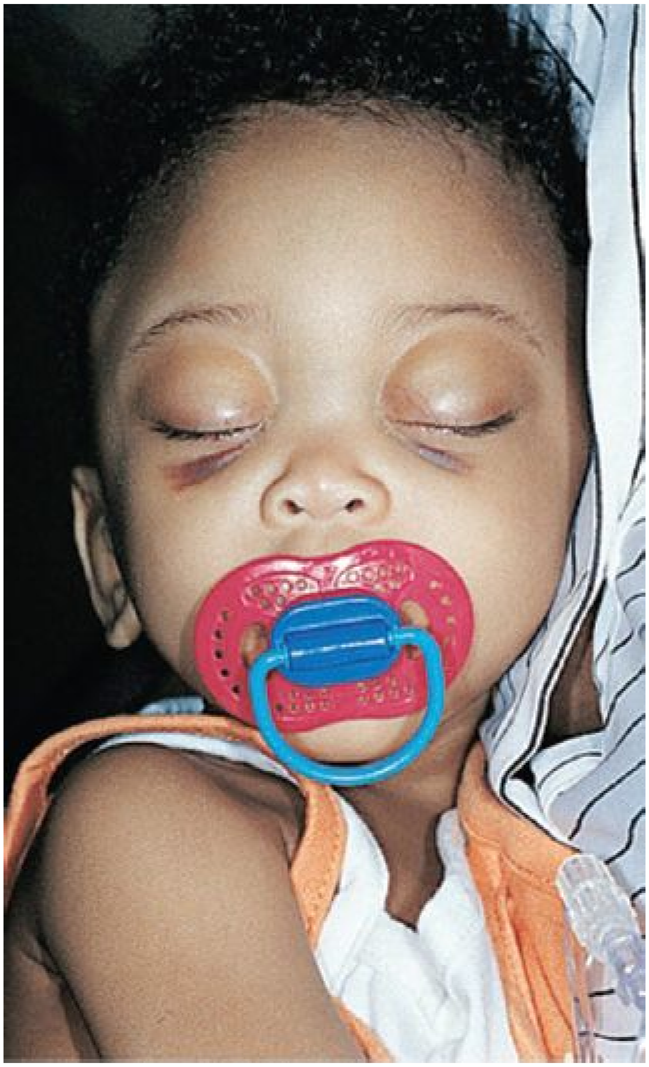

FIGURE 212-3 Bilateral periorbital ecchymoses (raccoon eyes) in an 11-month old infant with neuroblastoma. (*Used with permission from Binita R. Shah, MD, Atlas of Pediatric Emergency Medicine*, *Figure 8-4*, *www.accessemergencymedicine*, *McGraw Hill.*)

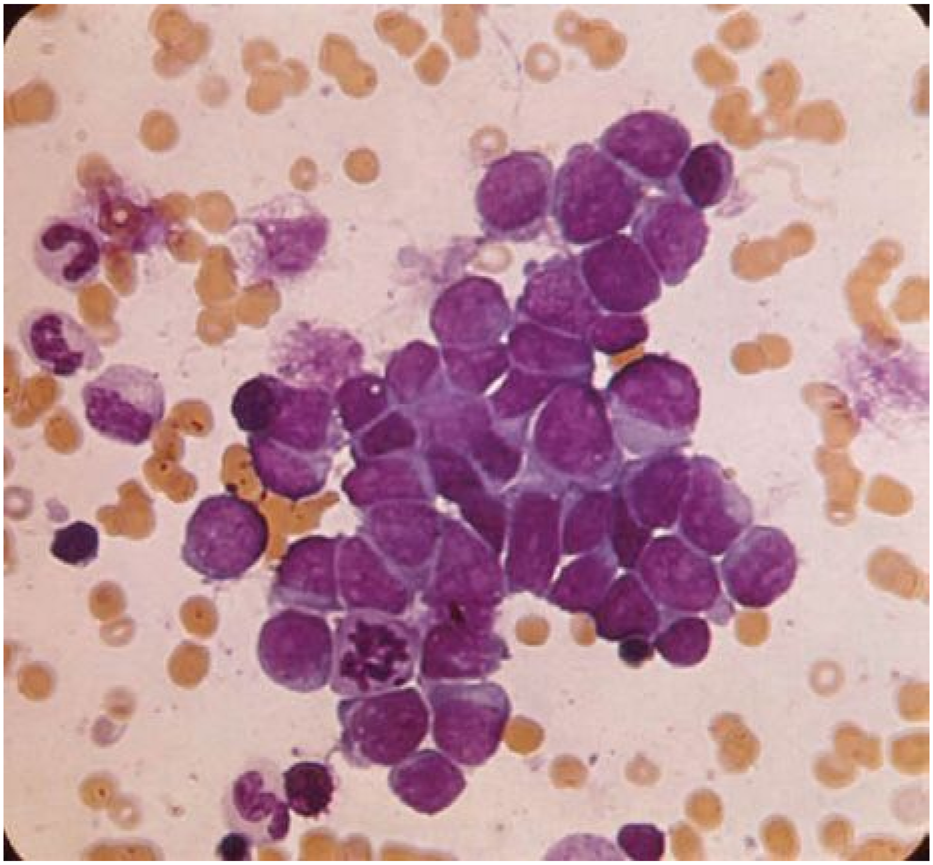

FIGURE 212-4 Neuroblasts in the bone marrow of a young child with metastatic neuroblastoma. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files.*)

- Systemic symptoms include weight loss, irritability, and fever.
- Patients may also present with hypertension as a result of catecholamine production by the tumor and diarrhea as result of vaso-intestinal peptide production by the tumor.
- Opsoclonus/myoclonus is an autoimmune paraneoplastic syndrome associated with neuroblastoma. Opsoclonus is rapid, involuntary, multivectorial, unpredictable, and conjugate fast eye movements.
- Infants under a year of age may present with wide spread metastatic disease including subcutaneous tumor nodules and extensive liver involvement but with limited bone marrow disease and a small primary tumor. This presentation is termed stage "4S" and does not include

patients with bone or other metastatic lesions. These patients have a surprisingly good outcome despite extensive disease at diagnosis.

DISTRIBUTION

- Tumors can arise from any site along the sympathetic nervous system chain including the adrenal gland. Approximately 65 percent of neuroblastomas occur in the abdomen with 40 percent being in the adrenal and 25 percent occurring in the paraspinal ganglia. Fifteen percent of neuroblastomas occur in the thorax presenting as a posterior mediastinal mass; 5 percent present in the pelvic region; 3 percent present as cervical tumors; and 12 percent elsewhere.
- Infants are more likely to present with thoracic and cervical primary tumors while children over one year of age are more likely to present with abdominal primaries.
- Metastatic spread, which is more common in children older than one year of age at diagnosis, occurs through both lymphatic and hematogenous routes. The most common sites are regional or distant lymph nodes, bone (long bones and skull), bone marrow, liver, and skin.[2,4] Lung and brain metastases are rare and occur in less than 3 percent of cases.[4]

LABORATORY TESTING

- Urine should be sent for measurement of the urine catecholamines, vanillylmandelic acid (VMA), and homovanillic acid (HVA), which are secreted by the majority of neuroblastomas.
- Complete blood count should be evaluated for evidence of bone marrow involvement.
- Complete metabolic panel should be performed to evaluate for evidence of tumor lysis syndrome as well as liver and kidney function.
- Biopsy is necessary for definitive diagnosis and risk-based staging. It may be taken from the primary tumor or a metastatic site. Histology will show a small round blue cell tumor. The tumor will be graded as

favorable or unfavorable based on degree of neuroblastic differentiation and mitotic index.[22,33]

- Bilateral bone marrow biopsies must be obtained to evaluate for evidence of metastatic disease in the bone marrow (**Figure 212-4**).

IMAGING

- CT and/or MRI are done to locate the primary site. Primary tumors are not encapsulated and often displace important structures (**Figure 212-5**).

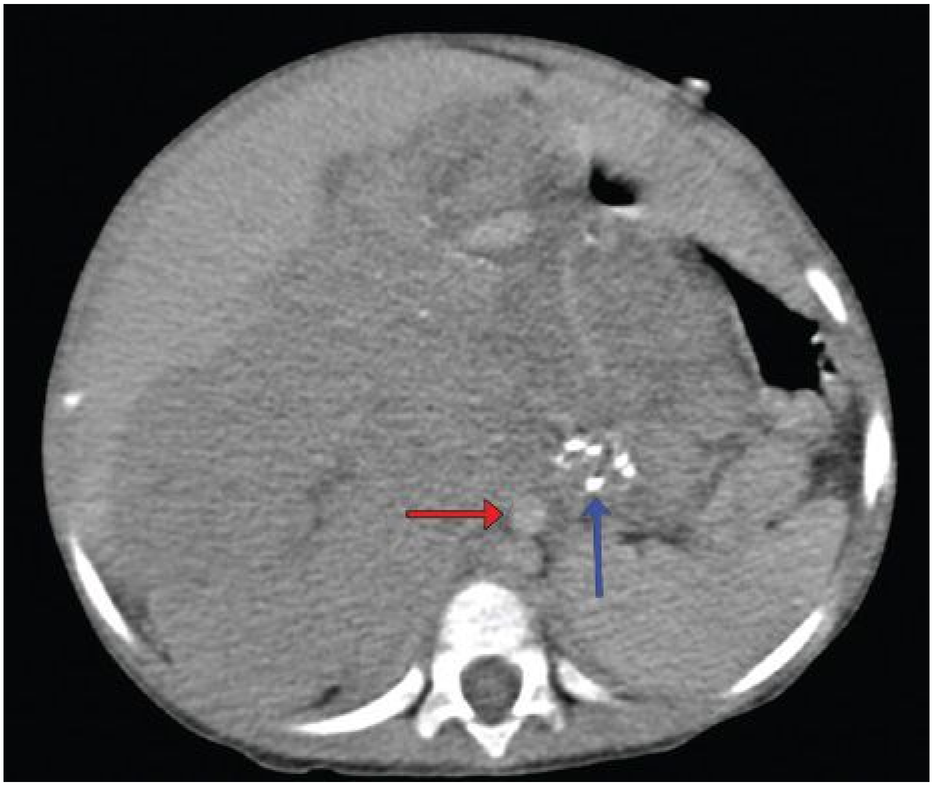

FIGURE 212-5 Large heterogenous upper abdominal mass on CT scan of a 2-year-old girl with neuroblastoma. The mass does not have well defined borders, displaces and encases the aorta (red arrow), compresses the kidneys, and has punctate calcifications (blue arrow), which are typical features of neuroblastoma. (*Used with permission from Margaret C. Thompson, MD, PhD.*)

- CT of the abdomen and pelvis to evaluate for evidence of metastatic disease if the adrenal is the primary site.
- Metaiodobenzylguanidine (MIBG) scan is a nuclear medicine study using the radio-isotope iodine-123-meta-iodobenzylguanidine. MIBG is specifically taken up by norepinephrine transporters on catecholamine producing tumors. MIBG is very sensitive and specific for catecholamine producing tumors and should be performed to evaluate for sites of metastatic disease and to evaluate the primary tumor for MIBG sensitivity.[5]
- Bone scan may be performed but is frequently replaced by the MIBG scan if the latter is positive.

DIFFERENTIAL DIAGNOSIS

- Wilm’s Tumor—Usually presents as an asymptomatic flank mass in a well appearing child (see Chapter 213, Wilms Tumor).
- Adrenal hemorrhage—Usually associated with overwhelming sepsis or significant trauma.
- Rhabdomyosarcoma—Soft tissue malignant tumor of skeletal muscle. Biopsy of tissue will distinguish this from neuroblastoma.

MANAGEMENT

- Treatment is risk stratified based on the age of the patient at diagnosis, stage of disease at diagnosis, histology of the tumor prior to treatment, and presence or absence of recurrent cytogenetic changes including amplification of NMYC in all tumors and DNA ploidy for children under 18 months at diagnosis.
- Adrenal tumors are sometimes identified in utero and perinatally. These tumors may spontaneously regress and are frequently observed with

resection performed only if they grow or the patient becomes symptomatic.

- Patients with 4S disease without MYCN amplification frequently have spontaneous regression of their disease. In cases where the patient is symptomatic, such as with large adrenal primary tumors causing hepatomegaly and respiratory compromise, chemotherapy, and/or low dose radiation may be used.[3]
- Low-risk patients include those with stage 1 disease regardless of biologic factors and those with stage 2 disease with favorable biologic factors. These patients may be treated with surgery alone with a low risk for relapsed. Those who do relapse are effectively salvaged with chemotherapy. Survival for these patients is greater than 95 percent.[22,44]
- The intermediate risk group includes patients with non-metastatic disease but with <50 percent resection of the primary tumor (including biopsy only) and whose tumor is MYCN non-amplified. Patients with metastatic disease under 18 months of age whose tumor shows favorable biologics may also be treated as intermediate risk. Treatment includes surgical resection plus radiation to residual disease along with 2 to 8 cycles of chemotherapy. Outcomes for this group of patients is greater than 95 percent.[2]
- With the exception of children with stage 1 disease, any patients whose tumor is MYCN amplified is treated on a high-risk protocol and requires multimodality therapy including intensive induction chemotherapy, surgery, consolidation therapy with high dose chemotherapy and stem cell rescue, radiation, immune therapy, and cis-retinoic acid as a differentiating agent.[22,33] Despite such aggressive treatment, survival is only 40 to 50 percent with significant treatment associated morbidities.

SURGERY

Surgery for removal of the primary tumor is required in all but perinatal and disease classified as 4S.

PREVENTION AND SCREENING

- Several studies have evaluated the effectiveness of routine screening for neuroblastoma in infants. While these studies doubled the incidence, because they detect tumors with good prognosis, there was no reduction of mortality rates due to neuroblastoma. Thus, routine screening for neuroblastoma is not recommended.[2]

PROGNOSIS

- Low risk neuroblastoma—5 year survival >95 percent.
- Intermediate risk neuroblastoma—5 year survival rate >95 percent
- High risk neuroblastoma—Long-term survival rate 30 to 40 percent.

213 WILMS TUMOR

Stefanie Thomas, MD
Margaret C. Thompson, MD, PhD

PATIENT STORY

A 6-year-old previously healthy boy presented to his pediatrician with abdominal fullness for one month. The child had no abdominal or gastrointestinal complaints. On examination, he had left-sided abdominal firmness. An ultrasound revealed a mass that appeared to originate from the kidney. He was referred to pediatric oncology. CT scan of the abdomen confirmed a large kidney mass with displacement of the structures within the left abdomen, most consistent with a Wilms tumor (**Figure 213-1**). Work-up for metastatic disease, including a chest CT was negative. The patient underwent nephrectomy (**Figure 213-2**). Pathology of the mass revealed Wilms tumor with favorable histology. The child received chemotherapy and has been tumor-free.

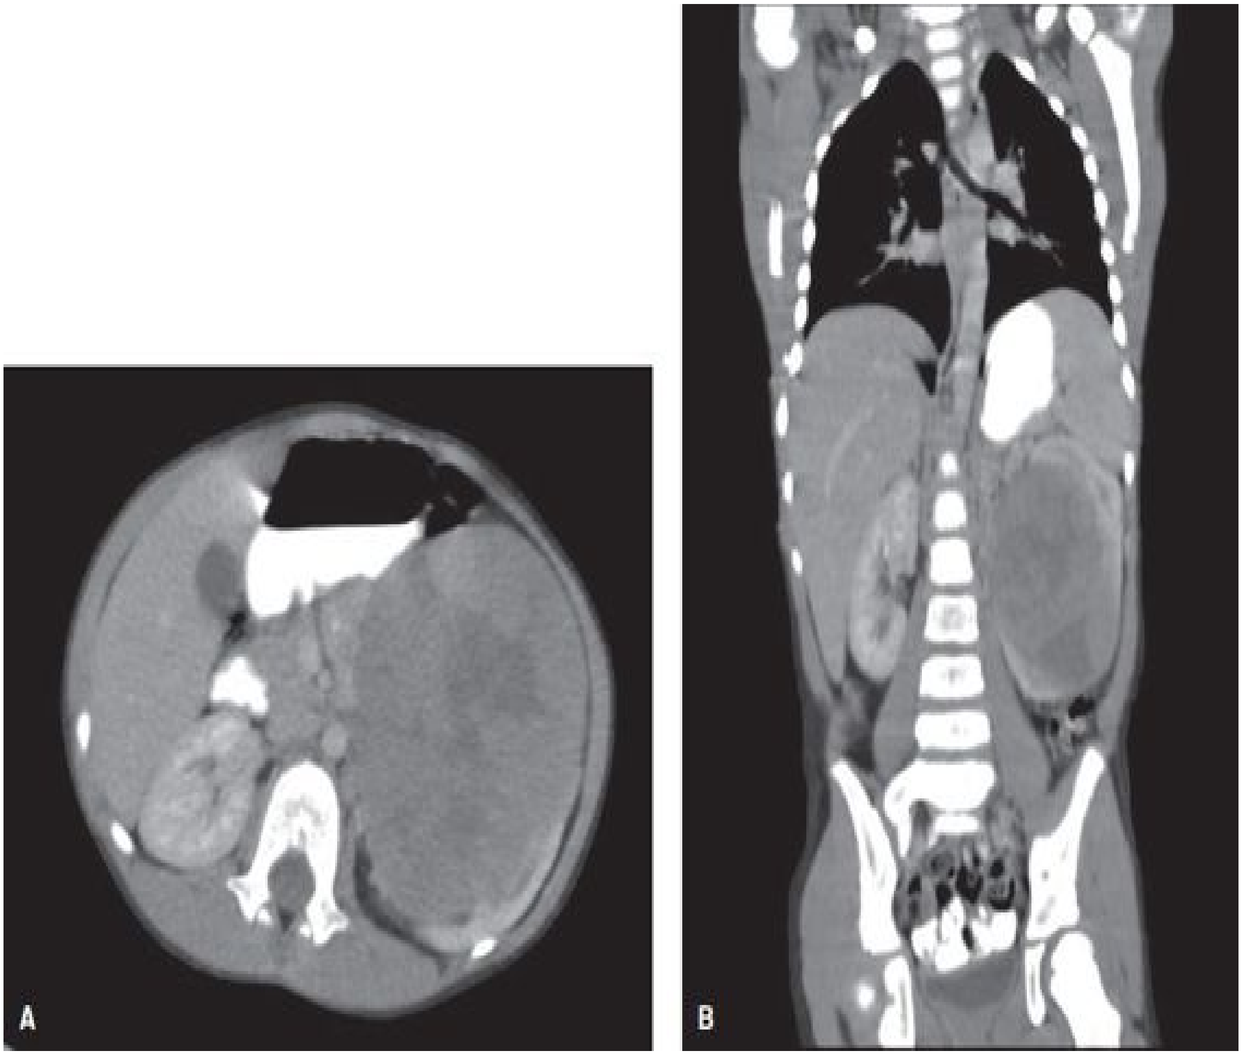

FIGURE 213-1 Large left-sided renal mass that is well circumscribed and without calcifications on transverse (**A**) and coronal (**B**) CT scan of the abdomen, in a 6-year-old boy with Wilms tumor. Note the normal appearing right kidney. (*Used with permission from Stefanie Thomas, MD.*

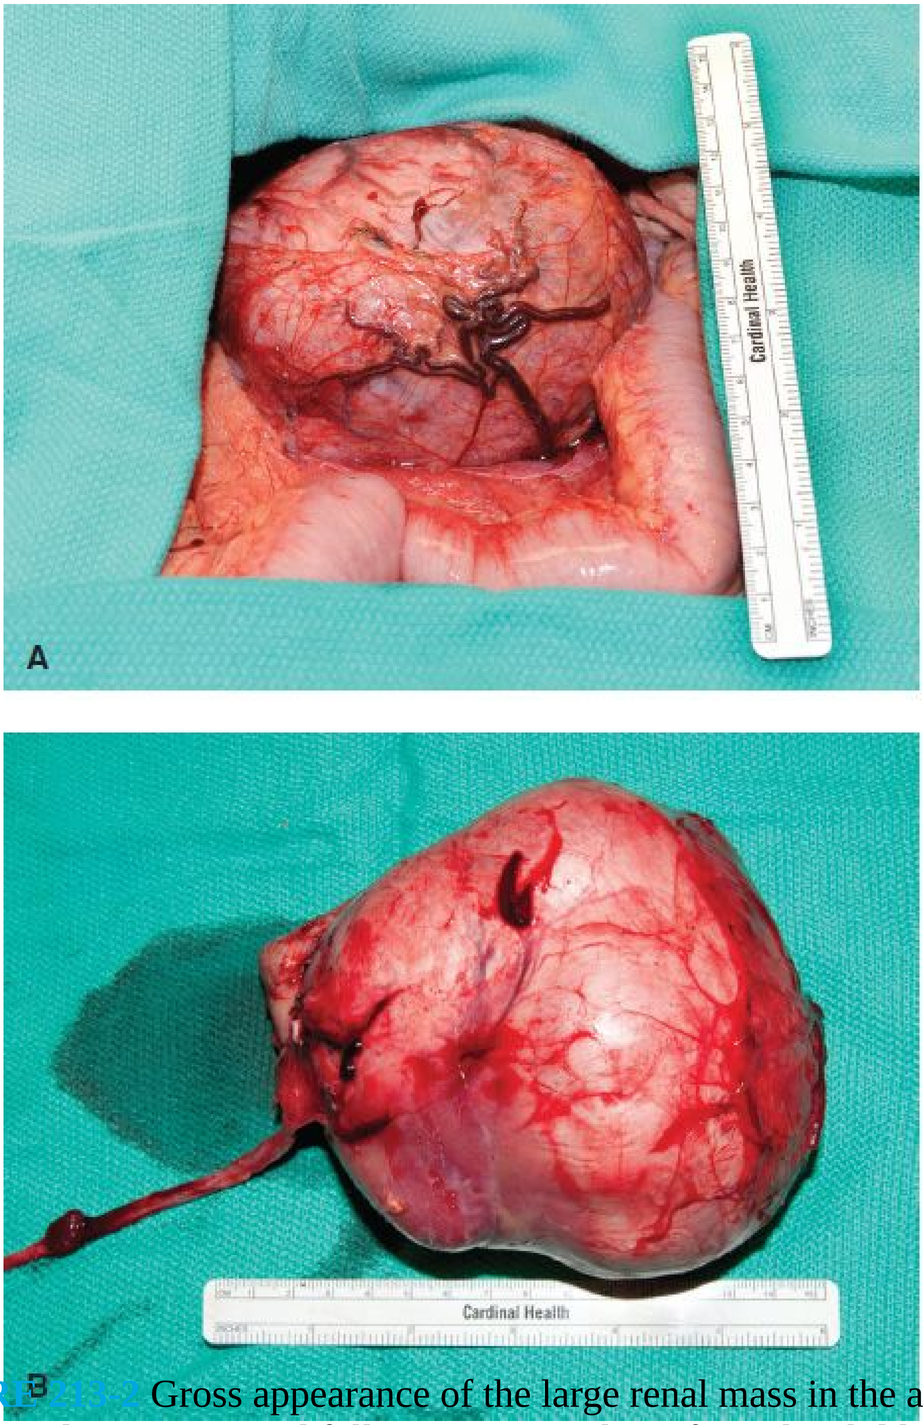

FIGURE 213-2 Gross appearance of the large renal mass in the abdomen (**A**) during laparotomy and following removal (**B**) from the child in **Figure 213-1**. This mass was well-demarcated from the renal parenchyma and well encapsulated, and was confirmed to be a Wilms tumor with favorable histology. INTRODUCTION

Renal cancer, including Wilms tumor, accounts for approximately 6.3 percent of cancer diagnosed in children under the age of 15 years and 4.4 percent of cancer diagnosed in children and young adults under the age of 20 years.[1] Treatment may include surgery, chemotherapy, and radiation. With multimodality therapy, long-term cure rates exceed 85 percent for children diagnosed with favorable histology, even in cases of higher stage disease.

SYNONYMS

Nephroblastoma.

EPIDEMIOLOGY

- Approximately 550 children and young adults under 20 years of age are diagnosed with renal tumors in the US each year and approximately 500 of these are Wilms tumor.[1]
- Wilms tumor accounts for approximately 95 percent of all renal cancers in children under 15 years of age.
- Wilms tumor occurs most commonly in children under age 5 years, with the highest incidence in the first 2 years of life.[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- Wilms tumor is an embryonal malignancy of the kidney.

- It is believed to develop in retained nephrogenic rests which are foci of persistent embryonal kidney cells. Although nephrogenic rests may be seen in approximately 1 percent of kidneys at birth, they usually regress or differentiate early in life.[2]
- Persistent nephrogenic rests outside of the perinatal period are felt to be precancerous lesions.
- The majority of cases of Wilms tumor occur in healthy children who do not have any identifiable risk factors.
- Approximately 10 percent of cases of Wilms tumor are associated with congenital urinary tract anomalies and may be associated with an established phenotypic syndrome.
- Associated urinary tract anomalies include cryptorchidism and hypospadias.
- Associated syndromes may be divided into overgrowth syndromes and nonovergrowth syndromes.
  - Overgrowth syndromes include:
    - Beckwith-Wiedemann (Wilms tumor and other manifestations such as macrosomia, macroglossia, omphalocele, prominent eyes, ear creases, large kidneys, pancreatic hyperplasia, and hemihypertrophy).
    - Perlman syndrome (Wilms tumor, fetal gigantism, visceromegaly, unusual face, and bilateral renal hamartomas with nephroblastomatosis).
    - Isolated hemihypertrophy.
    - Sotos syndrome (cerebral gigantism).
    - Simpson-Golabi-Behemel syndrome (Wilms tumor, organomegaly, bulldog facies, congenital heart disease, and polydactyly).
  - Nonovergrowth syndromes include:
    - WAGR syndrome (Wilms tumor, aniridia, genitourinary anomalies, and mental retardation).
    - Isolated aniridia.
    - Denys-Drash syndrome (Wilms tumor, progressive renal disease, and male pseudohermaphroditism).
    - Li-Fraumeni syndrome (Familial Wilms tumor).

- Approximately 1 to 3 percent of cases of Wilms tumor are familial and are usually inherited in a dominant pattern with incomplete penetrance.[3]
- Several genes have been identified as involved in the pathogenesis of Wilms tumor for both the sporadic form and those involving inherited predispositions syndromes, including familial occurrences.
- Genetic changes in inherited syndromes involve germline mutations. These mutations may be inherited or de novo.
- In addition to mutations in tumor suppressor genes, epigenetic changes at several sites have been identified as involved in the development of Wilms.[4]

DIAGNOSIS

CLINICAL PRESENTATION

- The most common presentation is an asymptomatic upper abdominal mass that is detected by a caretaker.
- Other findings and their approximate frequency include:
  - Abdominal pain (20 to 30%).
  - Fever (20 to 30%)
  - Hematuria (20 to 30%).
  - Hypertension (25%).
  - Anemia (bleeding into the tumor).
- The median age at presentation is 42 to 47 months for unilateral disease and 30 to 33 months for bilateral disease.[5]
- Five to ten percent of patients present with multicentric or bilateral disease (stage V).
- Bilateral and multicentric disease is usually associated with predisposition syndromes, the presence of nephrogenic rests, congenital malformations, or may be familial.[6]

- Extrarenal primary tumors can occur in the abdomen or pelvis but are rare.[7]
- Spread may be local through the renal capsule and into the renal sinus, renal vasculature, and ureter.[8]
- Local spread to the lymph nodes occurs in approximately 15 to 20 percent of cases.[8]
- The most common site of hematogenous spread involves the lungs, and less commonly liver, bone, bone marrow, or brain.[7]

LABORATORY TESTING

- Initial laboratory studies should include—Renal function tests, electrolytes, urinalysis, complete blood count, and liver function tests.
- Tumor specimens are evaluated for histology—Favorable histology versus anaplastic, extent of the tumor, and completeness of resection.

IMAGING

- CT scan of the primary tumor.
    - Commonly indicates an encapsulated mass originating from within the kidney. Calcifications are usually absent. An encapsulated tumor without calcifications helps to differentiate Wilms tumor from neuroblastoma (**Figure 213-1**).[7]

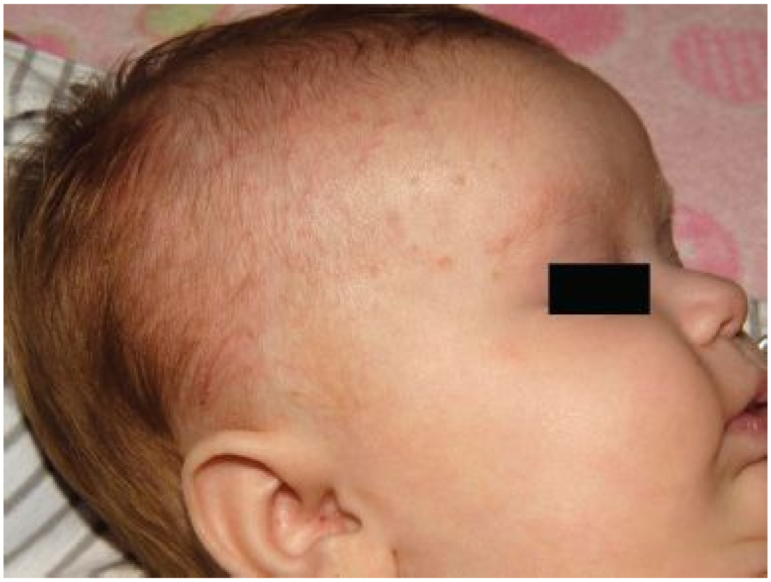

FIGURE 213-3 Extensive pulmonary metastatic disease on chest CT scan of a young child with Wilms tumor. (*Used with permission from Stefanie Thomas, MD.*)

  - CT scan of the abdomen and pelvis also helps to evaluate for lymph spread and for evidence of disease in the contralateral kidney.
- Kidney ultrasound is performed to evaluate renal artery and veins for evidence of thrombus.
- CT scan of the chest is performed to evaluate for evidence of pulmonary disease (**Figure 213-3**).

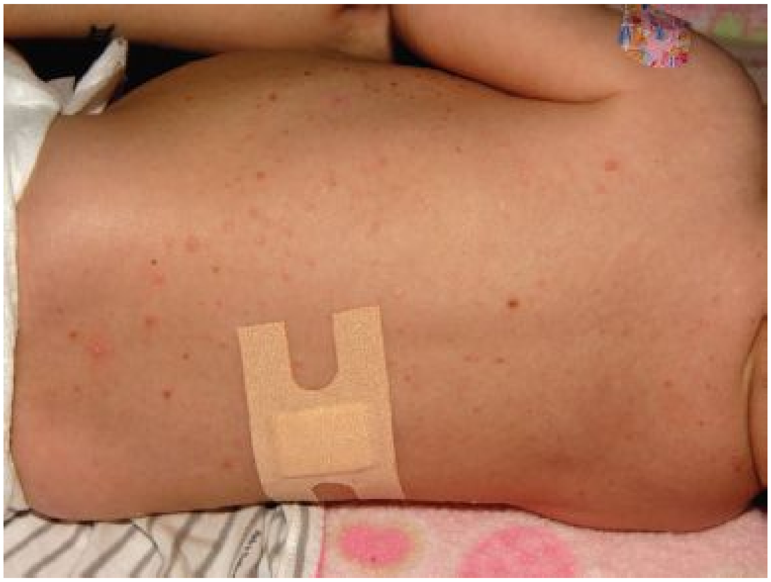

FIGURE 213-4 Bilateral pulmonary nodules, representing metastatic disease, on chest x-ray of the same child as in **Figure 213-3**. (*Used with permission from Stefanie Thomas, MD.*)

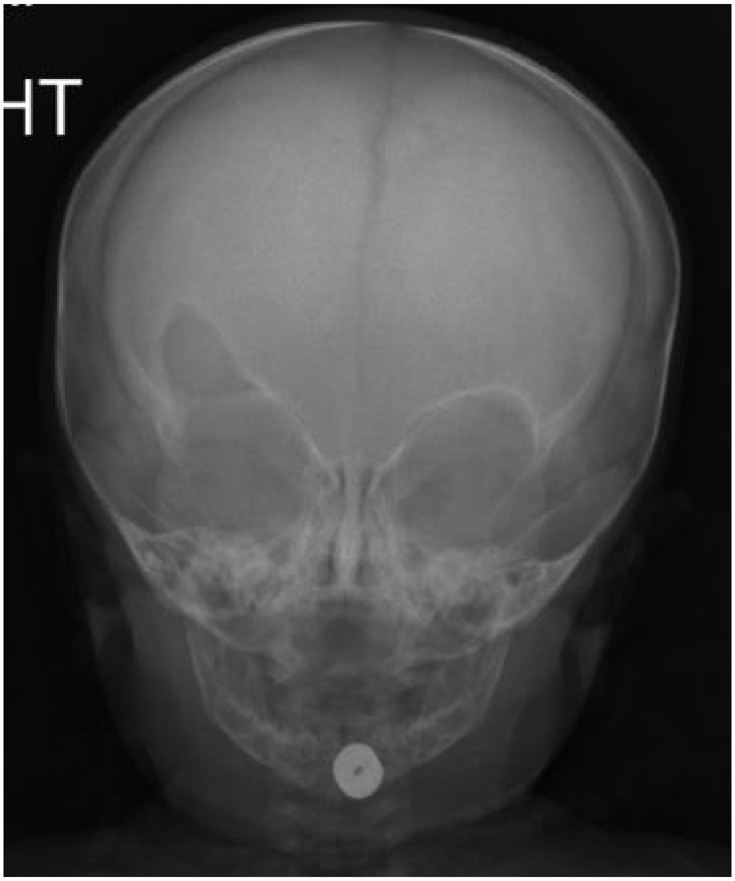

FIGURE 214-1 Multiple reddish-brown papules on the face and scalp of an infant with Langerhans cell histiocytosis. These lesions can be confused with chronic cradle cap (seborrheic dermatitis). (*Used with permission from Stefanie Thomas, MD.*)

- A chest x-ray may show metastatic lesions but is not sufficiently sensitive to identify metastatic disease for staging purposes (**Figure 213-4**).

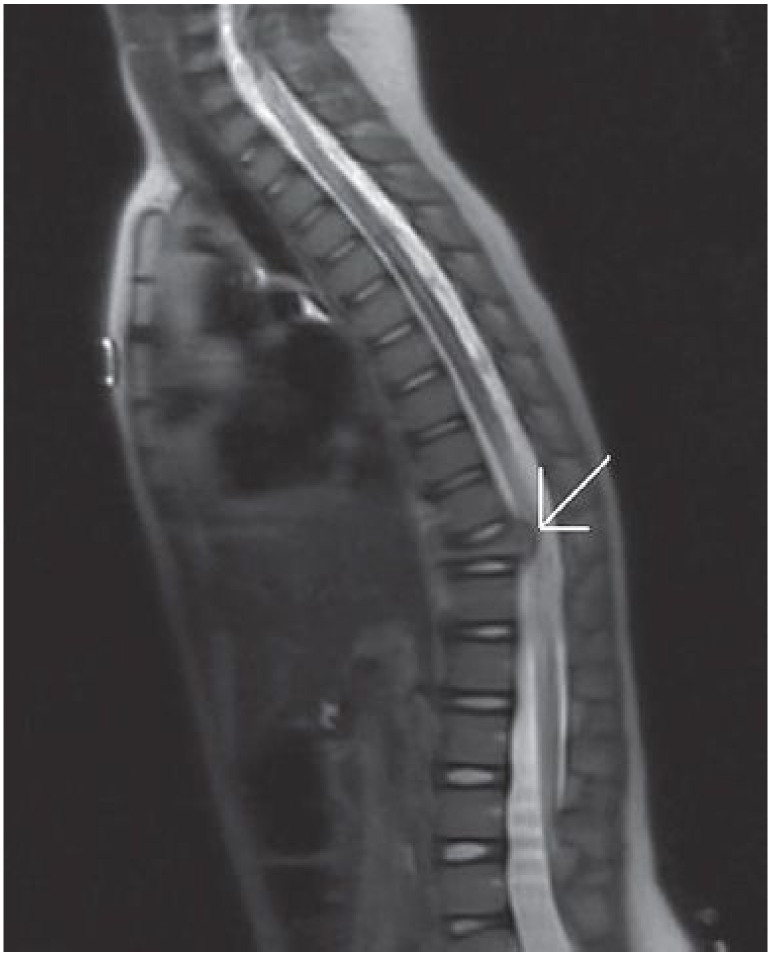

FIGURE 214-2 Multiple erythematous papules, vesicles and crusted papules on the back in the same infant as in Figure 214-1. Note the presence of some areas of postinflammatory hypopigmentation, where papules were previously present. (*Used with permission from Stefanie Thomas, MD.*)

- An MRI of the primary tumor may be performed and can be helpful in distinguishing between Wilms tumor and nephrogenic rests.

DIFFERENTIAL DIAGNOSIS

- Benign lesions that may mimic Wilms tumor include:
  - Congenital mesoblasticnephroma, diffuse hyperplastic perilobarnephrogenic rests (pre-cancerous lesions), nephrogenic rests

(pre-cancerous lesions), and polycystic kidney disease.

- Malignant Lesions that may mimic Wilms tumor on imaging include:
  - Clear cell sarcoma of the kidney, malignant rhabdoid tumor of the kidney, renal cell carcinoma, and neuroblastoma.
- Imaging studies read by experienced pediatric radiologists may help to distinguish these lesions from Wilms tumor but the ultimate diagnosis is based on pathology.

MANAGEMENT

- Treatment is risk stratified based on stage, histology (favorable or anaplastic), and completeness of resection.[9]
- Biopsy (including needle biopsy) upstages a patient and should be avoided in lieu of initial complete excision if possible.
- The more common approach in the US is up front resection followed by chemotherapy based on margins, tumor spill, and histology.
- In Europe, a more common approach is neoadjuvant chemotherapy based on presumed diagnosis followed by resection and subsequent further chemotherapy.
- Patients with evidence of regional lymph spread or tumor spillage either before or during surgery or those who had a biopsy of the tumor initially require abdominal or flank radiation.
- Radiation is directed to sites of metastasis including the lungs.
- Individuals with bilateral (stage V) disease are treated with a nephron sparing approach and may have partial nephrectomies for local control. These patients are frequently treated without biopsy. The need for radiation is based on the local stage of each primary kidney tumor.
- Standard chemotherapeutic agents include Vincristine, Dactinomycin, Doxorubicin, Cyclophosphamide, and Etoposide. Additional agents are used in patients with tumors with anaplastic histology or those whose tumor demonstrates chemotherapy resistance.

PREVENTION AND SCREENING

- Children with predisposition syndromes including Beckwith-Wiedemann, WAGR, Denys-Drash, idiopathic hemihypertrophy, or sporadic aniridia, and those with a family history of familial Wilms, should be screened with an ultrasound every 3 months until age 8 years.[10]

PROGNOSIS

- The overall survival rate for Wilms tumor is 90 percent.[11]
- For patients with favorable histology disease, 4-year overall survival is greater than 80 percent, including those with metastatic disease (stage 4) and/or bilateral disease at diagnosis.[11]
- Patients with anaplastic disease fare worse—Patients with low stage 1 or 2 disease have a 4-year overall survival rate of approximately 80 percent while those with stage 4 disease have a 4-year overall survival rate of only 33 percent.[11]
- Studies of long-term survivors of Wilms tumor show a cumulative incidence of 65 percent for all chronic conditions at 25 years after therapy with the cumulative incidence of severe chronic health conditions being 24 percent. The late effects include:[12]
    - Cardiomyopathy, arrhythmias, left ventricular dysfunction associated with doxorubicin, and whole lung radiation.
    - End-stage renal disease associated with surgery.
    - Secondary malignancies associated with doxorubicin, alkylating agents, and radiation.
    - Acute ovarian failure and premature menopause associated with pelvic radiation and exposure to alkylating agents.
    - Oligospermia/azoospermia associated with alkylating agents.
    - Linear growth changes associated with radiation affecting the spine.

214 LANGERHANS CELL HISTIOCYTOSIS

Stefanie Thomas, MD
Margaret C. Thompson, MD

PATIENT STORY

A 3-month-old female infant presented to her pediatrician with a history of a rash that had been present from birth. Her parents report that her rash initially involved her face and trunk, and the lesions had a red base. The rash seemed to slightly improve over the first 2 weeks of her life, but then progressed into red and brown, rough lesions involving her head, face, trunk, and spread to her back then bilateral lower extremities (**Figures 214-1** and **214-2**). They have also noted that her right eye has been watering and she has not been able to open it completely over the past few days. Based on the appearance and persistence of the rash, she was referred to a dermatologist, who performed a skin biopsy, which showed CD1 positive immuno-histochemical staining, consistent with the diagnosis of Langerhans Cell Histiocytosis. Further work-up included a skull film, which revealed an ocular bony lesion (**Figure 214-3**). She underwent treatment with a chemotherapy regimen and has done well without evidence of recurrence.

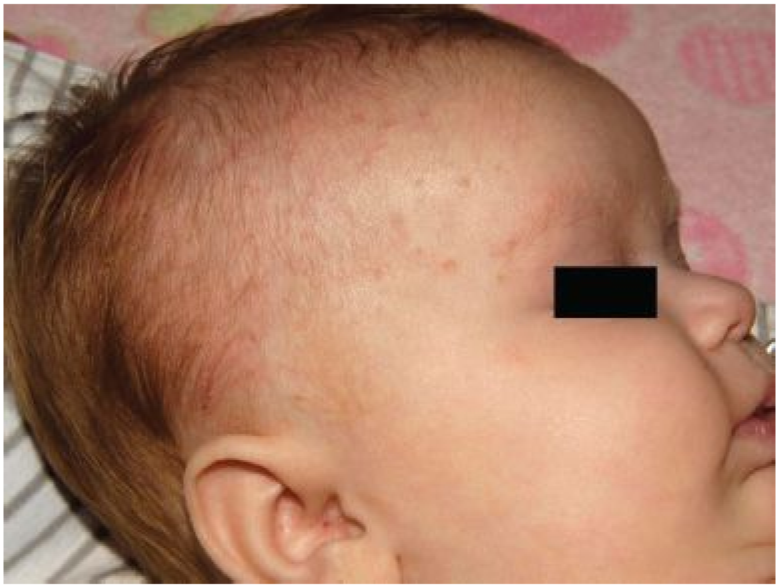

FIGURE 214-1 Multiple reddish- brown papules on the face and scalp of an infant with Langerhans cell histiocytosis. These lesions can be confused with chronic cradle cap (seborrheic dermatitis). (*Used with permission from Stefanie Thomas, MD.*)

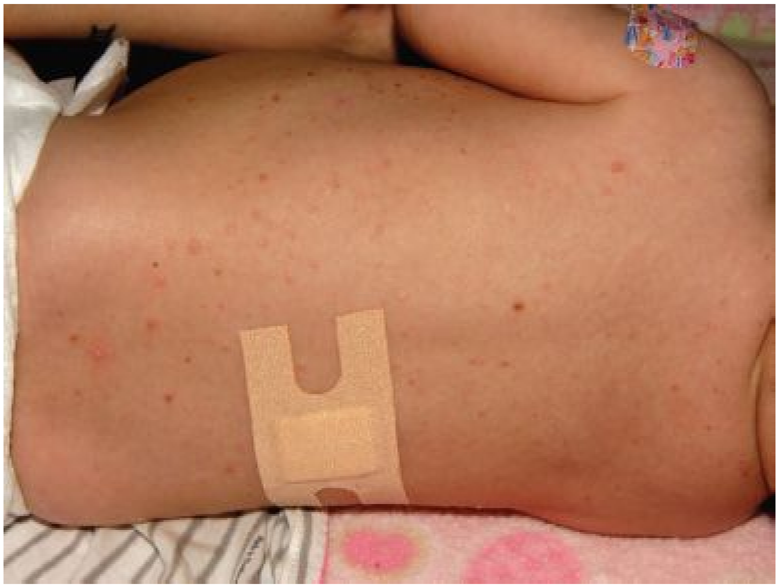

FIGURE 214-2 Multiple erythematous papules, vesicles and crusted papules on the back in the same infant as in **Figure 214-1**. Note the presence of some areas of postinflammatory hypopigmentation, where papules were previously present. (*Used with permission from Stefanie Thomas, MD.*)

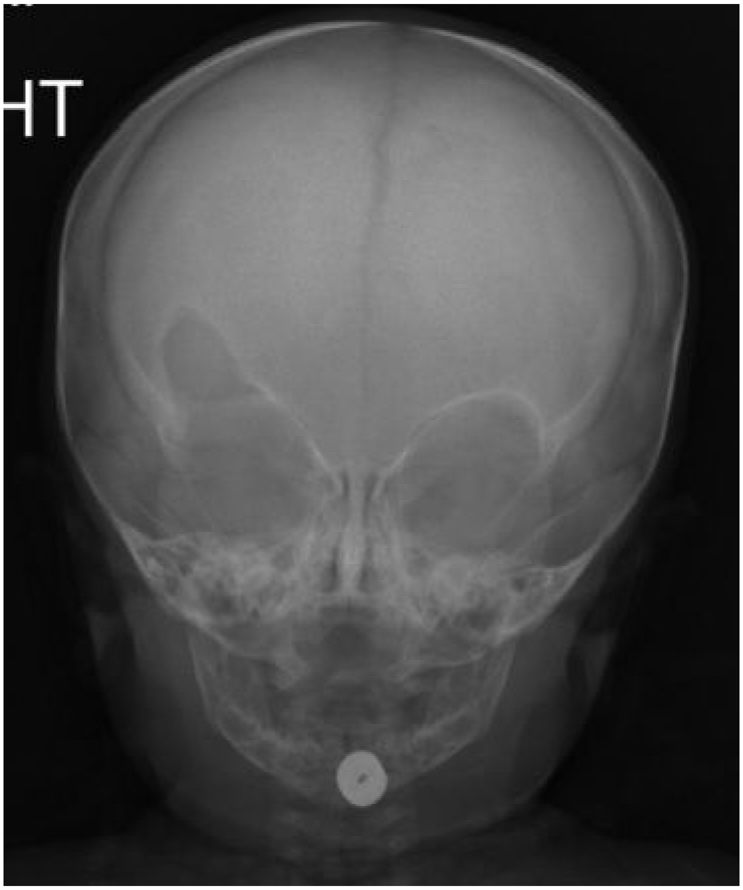

FIGURE 214-3 Lytic lesion of the lateral roof of the right orbit on skull x-ray in the same infant as in **Figure 214-1**. (*Used with permission from Stefanie Thomas, MD.*)

INTRODUCTION

Langerhans Cell Histiocytosis (LCH) is characterized by clonal proliferation of histiocytic cells that resemble Langerhans cells of the skin and can result in widely variable organ involvement and extent of disease.[1] Because of the wide spectrum of the disease, treatment depends on extent of disease.

SYNONYMS

- Eosinophilic granuloma of the bone—LCH with a single bone lesion.
- Hand-Schuller-Christian Disease—LCH with Exophthalmus, Diabetes Insipidus, and skull lesions.
- Letterer-Siwe Disease—Multifocal-multisystem LCH.
- Hashimoto-Pritzker Disease—LCH rash in an infant which is usually self-resolving.
- Histiocytosis-X.

EPIDEMIOLOGY

- Incidence is approximately 2 to 10 cases per million children under age 15 years with a median age at presentation of 30 months.[2]
- 1:1—Male to Female ratio.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- Exact etiology remains unknown.
- Exhibits features of both malignant transformation (proliferation and clonality) and immune dysregulation.[1]
- Recently, recurrent mutations in BRAF gene have been identified.[3]

RISK FACTORS

- Weak associations but no known risk factors to developing LCH.

DIAGNOSIS

CLINICAL FEATURES

- Most typical presentation is skin rash or bone lesion, which may be painful or asymptomatic (**Figures 214-1** to **214-3**).
- Non-specific inflammatory response may be present including fever, weight loss, diarrhea, edema, and dyspnea.[1]
- Because of the frequent involvement of the pituitary gland, symptoms of diabetes insipidus, including polydipsia and polyuria, may also be present.[1]
- Other presenting features depend on which organs are involved.

DISTRIBUTION

- The distribution of the skin and bony lesions are wide and varied.
- May result in single system/organ involvement with single or multiple sites of involved system.
- Organs that may be involved are classified as high-risk or low-risk organs. High-risk organs include the bone marrow, liver, spleen, and lungs. Low-risk organs include skin, bones, lymph nodes, gastrointestinal system, and the pituitary gland. The prognosis is worse for children with involvement of any of the high-risk organs.
- Most frequent bone lesions occur in the skull (**Figure 214-3**), but can also include the femur, ribs, humerus, and vertebrae (**Figure 214-4**).

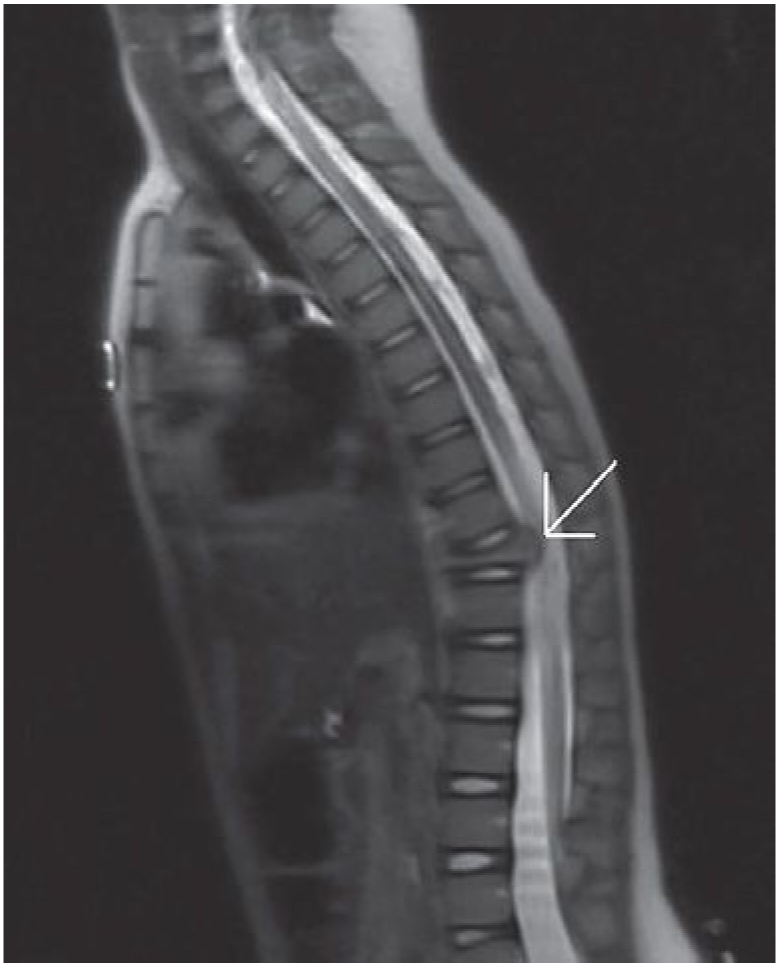

FIGURE 214-4 Vertebra Plana (flattening of the body of the vertebra), a feature of vertebral bone involvement in a patient with Langerhans cell histiocytosis. (*Used with permission from Margaret C. Thompson, MD.*)

LABORATORY TESTING

- The diagnosis is primarily made on biopsy. If skin lesions are present, skin biopsy is typically the least invasive diagnostic procedure.
- Positive immunohistochemical staining with CD207 (langerin) and CD1a are diagnostic.[1]
- Birbeck granules (tennis-racket shaped rods with handle appearance that are present in Langerhans cells) seen on electronic microscopy are pathognomonic for LCH but not required for diagnosis (**Figure 214-5**).

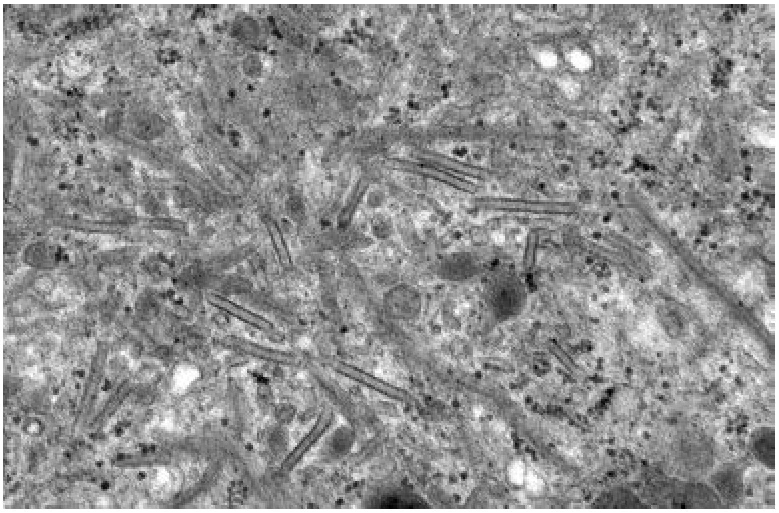

FIGURE 214-5 Birbeck granules seen on electron microscopy of a skin biopsy in a patient with Langerhans cell histiocytosis. (*Used with permission from Melissa Piliang, MD*.)

- Other laboratory testing is dependent on organ involvement.

IMAGING

- Lytic lesions of the bone are best seen on plain x-ray (**Figure 214-3**).
- MRI of the head is typically done at diagnosis to assess for pituitary involvement.

DIFFERENTIAL DIAGNOSIS

- The differential diagnosis of cutaneous LCH includes seborrheic dermatitis, erythema toxicum neonatorum, mastocytosis, acrodermatitis enteropathica, acropustulosis of infancy, and benign cephalic histiocytosis (**Figure 140-7**). LCH should be considered when cutaneous manifestations do not resolve despite appropriate treatment or observation for these entities.

- Differential of vertebral LCH includes tuberculosis of the spine, which can be excluded with a good history and biopsy results.

MANAGEMENT

Management depends on location and extent of disease.

NONPHARMACOLOGIC

- For isolated cutaneous LCH, particularly in an infant, observation alone may be an appropriate option.

MEDICATIONS

- For isolated cutaneous LCH, topical corticosteroids can be tried but are rarely effective alone.[4] Oral methotrexate[5] may also be used in this setting.
- Isolated single site bone involvement has been treated with oral corticosteroids or injection of corticosteroids into the area that is involved.[6]
- Single site bone involvement in a high-risk location such as a vertebral body or skull should be treated with systemic chemotherapy.
- Treatment of a single system (i.e., bone) but in multiple sites should be treated with systemic chemotherapy to decrease the risk of recurrence, particularly in the pituitary gland.
- Multisystem disease or disease involving high-risk organs requires treatment with systemic chemotherapy. Such treatment usually includes vinblastine, oral corticosteroids, and 6-Mercaptopurine. Treatment duration is typically for 1 year.

SURGICAL

- For single site bone involvement, curettage alone by an orthopedic surgeon may be sufficient.

REFERRAL

- Referral to a hematologist/oncologist is recommended.

PROGNOSIS

- Infants with single system LCH without high-risk organ involvement have a very favorable outcome.[1]
- Infants less than two years of age, particularly those with multi-organ involvement, have poor outcomes. With intensified therapy, infants without high-risk organ involvement have had significant improvement in survival.[7]
- Children with high-risk organ involvement continue to have poor outcome although this has improved with intensified treatment with mortality decreasing from 44 to 27 percent.[7]
- Children with high-risk organ involvement who do not respond to treatment within 6 weeks have the highest mortality.[1]
- Infants with skin only LCH often progress to multisystem LCH and should be monitored closely for development of other organ involvement.[4]

215 ALLERGIC RHINITIS

Brian Schroer, MD

A 9-year-old girl presents to her pediatrician for constant nasal congestion, runny nose, and intermittent bouts of sneezing and itching. Her symptoms occur year-round with increased symptoms in the spring and fall. On examination she has dark circles under her eyes (“allergic shiners”; **Figure 215-1**), bilateral conjunctivitis (**Figure 215-2**), swollen, pale, inferior turbinates, and a copious clear watery nasal discharge (**Figure 215-3**). Over-the-counter antihistamines have helped minimally so she is given a prescription for a nasal steroid spray to use daily. This significantly improves but does not eliminate the symptoms. She is seen by an allergist who obtains a history that she sleeps on feather pillows, lives with two cats, and also has eye itching and redness when outside in the spring. Skin prick testing to local environmental allergens shows positive reactions to dust mites, cats, and grass and ragweed pollens (**Figures 215-4** and **215-5**). Recommendations for avoidance of the dust mites, cats, and the outdoor pollens were given. Her technique and adherence with the nasal steroids was discussed and she was given nasal antihistamines to treat breakthrough symptoms.

INTRODUCTION

Allergic rhinitis is a syndrome of upper airway symptoms in patients who are sensitive to aeroallergens including but not limited to animal dander, dust mites, mold spores, pollen, cockroaches, and rodents. Many patients have a history of atopic dermatitis, allergic rhinitis and asthma that together make up the “atopic triad.” These symptoms may be present in a seasonal pattern or year-round with seasonal exacerbations.

SYNONYMS

Hay fever, Allergies, Pollinosis, the sniffles.

EPIDEMIOLOGY

- By 6 years of age, 42 percent of children will be diagnosed with allergic rhinitis by a physician.[1]
- Seasonal allergic rhinitis symptoms due to outdoor pollens rarely occur before the age of 2 years. However, sensitivity to indoor allergens can be present by the age of 1 year.
- The prevalence of allergic rhinitis increases throughout childhood and adolescence.
- Allergic rhinitis has been found in people from many different genetic backgrounds, but it tends to occur more often in people who have been raised in the urban/suburban areas of Westernized countries or in higher socioeconomic classes.[2]

RISK FACTORS

- Allergic rhinitis occurs in genetically predisposed individuals who are exposed to common aeroallergens.
- The prevalence of allergic rhinitis and all atopic disease is much higher in people who are raised in more modern/western communities and occurs in all ethnic groups.
- Most patients have a family history of atopic disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Genetically predisposed individuals can get allergic rhinitis symptoms when they are exposed to allergens, which float in the air, enter the nasal mucosa, and bind specific allergic antibodies called IgE.
- When IgE recognizes an allergen, it leads to mast cell degranulation and intracellular signaling causing the cells to release preformed mediators such as histamine and start production of other inflammatory cytokines such as leukotrienes.
- Histamine and other preformed mediators cause sneezing and itching.
- Late phase inflammation leads to congestion and rhinorrhea.
- Indoor allergens from cats, dogs, cockroaches, and dust mites are present year-round and lead to perennial allergic rhinitis.
- Mold spores germinate when weather conditions are warm and wet.
- Tree pollen, grass pollen, and weed pollen are produced by the 10 percent of plants, which use the wind to disperse their pollen. The pollen is released into the air when these plants flower, leading to seasonal allergic rhinitis.
- Flowers, which are showy such as rose bushes, daisies, or cherry trees, do not cause allergic rhinitis as the pollen is too heavy to get into the nose or eyes. These flowers need the flowers to attract pollinators such as bees and insects to carry the pollen from one flower to the other.

DIAGNOSIS

The diagnosis of allergic rhinitis is based on a history of typical symptoms, which occur after exposure to known allergens. Response to treatment with over-the-counter oral antihistamines can be helpful but will not decrease symptoms of congestion and runny nose in patients with severe allergy. Physical exam findings may include enlarged, pale colored turbinates (**Figure 215-3**) with clear rhinorrhea, mouth breathing (**Figure 215-1**), conjunctivitis (**Figure 215-2**), allergic crease (**Figure 215-6**), Dennie Morgan lines (infraorbital folds; **Figure 215-7**), or a gothic arch palate. Positive history of physical exam findings support but do not confirm a diagnosis.[2]

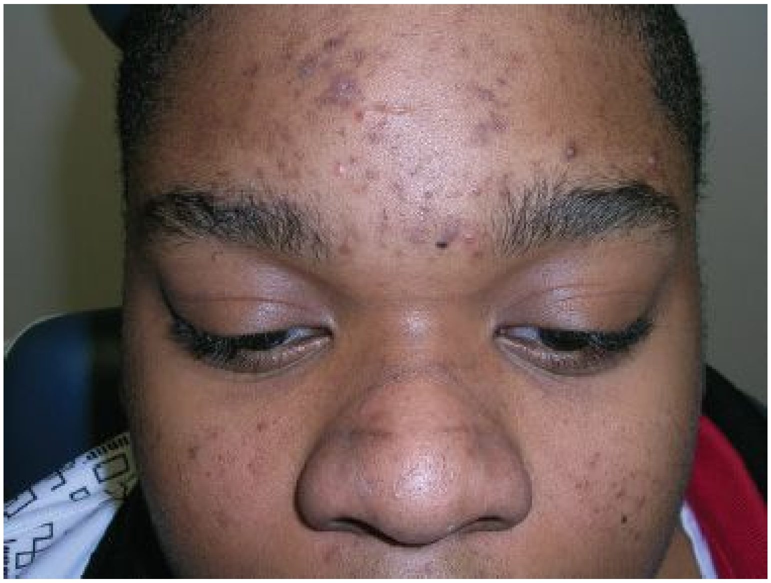

FIGURE 215-6 Allergic creases on the nose of a teenage boy with allergic rhinitis. He was observed performing the allergic salute in the office. (*Used with permission from Richard P. Usatine, MD.*)

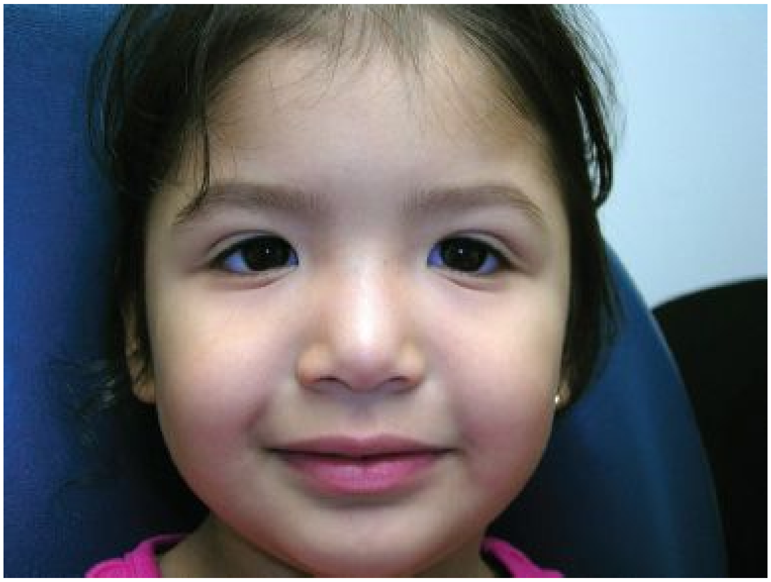

FIGURE 215-7 Dennie-Morgan lines (infraorbital lines) in a girl with the atopic triad. (*Used with permission from Richard P. Usatine, MD.*)

CLINICAL FEATURES

- Nasal congestion, stuffiness, inability to breath through the nose, or allergic shiners.
- Rhinorrhea—Clear watery mucous running out of the nose or down the throat.
- Sneezing—Fits of sneezing in the morning or when around an allergen.
- Itching—Allergic salute, rubbing the nose.
- Throat itching, ear itching.
- Associated with allergic conjunctivitis symptoms when outside—Eye redness, itching, swelling, watering, or asthma symptoms of coughing, chest tightness, shortness of breath, or wheezing.

LABORATORY TESTING

- Allergy skin prick or intradermal testing can be done in the office quickly and easily. Positive skin tests lead to a small hive for each allergen

(**Figures 215-4** and **215-5**).

- Blood testing for serum specific IgE to relevant allergens can also be obtained, although it is less sensitive than skin prick testing.[3]
- Positive skin or blood allergy tests should be correlated with the clinical history.

IMAGING

- CT scans are helpful in further evaluating other causes of nasal congestion such as polyps (**Figures 215-8** and **215-9**), anatomic changes such as concha bullosa (middle turbinate pneumatization; **Figure 215-8**), or Haller cells (infraorbital ethmoidal air cells) and chronic rhinosinusitis.

DIFFERENTIAL DIAGNOSIS

- Nonallergic rhinitis—Very similar nasal symptoms when exposed to weather changes, cold air, perfumes, tobacco smoke, air pollution, or strong odors such as cleaning agents or chemicals. Thirty-four percent of patients with allergic rhinitis also have nonallergic triggers and this can be called mixed rhinitis.[4] Various forms of nonallergic rhinitis include vasomotor rhinitis, gustatory rhinitis, occupational rhinitis, or drug induced rhinitis.[5]
- Infectious rhinosinusitis—Acute viral and bacterial infections often lead to acute nasal congestion and thick discolored discharge, which is different from the thin and watery mucous of allergic rhinitis. Chronic rhinosinusitis is diagnosed using a history of congestion, mucopurulent discharge, facial pain, or dysosmia, lasting over 12 weeks and confirmed with nasal endoscopy or imaging with CT or MRI (see Chapter 26, Sinusitis).[6]
- Nasal polyposis—Nasal polyps may occur as a consequence of allergic rhinitis or with no allergic sensitization. Characteristic symptoms include

hyposmia or anosmia along with refractory nasal congestion (**Figure 215-8** and **215-9**).

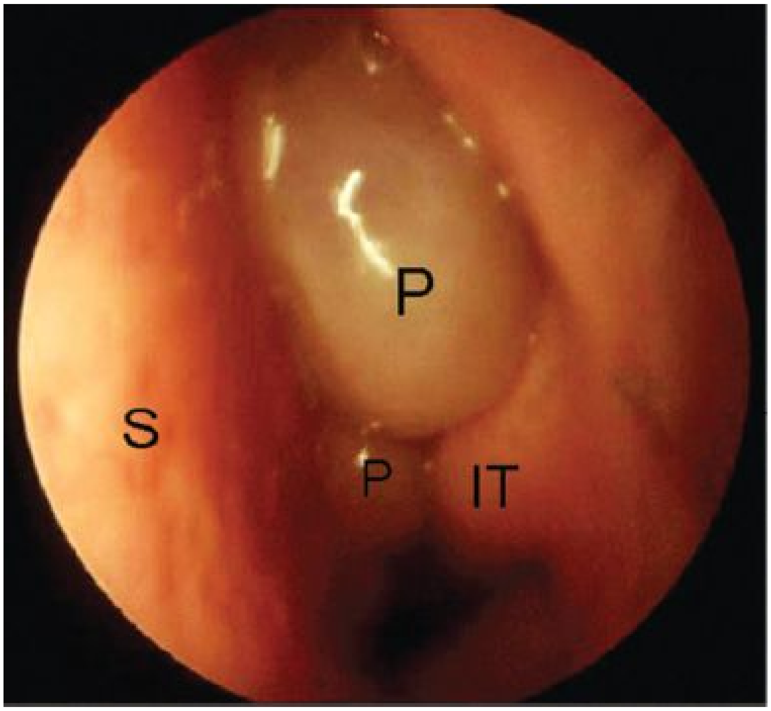

FIGURE 215-9 Nasal polyps seen on left sided nasal endoscopy in a young child. P=polyp; S=nasal septum; IT=inferior turbinate. (*Used with permission from Rudolph's Pediatrics 22nd edition, e-370-1, www.accesspediatrics.com*.)

- Adenoidal hypertrophy—Obstruction of the nasopharynx leads to nasal congestion, rhinorrhea, snoring, and allergic shiners but without sneezing and itching or other atopic diseases.
- Anatomic anomalies—Deviated septum, concha bullosa (**Figure 215-8**), or haller cells can cause obstruction leading to the symptom of congestion.

MANAGEMENT

NONPHARMACOLOGIC

- Allergen avoidance—The primary treatment of allergic rhinitis should involve avoiding known triggers. Avoidance can be targeted based on the results of allergy testing to the aeroallergens including animal dander, dust mites, cockroaches and rodents, mold spores, and outdoor pollens from trees, grasses, and weeds.

- Avoidance of animal dander requires complete removal of the animal from the home as there is no evidence that any cats or dogs are "hypoallergenic."[7] SOR A
- Cockroach and mouse allergen avoidance involves comprehensive pest control measures such as decreasing food sources or professional exterminator services.[3, 3] SOR A
- Dust mite allergens can be decreased by decreasing relative humidity levels, using special dust mite covers on the pillows, mattress, and any stuffed comforter on the bed, replacing carpeting with a solid surface floor, and frequent vacuuming/cleaning.[3, 3] SOR A
- Mold spores are ubiquitous both indoors and outdoors though central air conditioning can decrease exposure. SOR C Spore levels are often dependant on outdoor spore production, which occurs when it is warm and wet.
- Avoidance of the outdoor pollens may require remaining indoors during the peak pollen seasons. These seasons are dependent on geography with trees typically pollinating in the spring, grasses in the spring/early summer and weeds in the fall.
- Central or portable HEPA air filters can significantly decrease outdoor allergens but are not as helpful for most indoor allergens. SOR B
- Personal humidifiers are not recommended as they increase relative humidity levels allowing dust mites to survive and they may spread mold spores. SOR C

MEDICATIONS

- If avoidance measures are not possible or effective, then medications such as short or long acting oral antihistamines, nasal steroids, or nasal antihistamines can be used. The nasal steroid medications give the most relief for all of the typical symptoms including sneezing, itching, rhinorrhea, and congestion. They can be used daily and have few side effects with nose bleeding being the most common.[3, 3] SOR Ⓐ

- Nasal antihistamines can be helpful for all of the nose symptoms, which occur despite the nasal steroids or if the symptoms are not frequent. Nasal antihistamines generally have a bad taste, which can be minimized by using good technique when spraying.[2,3] SOR Ⓐ
- Second generation, long acting, nonsedating oral antihistamines are helpful for the symptoms of sneezing and itching but do not help for nasal congestion or rhinorrhea.
- **Allergy Immunotherapy**—If avoidance and medication use is not fully effective then allergy immunotherapy can be considered.
    - Allergy shots have long been proven to decrease symptoms and the need for medications for allergic rhinitis, conjunctivitis, and asthma.[2] SOR Ⓐ
    - This therapy is done by giving frequent subcutaneous injections containing increasing amounts of the naturally occurring purified allergens specific to each patient.
    - After 3 to 5 years, this therapy changes the immune response to the allergens leading to decreased symptoms, which can last for years after discontinuation.[2] SOR Ⓐ
    - The drawbacks include the time and expense of frequent visits to the doctor’s office, injection site reactions, or rarely anaphylaxis.

COMPLIMENTARY/ALTERNATIVE THERAPY

- Bee pollen has been used as a folk remedy to improve allergic rhinitis symptoms. No randomized studies support its efficacy in allergic rhinitis and anaphylaxis has been reported when used to treat allergic patients.
- The pollens bees collect are not typically the pollens which cause allergic rhinitis. Therefore, ingesting these pollens regularly would not lead to desensitization as occurs in allergy immunotherapy. However some may cross react and large oral doses may lead to local or systemic allergic reactions in highly sensitive individuals. SOR Ⓒ

SURGERY

- Surgery may help improve symptoms of nasal polyposis and chronic rhinosinusitis if present.

REFERRAL

- Further evaluation should be done by an allergist if the patient has not responded to typical therapies such as oral antihistamines or nasal steroid sprays.
- Surgical consultation to otolaryngology should be made if there is suspicion of adenoidal hypertrophy or other structural causes of the symptoms have been identified.

PREVENTION AND SCREENING

- There is no proven strategy for prevention of allergic sensitization.
- There is a controversy about whether having dogs or cats in the home prevent allergic rhinitis.
- Allergic rhinitis should be suspected in patients who present with typical symptoms, especially if they have a history of other atopic diseases such as atopic dermatitis, food allergy, or asthma.

PROGNOSIS

- Patients can outgrow their allergies, although this usually does not happen until the 4th or 5th decade of life. Some patients can continue to experience symptoms into old age.

FOLLOW-UP

- Follow-up can be based on the frequency and severity of symptoms or during evaluation of co-morbid conditions such as asthma.

216 DIGEORGE SYNDROME

Lisanne Newton, MD
Brian Schroer, MD

PATIENT STORY

A newborn infant is noted to have micrognathia, a bulbous nasal tip, a crumpled ear helix (**Figure 216-1**), hooded eyes, a high arched palate, and a submucosal cleft palate. She was diagnosed prenatally with Tetralogy of Fallot. Tetany due to hypocalcemia is noted in the first 48 hours of life and requires treatment. A chest x-ray obtained is notable for absence of a thymic shadow (**Figure 216-2**). Immunologic laboratory data reveal CD3+ T cells are <500/mm^3. Chromosomal analysis is sent and reveals a deletion of chromosome 22q11.2. She undergoes surgical repair of her heart lesion at one week of age, and requires close follow-up of her cardiac, immunological, and metabolic problems.

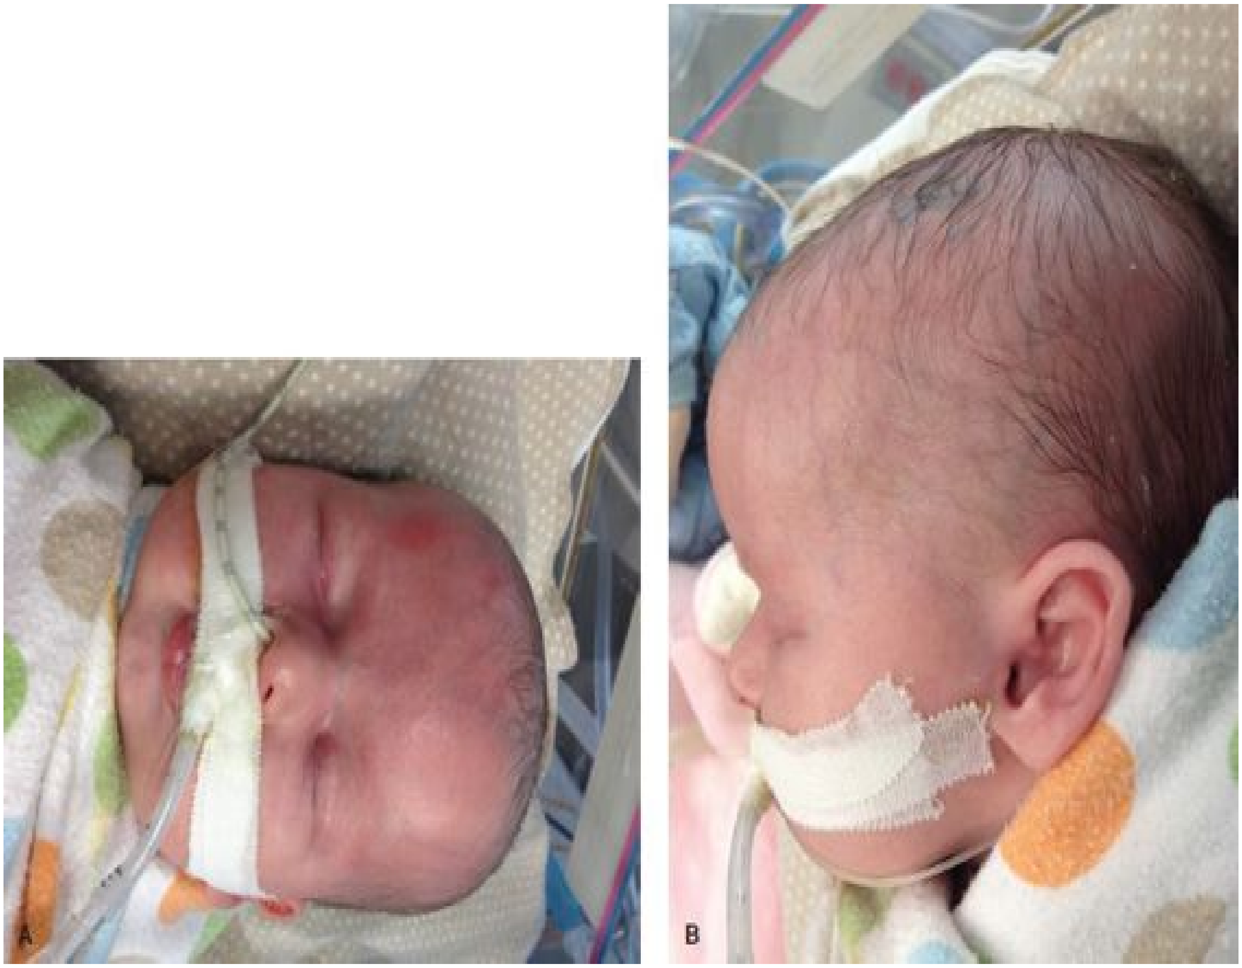

FIGURE 216-1 Dysmorphic facial features, including a small chin, crumpled ear helix, and bulbous nasal tip in a newborn girl with Di George syndrome on frontal (**A**) and lateral (**B**) view. (*Used with permission from Brian Schroer, MD.*)

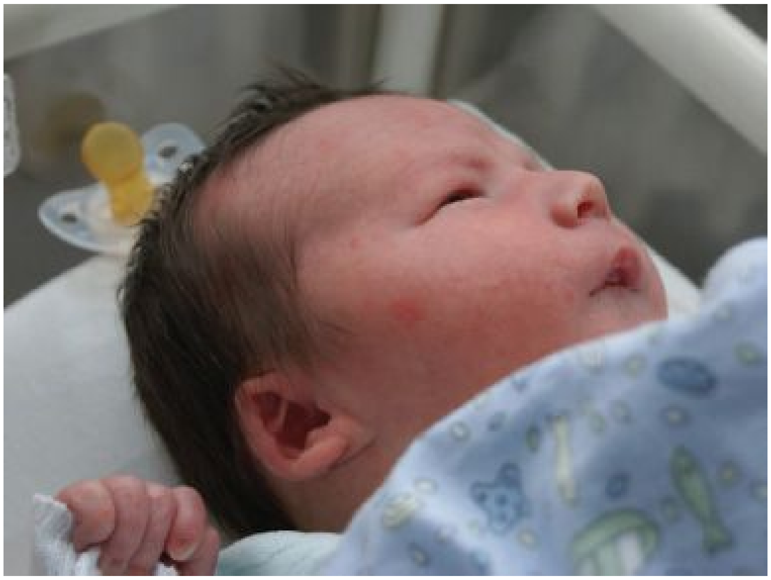

FIGURE 216-2 Decreased thymic shadow and cardiomegaly due to Tetralogy of Fallot in a newborn girl with DiGeorge syndrome. On operative repair of the cardiac defect, essentially no thymic tissue was noted. (*Used with permission from Brian Schroer, MD.*)

INTRODUCTION

DiGeorge Syndrome (DGS), also known as 22.q11 deletion syndrome, or velocardiofacial syndrome (VCFS), describes patients with a distinct clinical phenotype. Patients classically present with a triad of conotruncal cardiac anomalies, hypoplastic thymus, and hypocalcemia. However, there is a wide variation in phenotypic presentations.

SYNONYMS

- Velocardiofacial syndrome (VCFS).
- Chromosome 22q11.2 deletion syndrome (22qDS).
- Congenital Thymic hypoplasia/aplasia.

- Conotruncal Anomaly Face syndrome.
- Shprintzen syndrome.
- Strong syndrome.

EPIDEMIOLOGY

- DGS is the most common microdeletion syndrome.
- Population studies in the US have found an incidence of approximately 1:3,000 to 1:6,000 births.[1]
- This incidence may be increasing due to affected parents having their own children, and the incidence may be underestimated because of under diagnosis of patients with mild phenotypic features, particularly in African Americans.[2]
- DGS has an equal distribution in males and females, races, and geographic location.[3]
- The syndrome typically presents in infancy but diagnosis may be delayed in patients with partial DGS and mild phenotypes.

ETIOLOGY AND PATHOPHYSIOLOGY

- The features associated with DGS result from dysmorphogenesis of the 3rd and 4th pharyngeal pouches during embryogenesis, leading to thymus or parathyroid gland hypoplasia or aplasia. Related anomalies involve structures forming around the same time, including the great vessels, esophagus, uvula, heart, facial, and ear anomalies.[4]
- The most common genetic deletion is a hemizygous microdeletion from chromosome 22q11.2.[3] The size of the deletion does not appear to correlate with the clinical phenotype.

- Clinical features and are determined by which organs are affected and the degree to which they are affected.

RISK FACTORS

- Most cases (>90%) are spontaneous mutations and therefore are not inherited.
- Parents with 22q11 deletions can pass the deletion to their children in an autosomal dominant manner.[3]

DIAGNOSIS

CLINICAL FEATURES

- Diagnosis is made by identifying the clinical features and confirming the diagnosis with identification in the 22q11 deletion.
- Partial DGS is the most common phenotype and occurs if there is hypoplasia of the thymus and parathyroid glands. The severity of the immune disorder and hypocalcemia is determined by the level of hypoplasia but neonates with partial DGS typically present with non-life-threatening immunologic defects.
- Complete DGS is defined by total aplasia[4] and comprises <1 percent of patients. It is critical to confirm this diagnosis in a timely manner as they have a combined immunodeficiency similar to SCID and are susceptible to opportunistic pathogens. They will die within the first year of life without treatment.

DIAGNOSTIC CRITERIA FOR DIGEORGE SYNDROME

In general, if a patient has 2 or more of the following features, testing for chromosome 22q11.2 deletion should be sent:

- Hypocalcemia.
- Immunodeficiency (CD3+ T cells <1500/ml).
- Characteristic facial features.
  - Low set and posteriorly rotated ears, crumpled ear deformity (**Figure 216-1**, **216-3**, and **216-4**).

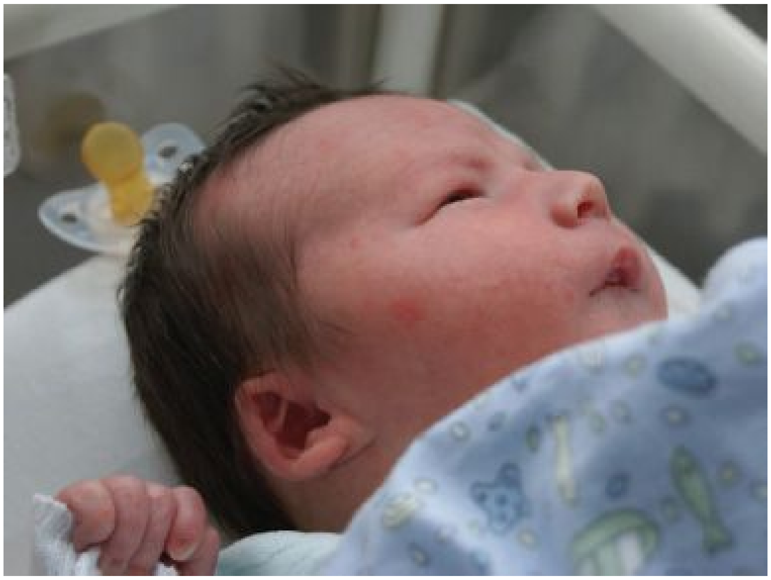

FIGURE 216-3 Posteriorly rotated, crumpled ear helix in a newborn boy with chromosome 22q11.2 deletion syndrome. (*Used with permission from Gregor Dueckers, MD and Tim Niehues, MD.*)

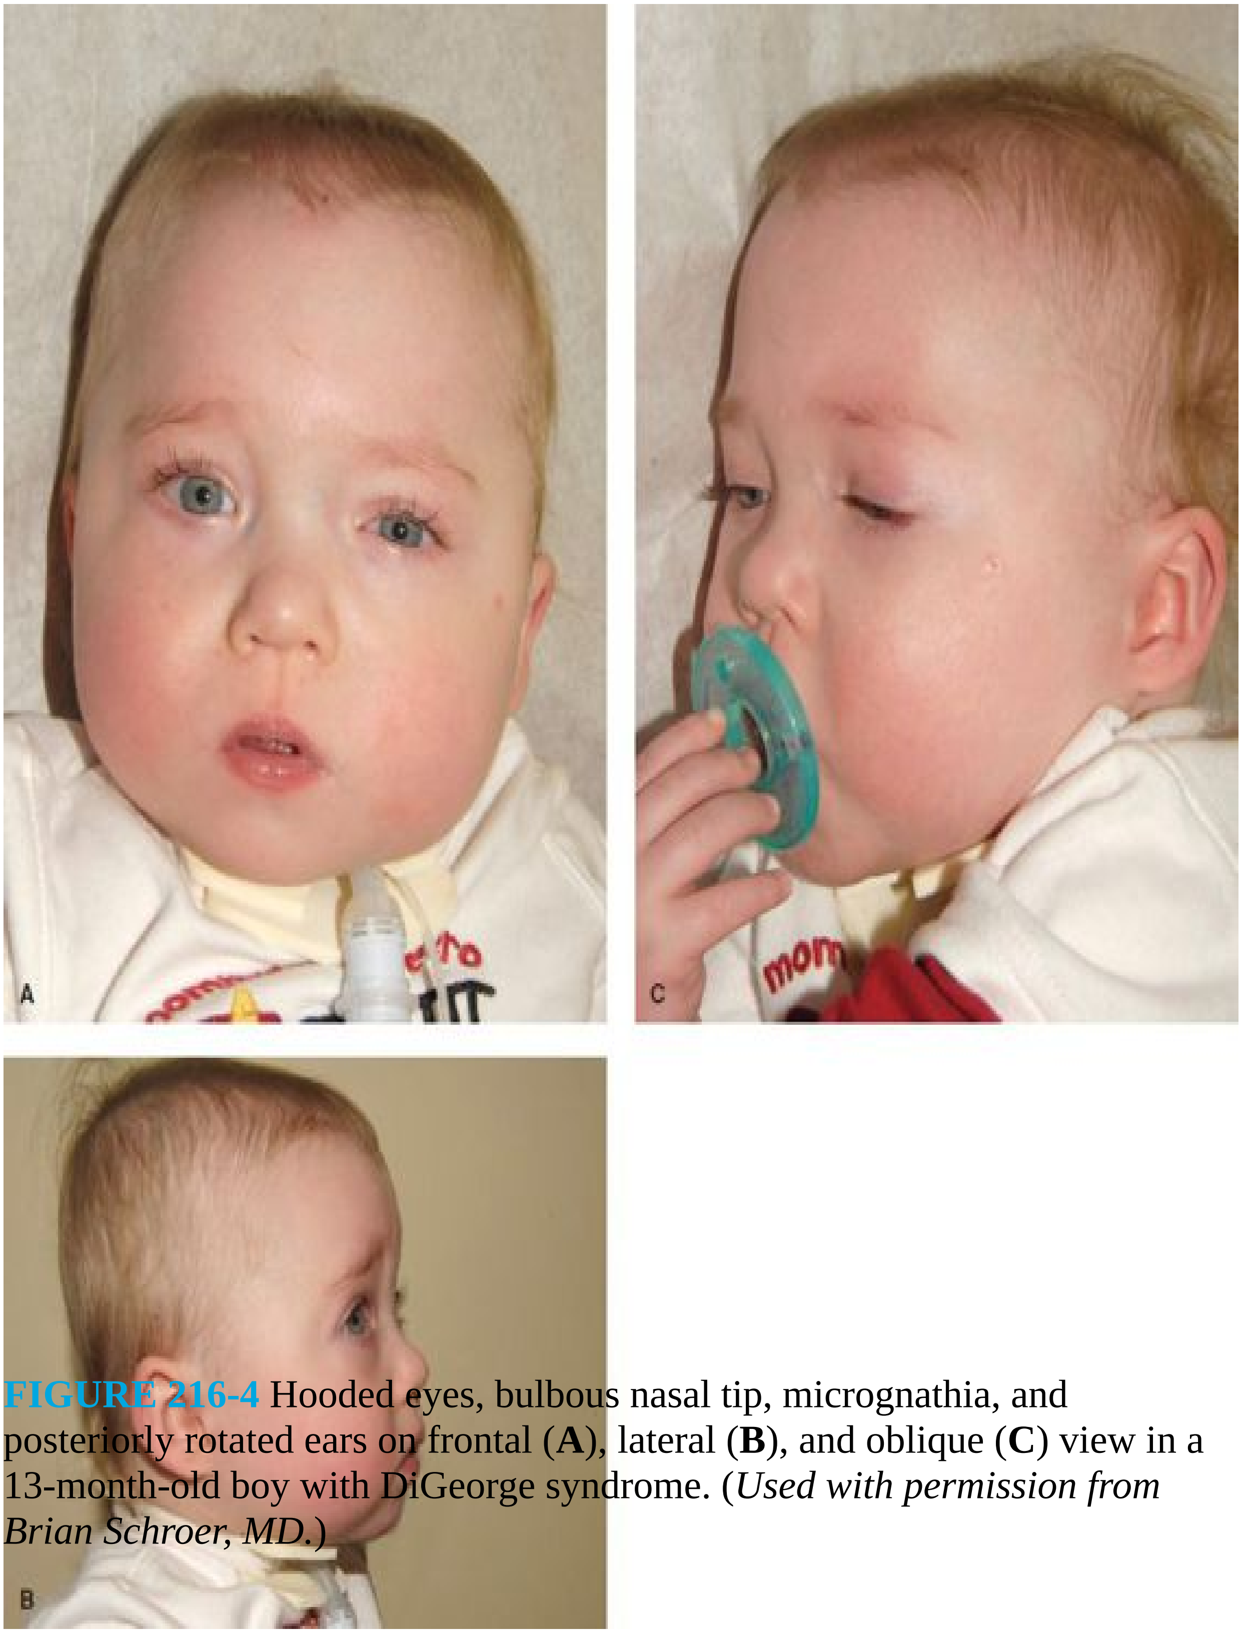

FIGURE 216-4 Hooded eyes, bulbous nasal tip, micrognathia, and posteriorly rotated ears on frontal (**A**), lateral (**B**), and oblique (**C**) view in a 13-month-old boy with DiGeorge syndrome. (*Used with permission from Brian Schroer, MD.*)

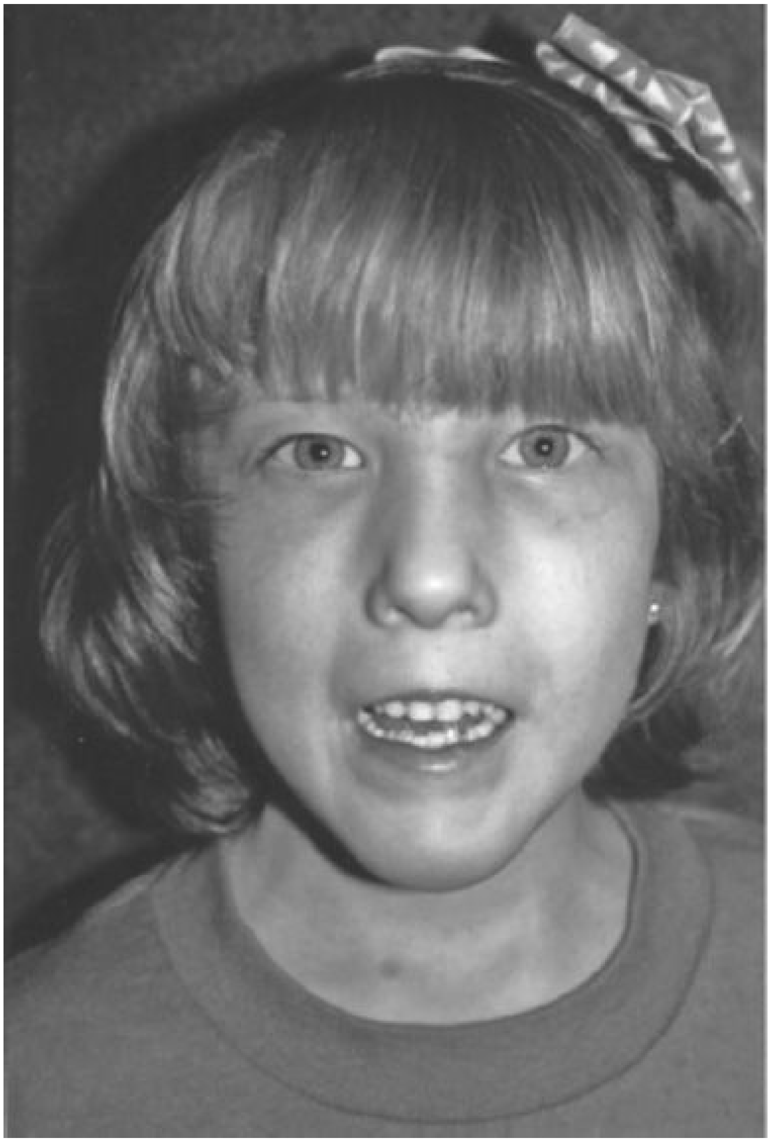

FIGURE 216-5 A 6-year-old girl with DiGeorge syndrome, illustrating the distinctive tall nasal root and bridge with a bulbous nasal tip and a small mouth. (*Used with permission from Jorde LB, Carey JC, Bamshad MJ, White RL. Medical Genetics. St. Louis, MO: Mosby; 2006. Rudolph's Pediatrics, 22nd edition. www.accesspediatrics.com. The McGraw Hill*

  - Tall nasal root and bridge (**Figure 216-1**, **216-3**, and **216-5**).
  - Bulbous nasal tip (**Figure 216-1**, **216-4**, and **216-5**).
  - Ocular hypertelorism (widely spaced eyes).
- Developmental or behavioral problems.

- Palatal problems, including overt and mucosal cleft palate and hyponasal speech.
- Conotruncal cardiac anomaly.

LABORATORY TESTING

- FISH (fluorescent in situ hybridization) method for chromosome 22q11.2 deletion.
- Chromosome SNP (single-nucleotide polymorphism) microarray, uses a “gene chip” to detect multiple micro-deletion and -duplication syndromes. It is more sensitive than FISH analysis.
- If 22q11.2 deletion testing is negative in a patient with a classic phenotype, consider sending testing for a point mutation in T-box 1 gene (TBX1), which is associated with 22q11.2 deletion.[1]
- Blood Testing for associated complications and immune function should include the following. The results will depend on the degree of thymic and parathyroid hypoplasia:
  - Calcium—Total and ionized.
  - Parathyroid hormone.
  - TSH.
  - CBC with differential.
  - Flow Cytometry for T and B cell Subsets (CD3, CD4, CD8, and CD19).
  - T and B cell Mitogen Stimulation panels, ATP assay.
  - Total immunoglobulin levels and specific antibody levels to infant vaccines at diagnosis and again at 6 and 12 months old.

IMAGING

- A chest x-ray may show absence of a thymic shadow in complete DiGeorge Syndrome (**Figure 216-2**). Most infants have hypoplasia of the thymus and the thymus will be visualized on chest x-ray (**Figure 216-6**).

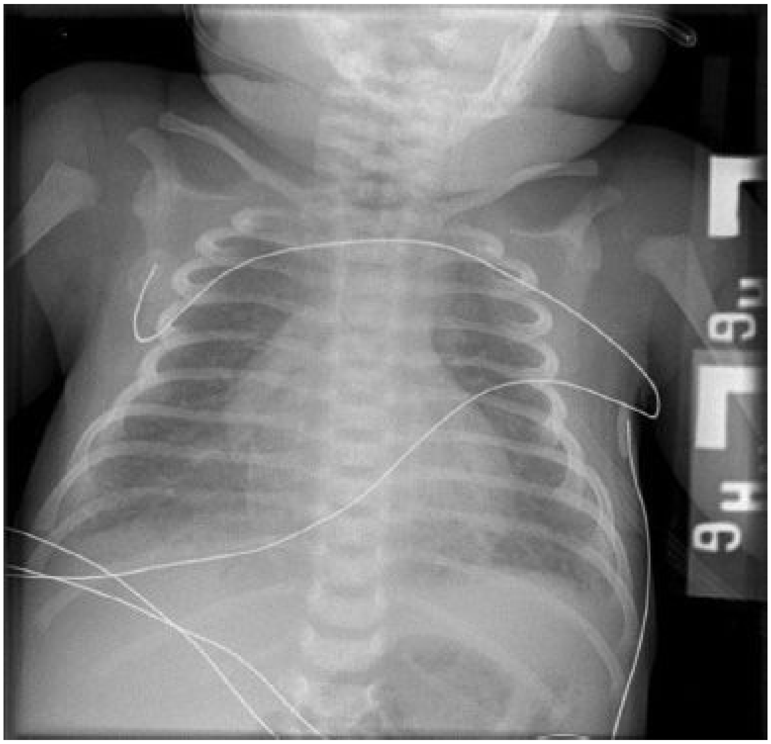

FIGURE 216-6 Normal thymic shadow on chest x-ray in a neonate with DiGeorge syndrome and Tetralogy of Fallot. (*Used with permission from Lisanne Newton, MD.*)

- Congenital heart disease may be identified on prenatal ultrasound or echocardiography in the neonate.
- Imaging studies to evaluate for intestinal malrotation should be obtained if there is abdominal distention, vomiting, or not passing stools or any other concerning clinical signs or symptoms.
- An MRI should be considered if there is microcephaly.
- Renal ultrasound will detect renal anomalies such as a structural anomaly, agenesis, dysplasia, hypoplasia, or hydronephrosis. A swallowing study may be needed if there are feeding difficulties.[2]

DIFFERENTIAL DIAGNOSIS

- CHARGE syndrome—Genetic disorder characterized by colobomas in the eye, heart defect, atresia of the choanae, retarded growth and development, genital abnormality, and ear abnormality.
- Zellweger syndrome—Genetic disorder caused by degeneration of myelin and characterized by central nervous system, cardiac, feeding, hearing, visual, and liver manifestations.
- Kabuki syndrome—Genetic disorder characterized by distinctive facial features (arched eyebrows, long eyelashes, long palpebral fissures, everted lids, flat, broadened tip of the nose, and large protruding earlobes), microcephaly, and hypotonia.
- Smith Lemli Opitz—Syndrome caused by a defect in cholesterol synthesis that results in multiple congenital malformations, dysmorphic facial features, and developmental delay.
- Goldenhar syndrome (Oculo-auricular-vertebral syndrome)—Genetic disorder resulting in malformations of the cheekbones, jaw, mouth, ears, eyes, and/or vertebrae (see Chapter 34, Congenital Malformations).
- Primary hypoparathyroidism—May manifest with severe hypocalcemia early in life but without the abnormal facial features and congenital heart disease.
- Fetal alcohol syndrome—Can manifest with dysmorphic facial features (widely set and narrow eyes, small upper jaw, and epicanthal folds), growth problems and nervous system abnormalities, and cardiac abnormalities (VSD and ASD; **Figure 216-7**).

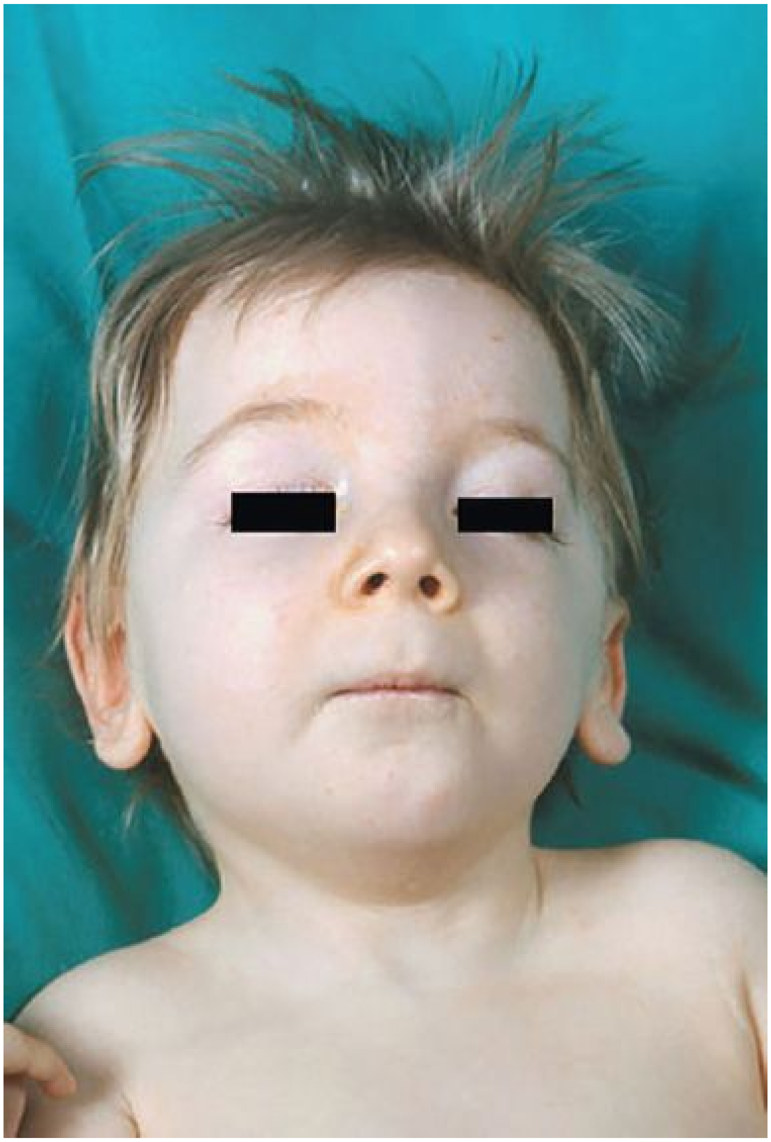

FIGURE 216-6 Wide-set and narrow eyes, small upper jaw, and epicanthal folds in an infant with characteristic features of fetal alcohol syndrome. (*Used with permission from Cleveland Clinic Children's*

- SCID in complete DGS—May manifest with severe immunosuppression in the neonatal period.

MANAGEMENT

- The management of DGS depends on the severity of the clinical phenotype and associated anomalies and the age of the patient.
- It requires a multidisciplinary approach including cardiology, genetics, immunology, otolaryngology, urology, or endocrinology based on clinical presentation.
- Life-threatening conditions should be evaluated without delay in neonates, including severe immune deficiency in patients with complete DGS, congenital heart disease if present, and significant hypocalcemia.

IMMUNOLOGIC

- Partial DGS—T cell function is largely intact in the majority of partial DGS patients. Most patients experience improvement in any abnormality in T cell production and function over time. In some DGS patients, there is a progressive decrease in T cell production, suggesting that patients may be at risk for increasing frequency of infections with age.[5]
- Increased risk for sinopulmonary infections is most common and should be treated with antibiotics as appropriate. Any deficiency in humoral immunity should be treated with immunoglobulin replacement if necessary.
- Complete DGS—These infants are similar to patients with severe combined immunodeficiency (SCID) and must be placed in isolation. Once identified, infants with complete DGS ideally should be promptly referred to a center capable of cultured unrelated thymic tissue transplants, or a center capable of bone marrow or hematopoietic cell transplants. Ideally, patients should be transplanted before the onset of significant infections, to optimize their chances for successful engraftment. Patients are at risk for opportunistic infections including fungi, viruses, and *Pneumocystis jiroveci* pneumonia (PJP) and should be on antimicrobial prophylaxis based on T cell number and function. However, stable infants may be observed for several weeks to monitor for T cell development.

CARDIAC

- Cardiac defects should be treated based on the specific defect and requires referral to cardiology/cardiothoracic surgery.

ENDOCRINE

- Hypocalcemia—Prompt identification and treatment of neonatal hypocalcemia may prevent complications such as seizures. This is especially important in patients with heart failure before or during surgery.

FEEDING

- Depending on associated palatal defects, feeding and swallowing problems can be extremely difficult in early infancy and can be distressing for parents. There can be poor coordination of pharyngeal muscles, tongue, and esophageal muscles.

NONPHARMACOLOGIC

- As previously described, much of the management of DGS is non-pharmacologic and medications vary greatly depending on the clinical phenotype and associated behavioral and psychiatric anomalies.

MEDICATIONS

- Hypocalcemia should be treated with calcium, vitamin D, or parathyroid hormone replacement.
- Prophylactic antibiotics should be used if the immune defect is severe. SOR Ⓒ Otherwise, antibiotics should be targeted to specific infections.
- IVIG should be given if immunoglobulin levels or function is low. SOR Ⓒ

SURGERY

- Surgery may be indicated for associated cardiac defects, thymus transplant for patients with complete DGS, and correction of palatal defects if present.

REFERRAL

- Referral to pediatric subspecialists again depends on the associated anomalies.
- Routine referral to cardiology, cardiothoracic surgery, endocrinology, genetics, immunology, and otolaryngology is indicated.
- Genetics is helpful at confirming diagnosis and discussing future reproductive issues.

PREVENTION AND SCREENING

SCREENING

- There is currently no available newborn screening for DGS.
- Complete DGS may be identified by newborn screening with T Cell Receptor Excision Circles (Trec) used to detect SCID, which is being done in some states.
- If an affected parent is found to have the same mutation as an affected offspring the risk of future children being affected is 50 percent, similar to an autosomal dominant condition.
- If the parents are not found to have the gene defect, then the risk of a future sibling of an affected child is low, less than 1 percent.
- Prenatal screening options include a level II ultrasound early in the 2nd trimester, a fetal echocardiogram, CVS sampling, and amniocentesis. FISH or SNP arrays can be performed on CVS or amniocentesis samples.[3]

VACCINATION

- The decision of whether to administer live vaccines (rotavirus, measles-mumps-rubella, varicella, and live attenuated influenza) depends on the degree of T cell dysfunction and should be made on a case-by-case basis.
- Generally, live vaccines should be withheld in patients with DGS until 1 year of age when immune function has been more firmly established and after referral to an immunologist.

PROGNOSIS

- Prognosis depends largely on the degree of immune deficiency and other associated anomalies, especially congenital heart disease.
- The overall mortality in childhood is approximately 4 percent.[1]
- Those infants who undergo thymic transplant have a survival rate of about 75 percent. Causes of death in the majority of these patients are infections.[6]

FOLLOW-UP

- It is important to continue regular follow-up with special attention paid to developmental delays, learning disabilities, speech delays, hearing, or vision difficulties.
- Adolescents with DGS are at higher risk for psychiatric disorders, including schizoaffective disorder, schizophrenia, and major depression.

PATIENT EDUCATION

- Each patient with DiGeorge Syndrome is treated individually depending on their unique features and the degree to which their organs are affected.
- The vast majority of patients have near-normal immune systems or only mild to moderate difficulty with infections that usually improves with age.
- The care of young infants with DGS will depend greatly on the presence and severity of heart disease.
- Most patients with DGS will need to be followed regularly by doctors in different specialties to ensure the best health and quality of life.

217 PRIMARY CILIARY DYSKINESIA

Timothy Campbell, MD
Brian Schroer, MD

PATIENT STORY

A 13-year-old boy presents for evaluation of a chronic productive cough and fever. Since birth, he has had persistent rhinitis, thick nasal drainage, and recurrent otitis media. He has been seen three times in the past year for pneumonia each time diagnosed and treated without a chest x-ray. On physical exam, heart sounds are greater on the right side and point of maximal impulse is felt in the right 5th intercostals space. A chest x-ray shows situs inversus totalis with dextrocardia (**Figure 217-1**). Computed tomography of the sinuses shows chronic sinusitis (**Figure 217-2**). The diagnosis of primary ciliary dyskinesia was considered and he underwent a biopsy of his nasal epithelium, which revealed abnormal ciliary structure and function. This confirmed the diagnosis and the physician explained the meaning of primary ciliary dyskinesia and the situs inversus to the patient and his parents. He was told that he will need aggressive treatments for all future infections.

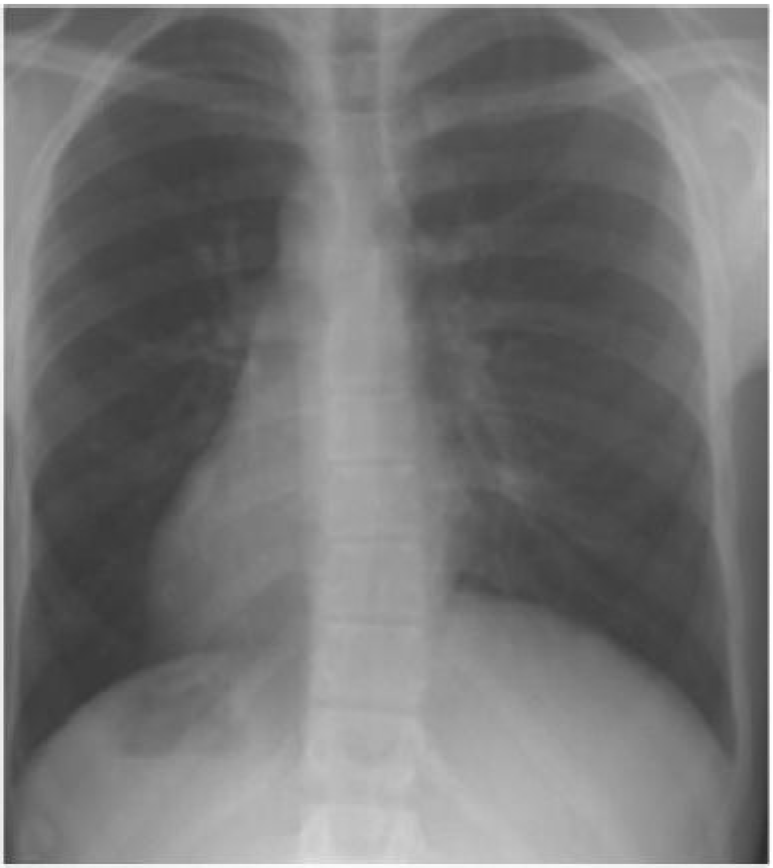

FIGURE 217-1 1 Dextrocardia on chest x-ray of a 13-year-old boy with Kartagener syndrome. (*Used with permission from McGraw-Hill Fig 30-6a. Clement P, Fisher BT.* Chapter 30*. Rhinosinusitis. In: Shah SS, ed. Pediatric Practice: Infectious Disease. New York: McGraw-Hill;*

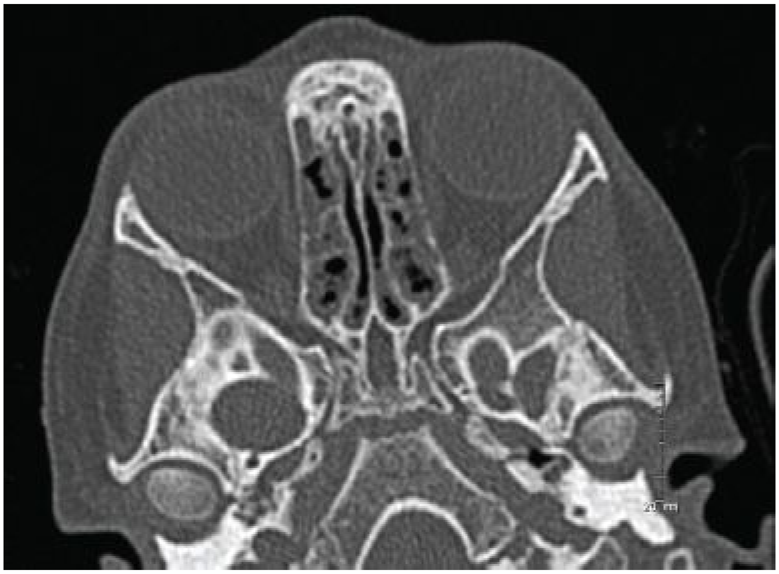

FIGURE 217-2 Soft tissue swelling of the sinuses on sinus CT scan in a patient with chronic sinusitis. (*Used with permission from Camille Sabella, MD.*)

INRODUTION

Primary Ciliary Dyskinesia (PCD) is a rare genetic disease associated with abnormal cilia structure and function causing impaired clearance of bacteria from the lungs, paranasal sinuses, and middle ear, which leads to recurrent infections. It can be associated with other developmental abnormalities such as situs inversus totalis, nasal polyposis, and frontal sinus agenesis. Clinical manifestations include chronic cough and chronic rhinosinusitis and recurrent sinopulmonary and ear infections.

SYNONYMS

- Primary Cilia Disorder.
- Immotile Cilia Syndrome (ICS).
- Kartagener syndrome—A triad consisting of situs inversus with bronchiectasis and paranasal sinusitis (secondary to PCD).

EPIDEMIOLOGY

- PCD is inherited in an autosomal recessive pattern and occurs in approximately 1 in 10,000 to 30,000 births.[2,3]

ETIOLOGY AND PATHOPHYSIOLOGY

PCD is caused by genetic mutations on genes which code for proteins found in the ciliary outer dynein arm which controls the cilia beat force and frequency.

- Motile cilia (**Figure 217-3**) contain a cylinder of 9 microtubule doublets, arranged around a central pair of microtubules in the characteristic “9 + 2” arrangement as viewed by cross-sectional views on electron microscopy.

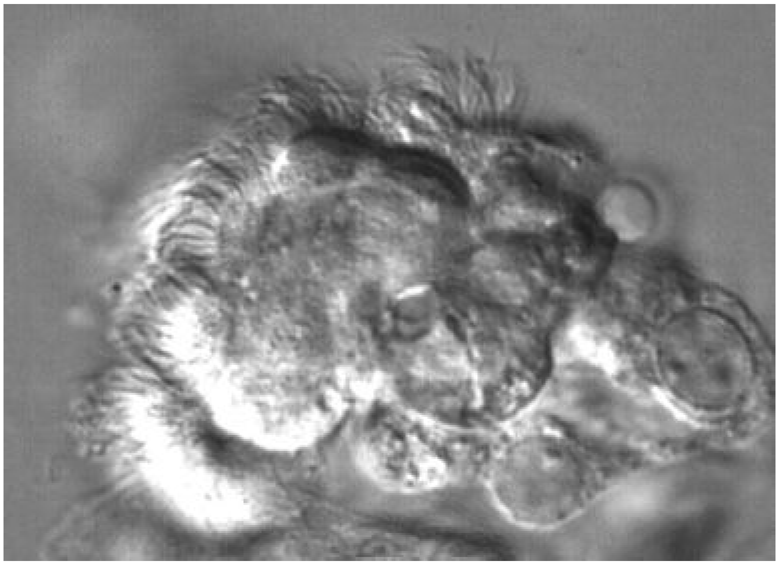

FIGURE 217-3 Electron micrograph of motile cilia. Notice the long curving cilia demonstrating active movement. (*Used with permission from Ian Myles MD, Steve Holland MD, and Harry Malech, MD. Scans were obtained for diagnostic and research purposes after informed consent under NIH IRB approved protocols.*)

- Defective cilia (**Figure 217-4**) resemble sensory or primary cilia, which lack a central microtubule doublet and outer dynein arms, thus creating a “9 + 0” arrangement and leaving these structures immotile.

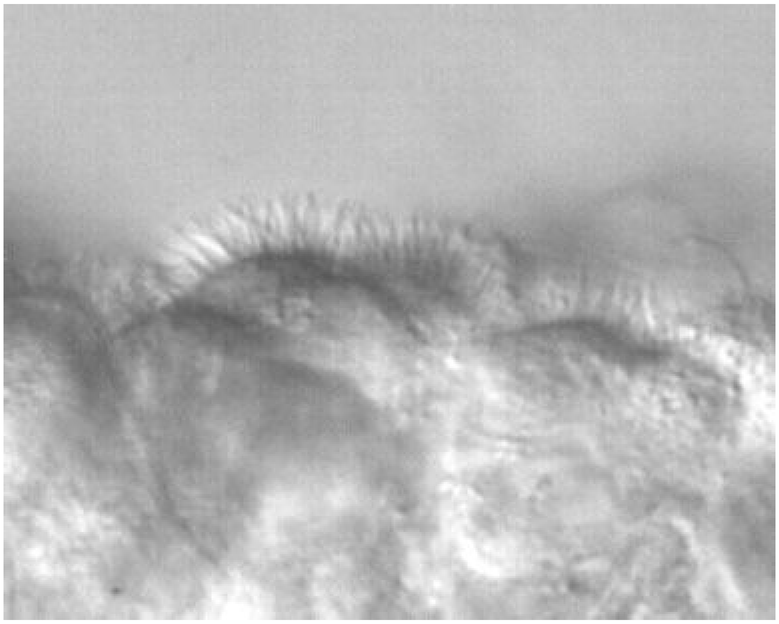

FIGURE 217-4 Electron micrograph of defective cilia. Notice the straight immotile cilia. (*Used with permission from Ian Myles MD*, *Steve Holland MD, and Harry Malech, MD. Scans were obtained for diagnostic and research purposes after informed consent under NIH IRB*

- Defects in cilia during embryogenesis may result in left-right body orientation abnormalities, such as situs inversus or situs inversus totalis (**Figure 217-1** and **217-5**).

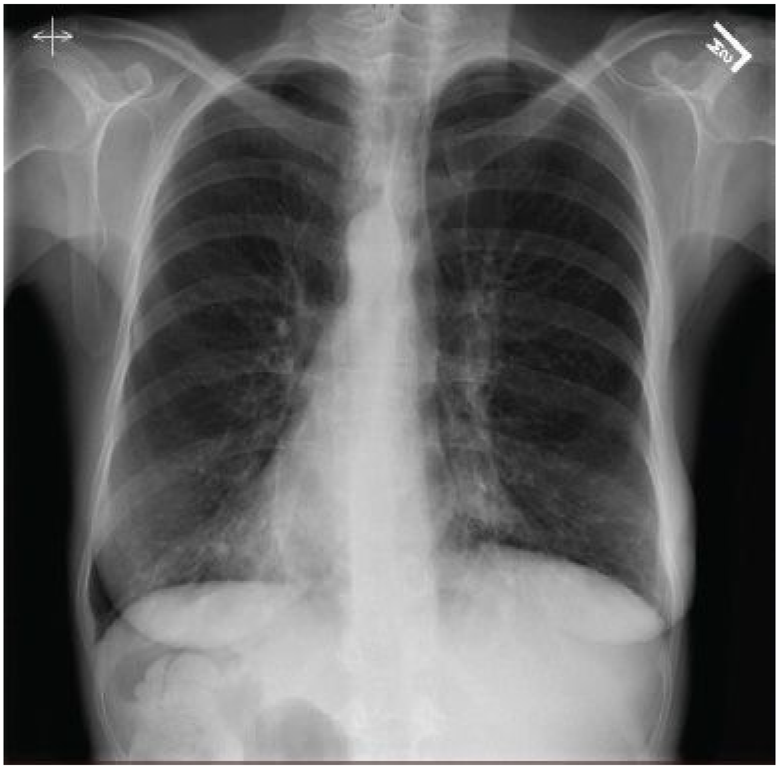

FIGURE 217-5 Situs inversus totalis on chest x-ray of a young woman. Note complete mirror image reversal of organs. (*Used with permission from Ian Myles MD, Steve Holland MD, and Harry Malech, MD. Scans were obtained for diagnostic and research purposes after informed consent under NIH IRB approved protocols.*)

- Any disturbance in the coordinated movement of cilia can contribute to poor mucous clearance resulting in more frequent and severe infections. It can inhibit sperm motility leading to infertility in men or cause fallopian tube dysfunction and infertility in women.[4]

DIAGNOSIS

- Patients must exhibit the characteristic clinical phenotype and specific ciliary ultrastructural defects identified by electron microscopy from biopsy samples of the respiratory epithelium such as from the mucosa of the nasal turbinates.

- Saccharin test—Assesses mucociliary function of nasal epithelium by depositing small particles of saccharin (or radiotracer dye particles) in the inferior nasal turbinate and measuring the time required for the patient to taste the sweet flavor or for the dye to become visible in the throat.[5]
- An exhaled nasal nitric oxide test is a useful screening test in patients with PCD. Patients with PCD will have low or absent exhaled nitric oxide.[6]

CLINICAL FEATURES

- Unexplained respiratory distress in the newborn period.[7]
- Chronic recurrent respiratory infections, including sinusitis, bronchitis, bronchiectasis (**Figure 217-6**), pneumonia, or otitis media. Bronchiectasis is the irreversible dilation of the bronchi secondary to repeated infections damaging the elastic tissue and smooth muscle within the bronchi.

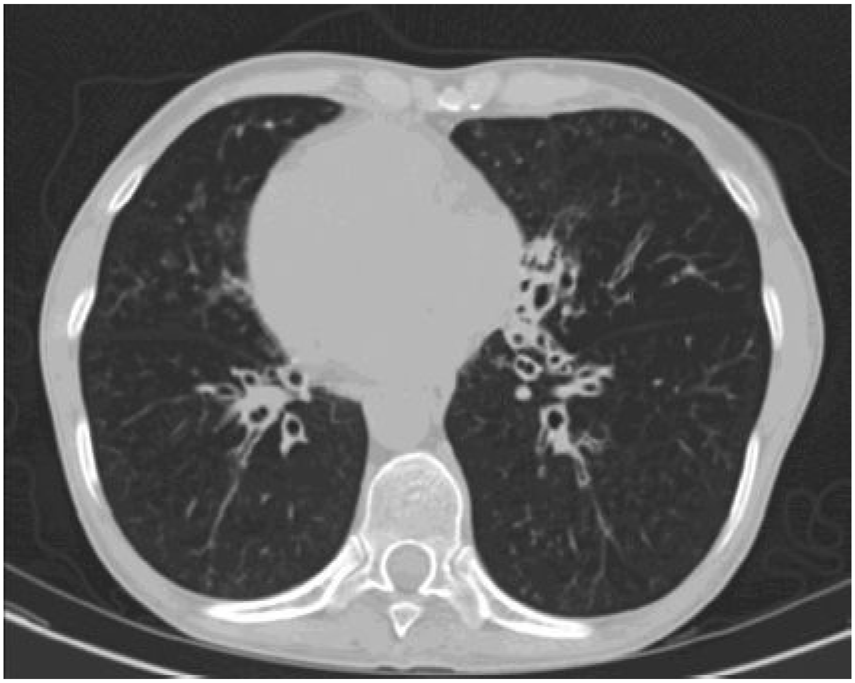

FIGURE 217-6 Bronchiectasis on coronal CT scan of the lungs. (*Used with permission from Ian Myles MD, Steve Holland MD, and Harry Malech,*

MD. Scans were obtained for diagnostic and research purposes after informed consent under NIH IRB approved protocols.)

- Conductive hearing loss due to damage of the middle ear from recurrent infections.[8]
- Situs inversus totalis (mirror-image reversal of all visceral organs with no apparent physiologic consequences) is present in 50 percent of individuals with PCD (**Figure 217-5**).[9]
- Approximately 50 percent of males are infertile as a result of abnormal sperm motility. Female infertility has also been reported due to dysfunctional fallopian tubes.[4]

LABORATORY STUDIES

- Respiratory cultures (typically sputum cultures) are obtained to determine the etiology of infections in order to be more precise with antibiotic therapy.

IMAGING

- Chest radiographs and/or chest CT should be obtained to define distribution and severity of airway disease and bronchiectasis.
- Sinus imaging (sinus x-rays or preferably sinus CT) should be obtained when symptoms suggest sinus disease.

DIFFERENTIAL DIAGNOSIS

- Cystic fibrosis—May present in a similar manner and must be excluded (see Chapter 51, Cystic Fibrosis).
- Immunodeficiency—may have similar clinical features, but can be ruled out with measurement of serum immunoglobulins and B- and T-cell

studies (see Chapters 218, B Cell Immunodeficiencies, 219, B and T Cell Immunodeficienies, and 220, Chronic Granulomatous Disease).

- Allergic rhinitis and asthma—may have similar clinical features, but usually responds well to standard therapies (see Chapters 49, Asthma, and 215, Allergic Rhinitis).
- Gastroesophageal reflux disease—Will often have symptoms specific for reflux and does not usually lead to chronic infections.
- Young syndrome—Male infertility (obstruction of the epididymis by inspissated secretions) with chronic sinopulmonary infection.[10]
- Wegener's granulomatosis—Upper- and lower-airway disease involvement may present with chronic lung and sinus disease.
- Situs inversus totalis or dextrocardia—May occur as isolated findings without ciliary dysfunction.

MANAGEMENT

- At present, no specific therapies can correct ciliary dysfunction. Therapies are empiric and aimed at treating consequences of dysfunctional cilia and are extrapolated from treatments of other lung diseases such as cystic fibrosis.
- Pulmonary disease.
    - Pulmonary function tests (spirometry) to define severity of obstructive impairment.
    - Chest percussion and postural drainage, oscillatory vest, and breathing maneuvers to enhance mucus clearance.
- Chronic/recurrent ear infections. Formal hearing evaluation with hearing aids and speech therapy when necessary.
- Prompt institution of antibiotic therapy for bacterial infections of the airways (bronchitis, sinusitis, and otitis media) is essential for preventing irreversible damage.
- Because cough is an effective clearance mechanism, patients should be encouraged to cough and engage in activities that promote deep breathing

and cough (e.g., vigorous exercise).

- Routine immunizations to protect against respiratory pathogens including pertussis, *Haemophilus influenzae* type b, pneumococcus, and influenza (annually).
- Lung transplantation has been performed in persons with end-stage lung disease.
- Typically, situs abnormalities do not require intervention unless physiologic dysfunction requiring surgical intervention is present.
- Sperm harvesting and in vitro fertilization have been successful for male infertility.

FOLLOW-UP

The patient should be followed by his pulmonary, ENT, and/or cardiology specialists regularly and as the clinical presentation dictates.

PATIENT EDUCATION

- Patients should remain up-to-date on vaccinations, avoid the use of cough suppressants, avoid exposure to respiratory pathogens, tobacco smoke, and other pollutants that may damage airway mucosa and stimulate mucus secretion.
- Relatives with symptoms or findings suggestive of PCD including neonatal respiratory distress despite term gestation, chronic sinopulmonary disease, bronchiectasis, situs inversus totalis, other situs abnormalities, and male infertility should undergo diagnostic evaluation for PCD.

218 B CELL IMMUNODEFICIENCIES

Ahila Subramanian, MD, MPH
Brian Schroer, MD

PATIENT STORY

A 13-month-old boy is hospitalized with high fever, cough, and decreased oral intake. Diagnostic work up reveals pneumococcal pneumonia (**Figure 218-1**). He responds well to intravenous and oral antibiotic treatment with complete resolution of symptoms. His birth history is unremarkable with a normal full-term delivery and birth weight (3.3kg). At 4 months of age, he developed otitis media successfully treated with oral antibiotics. Since then he has had numerous upper respiratory and ear infections. At 8 months of age, he was hospitalized for treatment of *Staphylococcus aureus* cellulitis. Each infection responded well to short courses of antibiotic therapy. He has received all scheduled immunizations up to 12 months. Physical exam reveals a pale, thin child who is below the 3rd percentile for height and weight. He has normal features and developmental milestones. Further family history reveals a maternal uncle with similar symptoms in childhood. Immunologic work up is notable for severe hypogammaglobulinemia and low antibody vaccine titers. Genetic testing for BTK mutation confirms the diagnosis of X-Linked Agammaglobulinemia (XLA). Treatment with intravenous immunoglobulin replacement is started for management of antibody deficiency. Over the next 12 months, the boy has a significant decrease in infections and is noted to have improved growth.

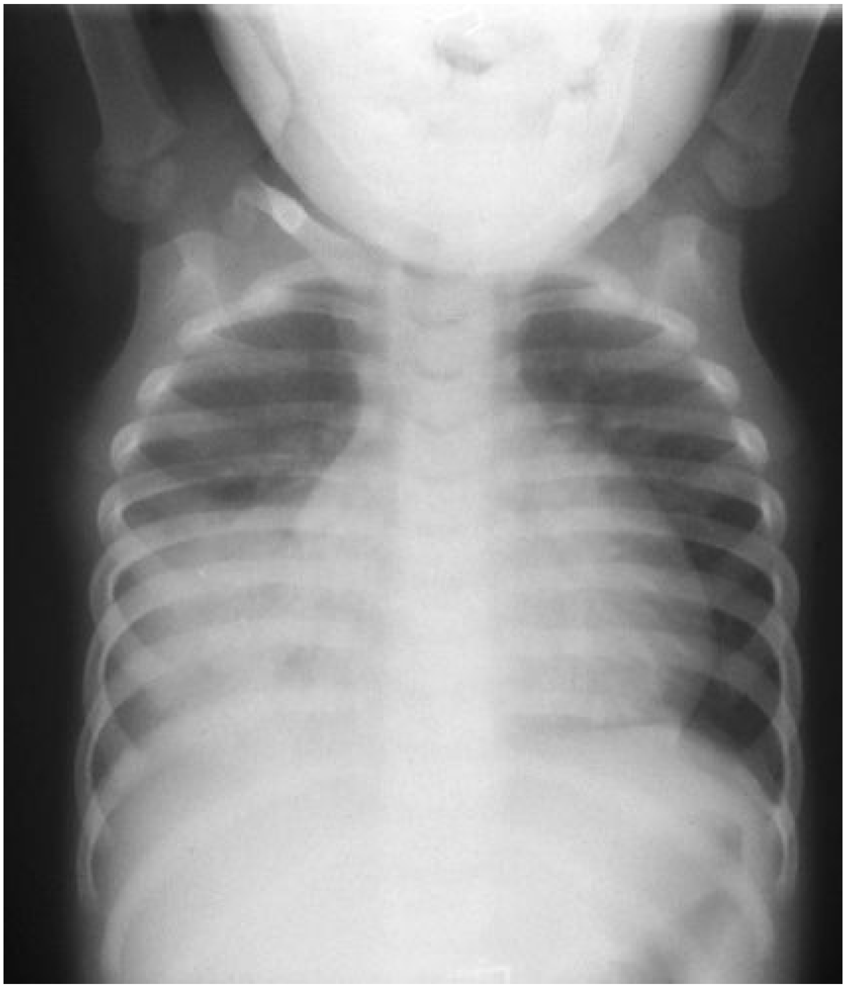

FIGURE 218-1 Right middle lobe consolidation on chest x-ray on an infant with X-linked agammaglobulinemia. Blood culture from this infant grew *Streptococcus pneumonia*. (*Used with permission from Camille Sabella, MD*.)

INRODUTION

Disorders of primary B cell immunodeficiency comprise approximately half of all primary immunodeficiencies. They are a group of heterogeneous disorders resulting from disruption of B cell maturation and function at various stages of development. The main role of B lymphocytes is production of antibodies for recognition and destruction of foreign antigens. Dysfunction of B lymphocytes results in impaired antibody production leading to illness characterized by unusual susceptibility to recurrent infections, particularly by encapsulated bacterial pathogens.

B cell immunodeficiencies are distinguished phenotypically by clinical severity, mode of inheritance, and age of onset. As a group, they share common clinical features and strategies for evaluation and management that will be discussed in this chapter.

SYNONYMS

- Humoral immune deficiency.
- Antibody deficiency syndrome.
- X-Linked Agammaglobulinemia (XLA)/Bruton's Agammaglobulinemia.
- Common Variable Immunodeficiency (CVID).
- Acquired Hypogammaglobulinemia.
- Transient Hypogammaglobulinemia of Infancy.
- Hyper IgM Syndrome.

EPIDEMIOLOGY

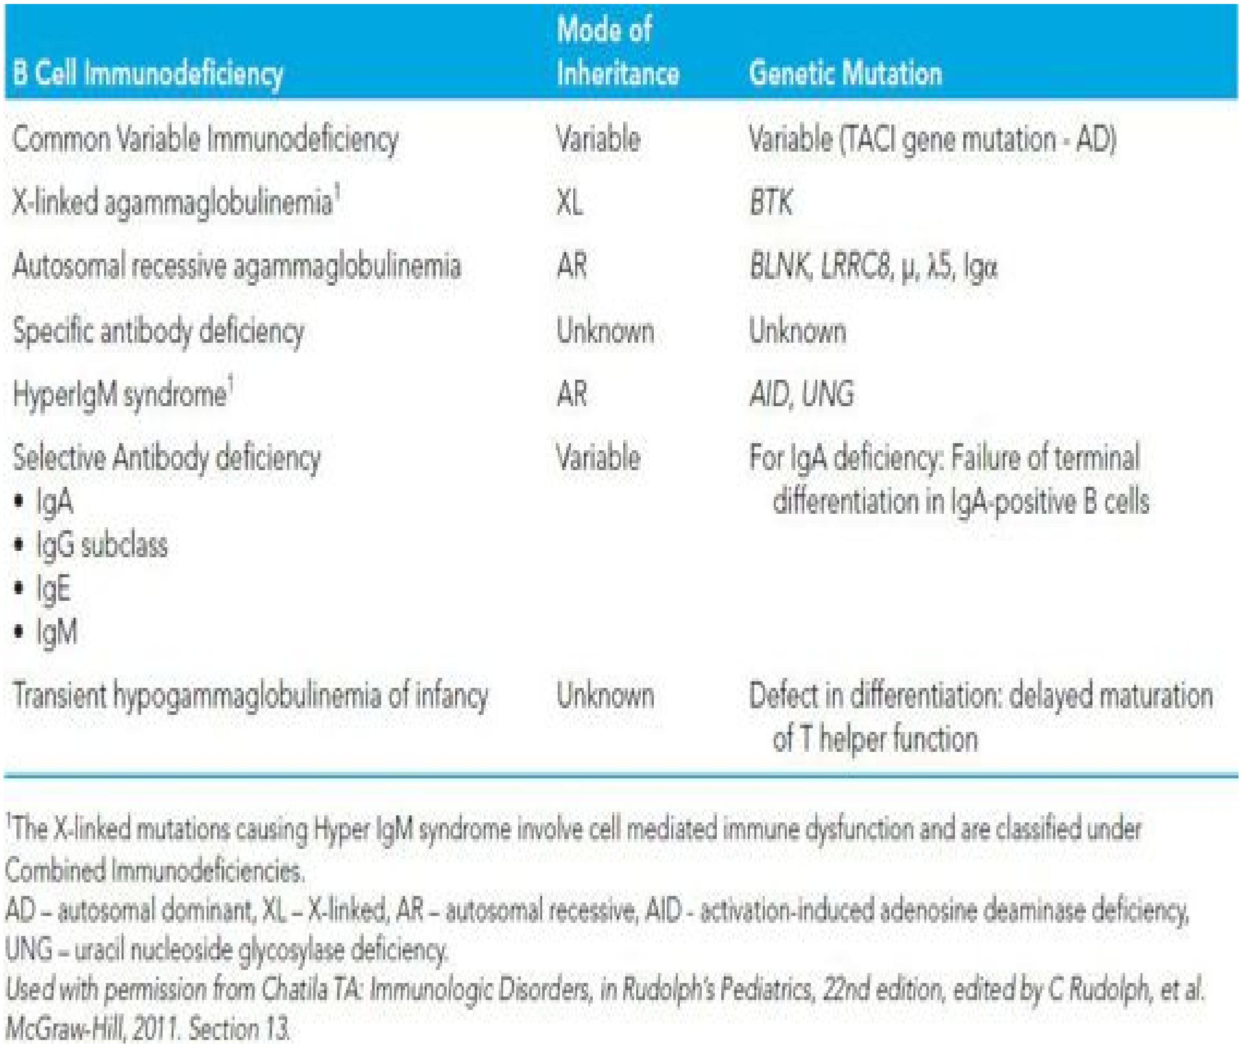
- B cell immunodeficiencies make up approximately 50 percent of primary immune deficiencies.[1]
- IgA deficiency is the most common B cell disorder (estimated incidence of 1 in 700 persons of European ancestry).[2]
- The second most common B cell disorder is CVID (estimated incidence of 1 in 30,000 ro 50,000 persons).[3]
- Early B cell defects such as X-linked Agammaglobulinemia (XLA) are rare (estimated incidence of XLA is 1 per 200,000 male births).[2]

- XLA accounts for approximately 85 percent of individuals with profound hypogammaglobulinemia and markedly reduced or absent B cells.[1]
- Age of onset is variable among primary B cell immunodeficiencies.
- The degree of immunoglobulin deficiency is a key determinant of disease severity and time of presentation. Individuals with more severe hypogammaglobulinemia or agammaglobulinemia have clinical presentation earlier in life.
- Disorders with severe hypogammaglobulinemia present most commonly between 6 and 18 months of age. Their first infections can present as early as 4 months as protection from passive maternal IgG wanes.
- CVID can present as early as 4 years of age but is more commonly diagnosed as an adult with onset between the 2nd and 4th decade of life.
- Transient Hypogammaglobulinemia of infancy occurs in patients with low IgG, with or without low IgA or IgM, whose immunoglobulin levels are low but increase over time.

ETIOLOGY AND PATHOPHYSIOLOGY

- B cells originate in the bone marrow and undergo maturation in peripheral lymphoid organs including the lymph nodes, spleen, and mucosa-associated lymphoid tissue (MALT).
- B cell immunodeficiencies are caused by molecular defects leading to disruption of B cell development or the interactions between B and T cells required for B cell function.
- The etiologies of these defects are variable including genetic inheritance and spontaneous mutation.
- Table 218-1 summarizes the modes of inheritance and known genetic mutations of the major disorders of B cell immuno deficiency.[4]

TABLE 218-1 Mode of Inheritance and Important Genetic Mutations of the Major B Cell Immunodeficiency Syndromes



B Cell Immunodeficiency	Mode of Inheritance	Genetic Mutation
Common Variable Immunodeficiency	Variable	Variable (TACI gene mutation - AD)
X-linked agammaglobulinemia[1]	XL	*BTK*
Autosomal recessive agammaglobulinemia	AR	*BLNK, LRRC8,* μ, λ5, Igα
Specific antibody deficiency	Unknown	Unknown
HyperIgM syndrome[1]	AR	*AID, UNG*
Selective Antibody deficiency • IgA • IgG subclass • IgE • IgM	Variable	For IgA deficiency: Failure of terminal differentiation in IgA-positive B cells
Transient hypogammaglobulinemia of infancy	Unknown	Defect in differentiation: delayed maturation of T helper function

[1] The X-linked mutations causing Hyper IgM syndrome involve cell mediated immune dysfunction and are classified under Combined Immunodeficiencies.

AD – autosomal dominant, XL – X-linked, AR – autosomal recessive, AID - activation-induced adenosine deaminase deficiency, UNG – uracil nucleoside glycosylase deficiency.

Used with permission from Chatila TA: Immunologic Disorders, in Rudolph's Pediatrics, 22nd edition, edited by C Rudolph, et al. McGraw-Hill, 2011. Section 13.

DIAGNOSIS

CLINICAL FEATURES

- Recurrent fever.
- Recurrent bacterial infections with encapsulated pyogenic organisms (i.e., *Haemophilus influenzae, Streptococcus pneumoniae, Staphylococcus aureus, Neisseria meningitides*).
- Chronic gastrointestinal infections (i.e., *Giardia lamblia, Campylobacter jejuni*)

- Enterovirus infections (i.e., Coxsackievirus, ECHOvirus, wild-type and vaccine-associated polio virus).
- Opportunistic viral infections are rare in pure B cell disorders but can be seen in subset of CVID involving T cell dysfunction (**Figure 218-2**).

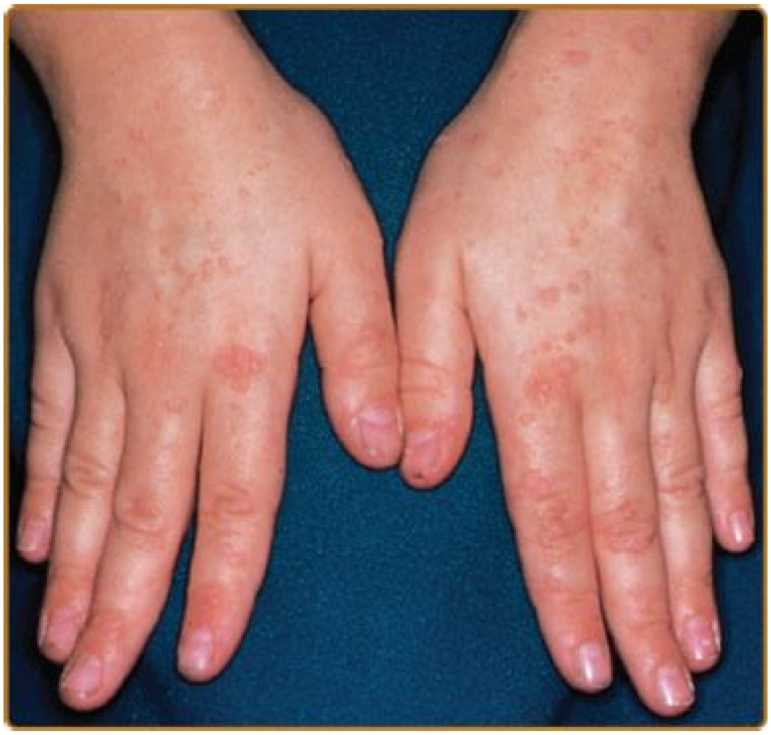


FIGURE 218-2 Recalcitrant verrucae vulgaris on the dorsal hands of a girl with common variable immunodeficiency. (*Used with permission from RL Fuleihan, AS Paller: Genetic Immunodeficiency Disease, in Fitzpatrick's Dermatology in General Medicine, 8th edition, edited by LA Goldsmith, et al. McGraw-Hill, 2012. Chapter 143*).

- Poor growth, failure to thrive.
- Chronic diarrhea.
- Concomitant autoimmune conditions (i.e., diabetes mellitus, autoimmune hepatitis, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, rheumatoid arthritis, interstitial lung disease, inflammatory bowel disease, or uveitis).
- Family history of immunodeficiency or frequent infections.

PHYSICAL FINDINGS

- Absent tonsils, small lymph nodes (seen only in early B cell defect disorders that result in severe hypogammaglobulinemia; **Figure 218-3**).

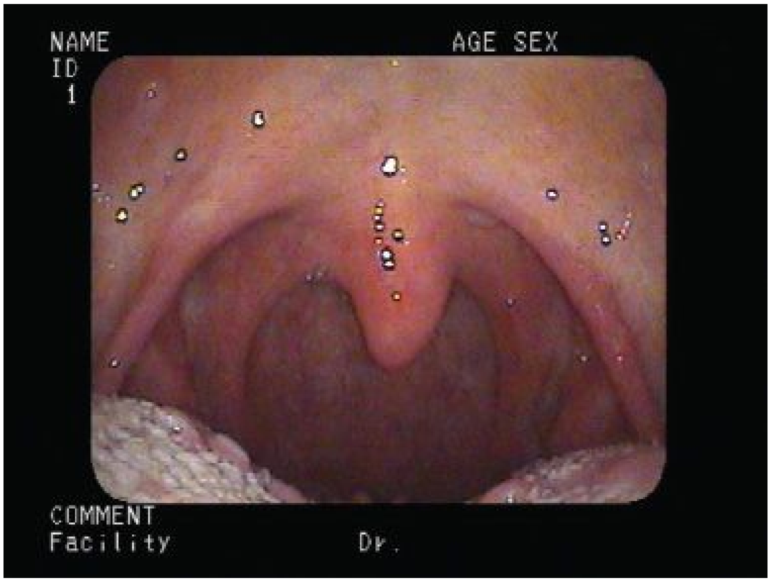

FIGURE 218-3 Oropharynx showing absence of tonsils in a patient with X-linked agammaglobulinemia. (*Used with permission from David Kosakowski, MD*.)

- Nodular lymphoid hyperplasia in peripheral lymph nodes, mesenteric lymph nodes, tonsils, liver, and spleen.
- Hepatomegaly, splenomegaly (**Figure 218-4**).

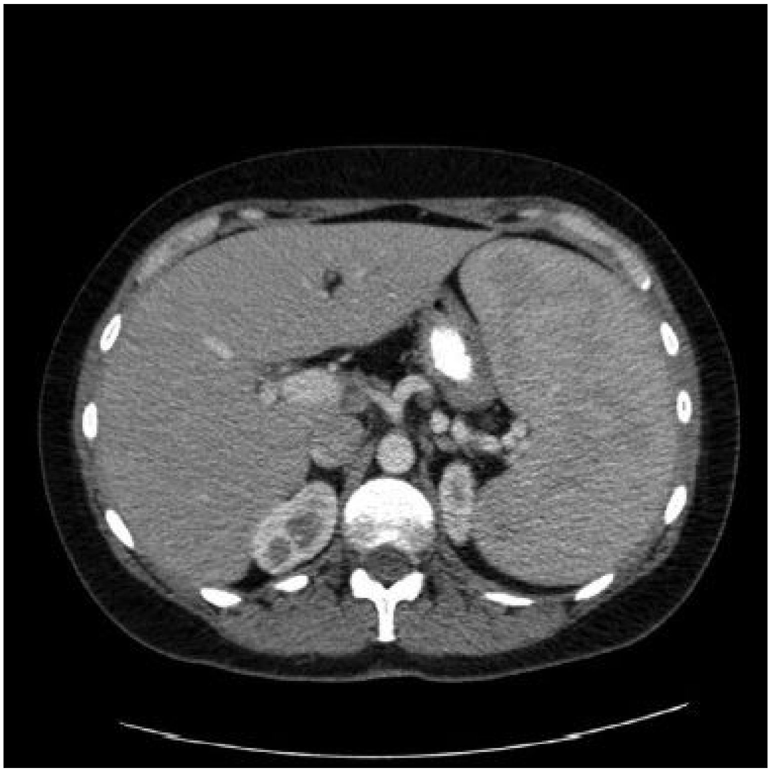

FIGURE 218-4 Splenomegaly in a woman with common variable immunodeficiency. (*Used with permission from James Fernandez, MD.*)

- Chronic inflammation and swelling of joints.
- Bronchiectasis (**Figure 218-5**).

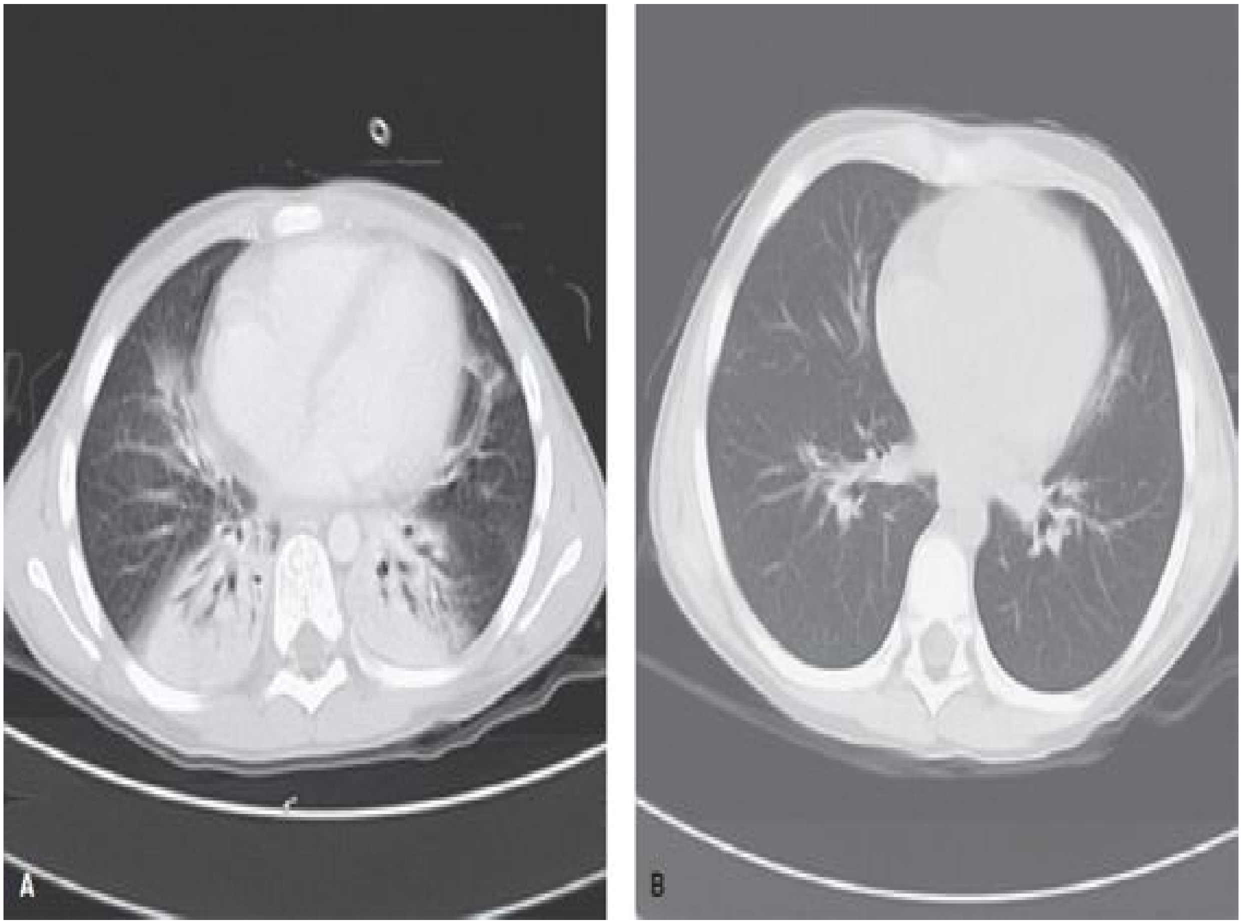

FIGURE 218-5 Initial and follow-up high resolution CTs of the chest of a 10-year-old boy with common variable immunodeficiency. **A.** Initial study demonstrating bilateral densities with areas of early bronchiectasis and tree-in-bud formations; **B.** Following 2 months of intravenous gamma globulin therapy and antibiotics, there is a resolution of parenchymal disease. (*Used with permission from Fiorino, EK, Panitch HB: Recurrent Pneumonia, in Pediatric Practice: Infectious Disease, edited by SS Shah, McGraw-Hill; 2009. Chapter 35.*)

- Granulomatous lesions on skin and internal organs (**Figure 218-6** and **218-7**).

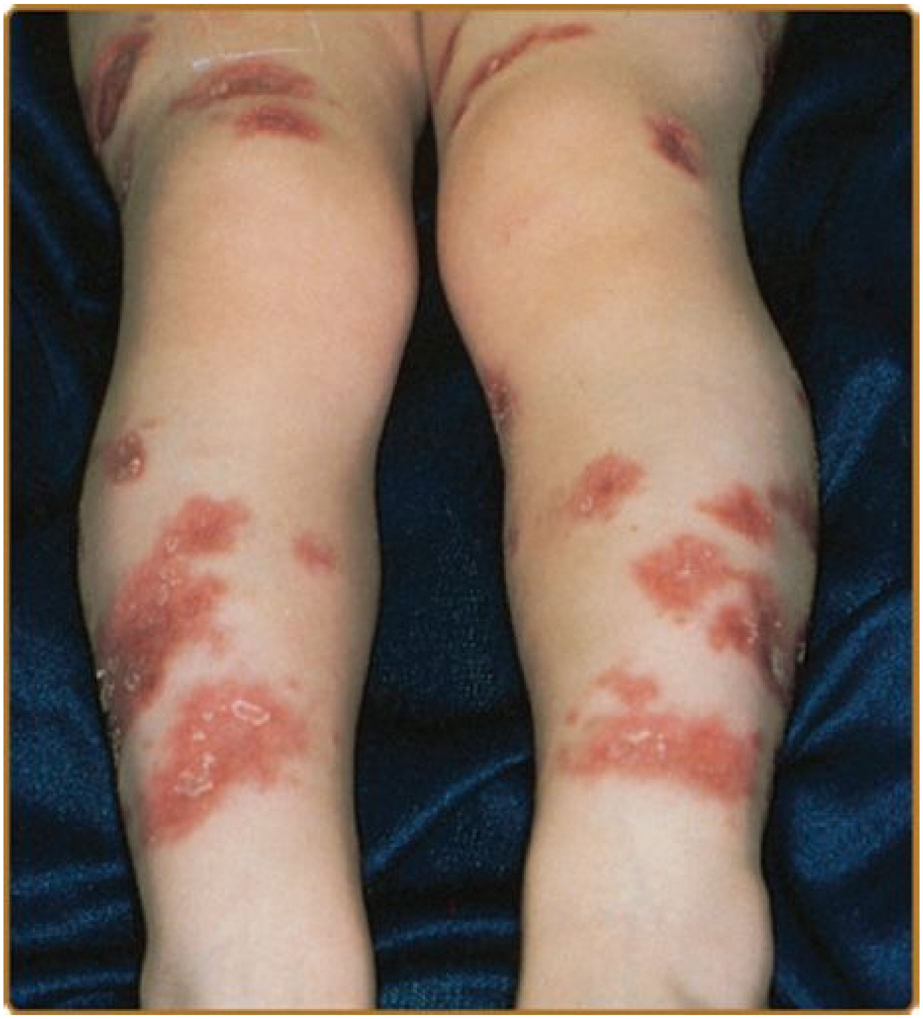

FIGURE 218-6 Non-caseating granulomas on the legs of a child with common variable immunodeficiency. Cultures and special stains showed no organisms. (*Used with permission from RL Fuleihan, AS Paller: Genetic Immunodeficiency Disease, in Fitzpatrick's Dermatology in General Medicine, 8th edition, edited by LA Goldsmith, et al. McGraw-Hill; 2012. Chapter 143*).

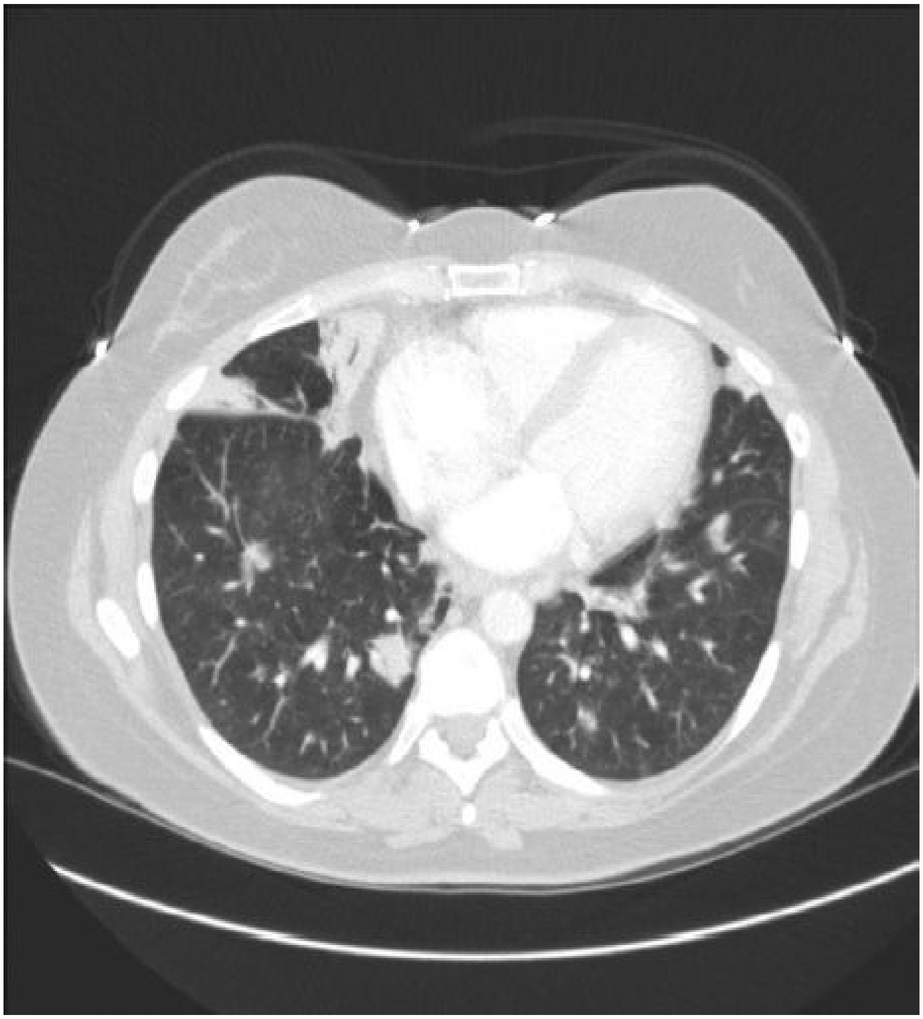

FIGURE 218-7 Bronchiectasis and lung granulomas in a patient with common variable immunodeficiency. (*Used with permission from James Fernandez, MD.*)

LABORATORY TESTING

  - Total serum IgG, IgA, IgM, and IgE.

- Immunoglobulin vaccine titers:
  - Pneumococcal antigen serotypes (polysaccharide).
  - *H influenza* type B (polysaccharide).
  - Diphtheria (protein).
  - Tetanus (protein).

- If vaccine titers are low, individual should be challenged with the relevant vaccine followed by reevaluation of vaccine titers in 4 to 6 weeks to assess antibody response.
- Isohemagglutinins in infants who have not completed the primary immunization series.
- B cell enumeration using flow cytometry.
- B cell phenotypes, specific genetic mutation analysis.
- Table 218-2 summarizes the common lab findings among B cell immunodeficiencies.

TABLE 218-2 Laboratory Features of the B Cell Immunodeficiency Syndromes

			Specific Antibody Response	
B Cell Immunodeficiency	B/T Cells	Serum Ig	Protein	Polysaccharide
Common Variable Immunodeficiency	Variable: normal or low B/T cells	• Decreased IgG • Decreased IgA or IgM	Usually low	Usually low
X-linked agammaglobulinemia	Very low or absent B cells	All isotypes very low or absent	None	None
Autosomal recessive agammaglobulinemia	Very low or absent B cells	All isotypes very low or absent	None	None
Specific antibody deficiency	Normal	Normal	Usually normal	Low
Hyper IgM syndrome	Normal	• Normal or high IgM • Decreased IgA, IgG	IgM only	IgM only
Selective Antibody deficiency • IgA • IgG subclass • IgE • IgM (rare)	Normal	• Very low or absent Ig for respective condition	Usually normal	Variable
Transient hypogammaglobulinemia of infancy	Normal	Low IgG	Usually normal	Usually normal

IMAGING

- CT imaging can be helpful in identification of chronic and acute sequelae of B cell immunodeficiencies including size of adenoid tissue, infection, granulomas, and bronchiectasis.
- MRI may be used in assessment of soft tissue infections.
- Imaging should be guided by localization of symptoms.

DIFFERENTIAL DIAGNOSIS

- Combined immunodeficiency- Primary and Acquired (HIV)—These children will have features of both B- and T-cell immunodeficiency, rather than just B cell deficiency manifestations (see Chapter 219, B and T cell Immunodeficiencies).
- Protein-losing enteropathy—Loss of immunoglobulins through the gut usually secondary to a chronic condition such as heart disease. Will generally not respond to immunoglobulin replacement.
- Nephrotic syndrome—Loss of function and quantity of immunoglobulins (see Chapter 67, Nephrotic Syndrome).
- Malnutrition or decreased protein production—Will be apparent on history and physical examination.
- Acquired humoral immune deficiency secondary to drugs (i.e., chronic steroids, immunosuppressants, and anti-B cell cytotoxic therapeutics) in children with chronic conditions.

MANAGEMENT

- Aim of treatment is to prevent future infections and minimize progression of chronic disease (i.e., bronchiectasis).

NONPHARMACOLOGIC

- Standard infection prevention measures including hand hygiene and avoidance of sick contacts may be helpful for mitigating pathogen exposure.

MEDICATIONS

- Replacement of immunoglobulin is the primary treatment in individuals with immunoglobulin deficiency and associated clinical symptoms.[5–9] SOR Ⓐ
- Replacement immunoglobulin is available in two forms:
    - Intravenous immunoglobulin (IVIG) given once every 3 to 4 weeks.
    - Subcutaneous immunoglobulin given once a week.
- Antibiotic treatment for acute infections should be started early and in conjunction with a diagnostic workup to identify the organism and its antibiotic susceptibilities if possible.
- Antibiotic prophylaxis may be helpful in prevention of chronic infections. While the risk of antibiotic resistance should be considered, prophylaxis may be indicated in individuals who continue to have clinical symptoms while on immunoglobulin replacement. SOR Ⓒ
- Antibiotic prophylaxis is recommended prior to dental and surgical procedures. SOR Ⓒ
- Killed vaccinations can be safely administered and have found to have some benefit. Patients as well as close household contacts should receive an annual influenza vaccine.[10] SOR Ⓒ
- Live virus vaccines are contraindicated in all individuals with B cell immunodeficiencies.[10] SOR Ⓒ

REFERRAL

- Refer patients with any of the clinical features mentioned above or following criteria to an immunologist:[11]

  - Four or more new ear infections within one year.
  - Two or more serious sinus infections within one year.
  - Two or more months on antibiotics with minimal effect or need for intravenous antibiotics for clearing infections.
  - Two or more pneumonias in lifetime.
  - Recurrent deep skin or organ abscesses.
  - Family history of primary immunodeficiency.
  - Two or more serious infections including septicemia.

PREVENTION AND SCREENING

- Routine assessment of growth parameters and frequency/severity of infections at well child visits.

PROGNOSIS

- Prognosis is variable depending on the severity of antibody deficiency. Overall, individuals with B cell immunodeficiencies who are treated with immunoglobulin replacement have a reasonably good prognosis.
- Early initiation of immunoglobulin replacement in patients with profound hypogammaglobulinemia is crucial for improved outcome.
- Individuals with B cell immunodeficiencies have an increased risk of malignancy and autoimmune disease that in turn increase morbidity and mortality.
- The presence of chronic disease sequelae is a predictor of poor outcomes.

FOLLOW-UP

- Patients with evidence of B cell immunodeficiency should have regular follow-up with an immunologist.
- Frequency of monitoring with labs and imaging is dependent on the degree of immunoglobulin impairment and clinical severity.

219 B AND T CELL IMMUNODEFICIENCIES—SEVERE COMBINED IMMUNODEFICIENCY (SCID) AND OTHER WELL DEFINED PRIMARY IMMUNODEFICIENCIES

Brian Schroer, MD
Tim Niehues, MD
Gregor Dückers, MD

PATIENT STORY

A 2.5-month-old-baby boy presented to his pediatrician because of a 10-day history of diarrhea, which began soon after his first series of immunizations, which included the oral rotavirus vaccine. He was born via uncomplicated vaginal delivery and his birth weight and height were at the 55 percent percentile. There were no known ill contacts. His weight and height, which had been 15 percent at two months, was now lower and he had a fever to 101F. Thrush was noted on his tongue and throat, and he was noted to have a diffuse scaling rash on the face and hands (**Figure 219-1** and **219-2**). A CBC with differential showed an absolute lymphocyte count of 1,200 cells/microliter. A chest x-ray was performed which showed diffuse infiltrates and the absence of a thymic shadow. He was referred to an immunologist for immediate evaluation and treatment. T and B cell subsets were obtained, which revealed that 90 percent of his lymphocytes are B cells and that he had very low numbers of T of maternal origin and NK cells. He was treated with intravenous immune globulin (IVIG), placed on trimethoprim-sulfamethoxazole for *Pneumocystis jirovecii* prophylaxis and referred to a specialized immunology center for a bone marrow transplant. His bone marrow transplantation was successful.

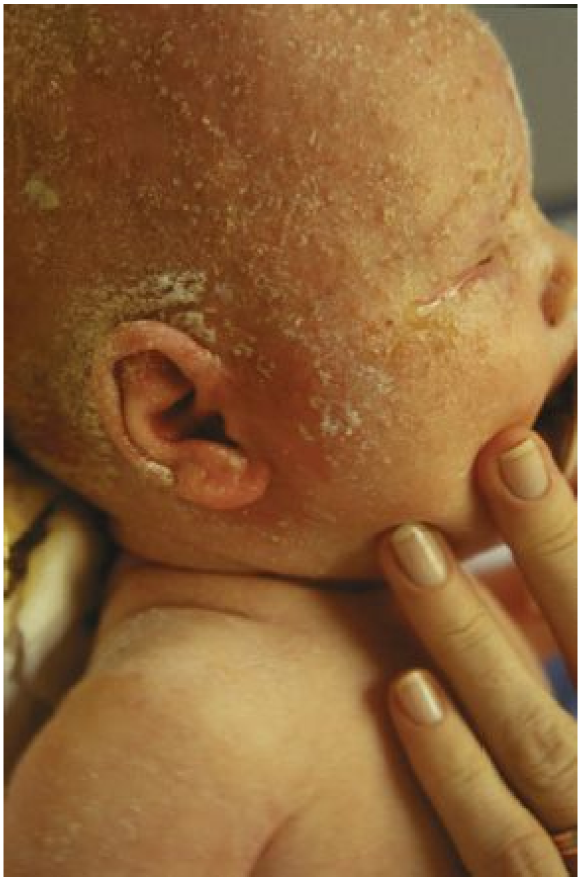

FIGURE 219-1 Exfoliative dermatitis caused by maternal T-cells in a young infant with severe combined immunodeficiency. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD*.)

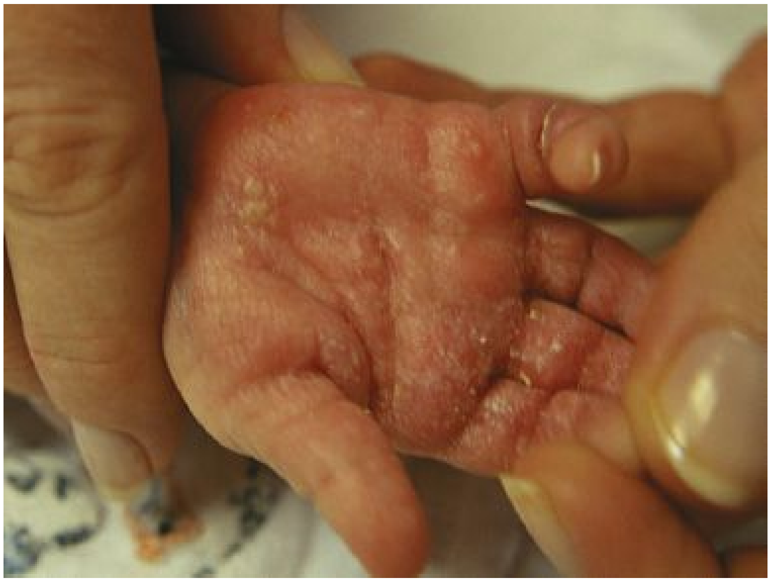

FIGURE 219-2 Exfoliative dermatitis on the palms of the same infant as in **Figure 219-1**. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD. Reprinted from Clinical Immunology, 2010, p. 187, with permission from Elsevier*.)

INRODUTION

Combined immunodeficiency syndromes arise from genetic defects leading to T lymphocyte dysfunction. Because B cells require T cells to produce antibodies, these patients are susceptible to opportunistic infections as well as skin and sinopulmonary infections due to bacterial, viral and fungal organisms. Immune dysregulation can lead to autoimmune disease and auto-inflammation in some syndromes. A diagnosis of a Severe Combined Immunodeficiency (SCID) is fatal before the age of 2 years if untreated and is a medical emergency. Some well-defined primary immunodeficiencies including Wiskott-Aldrich Syndrome, Hyper IgE syndrome, and Ataxia Telangiectasia may present in older patients.

SYNONYMS

- Primary or Congenital Immunodeficiency.
- Swiss type agammaglobulinemia.
- T-Cell Deficiency.
- Bubble Boy Disease.

EPIDEMIOLOGY

- SCID is very rare with an incidence reported at 1.8/100,000 live births per year.[1]
- Newborn screening with T cell receptor excision circles (Trec) has found a rate of 1.64/100,000 tests in Wisconsin. Trec screening does miss some atypical forms of SCID.[2]

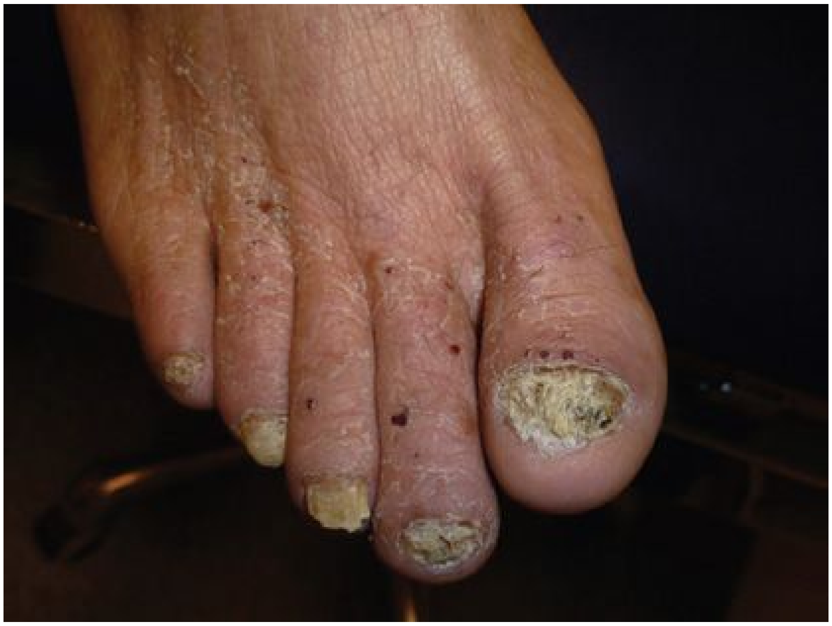

FIGURE 219-3 Onychomycosis of the toes and severe eczema of the skin in a patient with AD- Hyper IgE syndrome. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD*.)

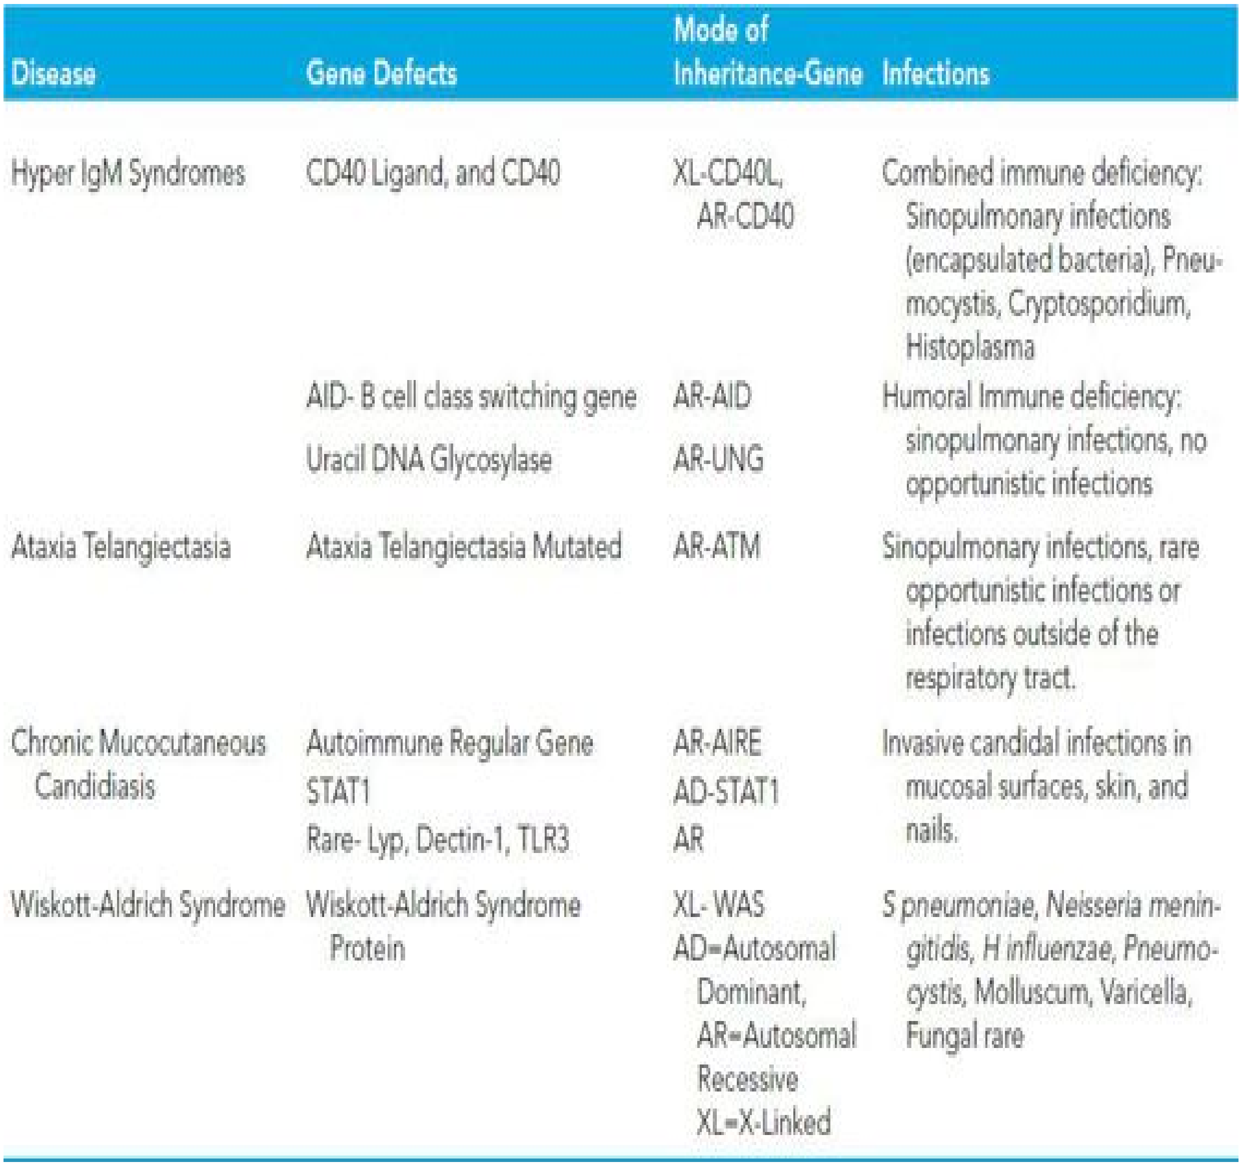
- The etiologies of these defects are variable including genetic inheritance and spontaneous mutation.

- Modes of inheritance (Table 219-1).

TABLE 219-1 Representative Combined Immunodeficiency Syndromes with their Gene Defects, Mode of Inheritance, and the Types of Characteristic Infections the Patients are Susceptible to

Disease	Gene Defects	Mode of Inheritance-Gene	Infections
Severe Combined Immunodeficiency (SCID)			
T-B+NK-	Common gamma chain (Most common: 45 to 50% of cases)	XL-IL2RG	Mucocutaneous candidiasis, Pneumocystis, Chronic diarrhea, Severe Viral infections including from attenuated vaccines
	Janus Kinase 3	AR-JAK3	
T-B+NK+	Il-7 Receptor Alpha Chain	AR-IL-7RA	
	CD3 components	AR-CD3 Delta, Epsilon, Zeta	
T-B-NK+	Recombinase activating genes 1/2	AR-RAG1/RAG2	
	Artemis	AR-DCLER1C	
	DNA Ligase IV	AR-LIG4	
T-B-NK-	Adenosine Deaminase	AR-ADA	
	Reticular Dysgenesis	AR-AK2	
ZAP70 Deficiency	Zeta Chain Associated Protein Kinase 70kd	AR-ZAP70	Similar to SCID
T+B+NK+: CD8 Lymphopenia, CD4 Dysfunction	Defective T-cell receptor–associated tyrosine kinase	AR-P56lck	
Complete DiGeorge Syndrome	22q11 deletion	AD. Spontaneous- 22q11	Similar to SCID
Nijmegen Breakage Syndrome	DNA Repair Mechanisms	AR-NBN	Viral URI, UTI, Gastrointestinal infections.
DNA Ligase IV Deficiency	DNA Repair Mechanisms	AR-LIG	Variable severity- some similar to SCID, others less severe.
Hyper IgE Syndrome (HIES)	Signal transducer and Activator of Transcription- 3	AD-STAT3	Cold Abscesses, *Staphylococcus aureus*- Impetigo and lung abscesses, *Aspergillus*, *Pseudomonas*, *Pneumocystis*, Mucocutaneous Candidiasis (**Figure 219-3**), Sinopulmonary- *Haemophilus*, *Streptococcus pneumoniae*
	Dedicator of Cytokinesis- No skeletal anomalies	AR-DOCK8	Severe viral skin infections- (**Figures 219-4** and **219-5**) molluscum, warts. Bacterial and fungal infections. Do not form abscesses or pneumatoceles
	Tyrosine Kinase 2	AR-TYK2	Nontuberculous Mycobacteria Infections



Disease	Gene Defects	Mode of Inheritance-Gene	Infections
Hyper IgM Syndromes	CD40 Ligand, and CD40	XL-CD40L, AR-CD40	Combined immune deficiency: Sinopulmonary infections (encapsulated bacteria), Pneumocystis, Cryptosporidium, Histoplasma
	AID- B cell class switching gene Uracil DNA Glycosylase	AR-AID AR-UNG	Humoral Immune deficiency: sinopulmonary infections, no opportunistic infections
Ataxia Telangiectasia	Ataxia Telangiectasia Mutated	AR-ATM	Sinopulmonary infections, rare opportunistic infections or infections outside of the respiratory tract.
Chronic Mucocutaneous Candidiasis	Autoimmune Regular Gene STAT1 Rare- Lyp, Dectin-1, TLR3	AR-AIRE AD-STAT1 AR	Invasive candidal infections in mucosal surfaces, skin, and nails.
Wiskott-Aldrich Syndrome	Wiskott-Aldrich Syndrome Protein	XL- WAS AD=Autosomal Dominant, AR=Autosomal Recessive XL=X-Linked	*S pneumoniae, Neisseria meningitidis, H influenzae, Pneumocystis,* Molluscum, Varicella, Fungal rare

- Spontaneous mutations—All forms of congenital immune deficiency can occur as a spontaneous mutation.
- The rate of all combined immunodeficiencies is likely an underestimate due to children who die at an early age before a diagnosis can be made.

ETIOLOGY AND PATHOPHYSIOLOGY

- Table 219-1 describes the gene defects and infections, which occur with many primary immunodeficiencies. The table does not include every immunodeficiency but is meant to highlight representative examples.

RISK FACTORS

- Family history of recurrent infections or early unexplained death.
- Parents who have been previously diagnosed with a congenital immune deficiency.
- Consanguinity.

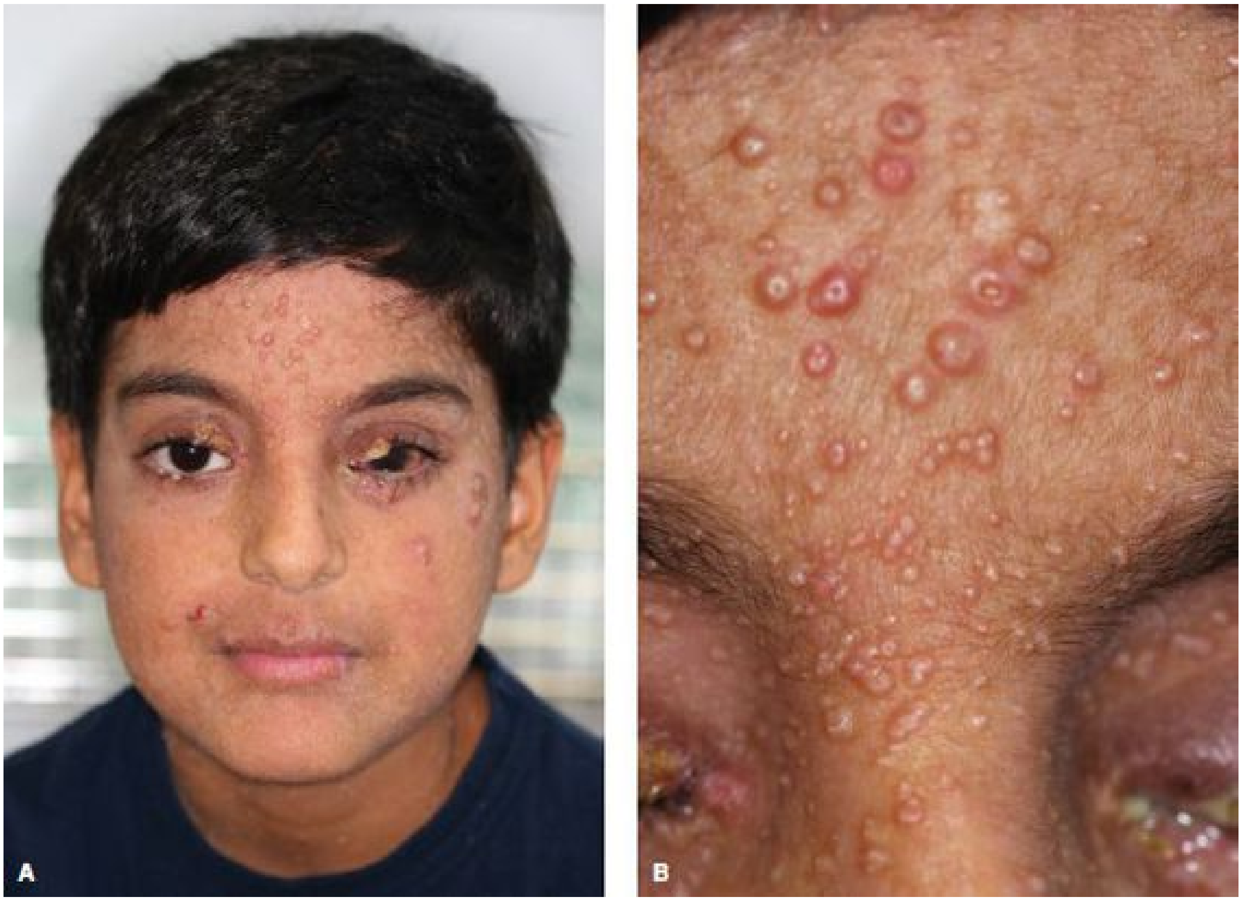


FIGURE 219-4 Disseminated molluscum viral infection and granulomas on upper eyelids bilaterally (**A**) and on close up view (**B**) in a young boy with AR-Hyper IgE syndrome. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD. Photo B is reprinted from Journal of Allergy and Clinical Immunology, 2009, p. 1296, with permission from Elsevier.*)

DIAGNOSIS

CLINICAL FEATURES (See Table 219-2)

- Most patients with immune deficiency present with failure to thrive as the first physical exam finding.
- SCID in infants is often not associated with specific physical exam findings.

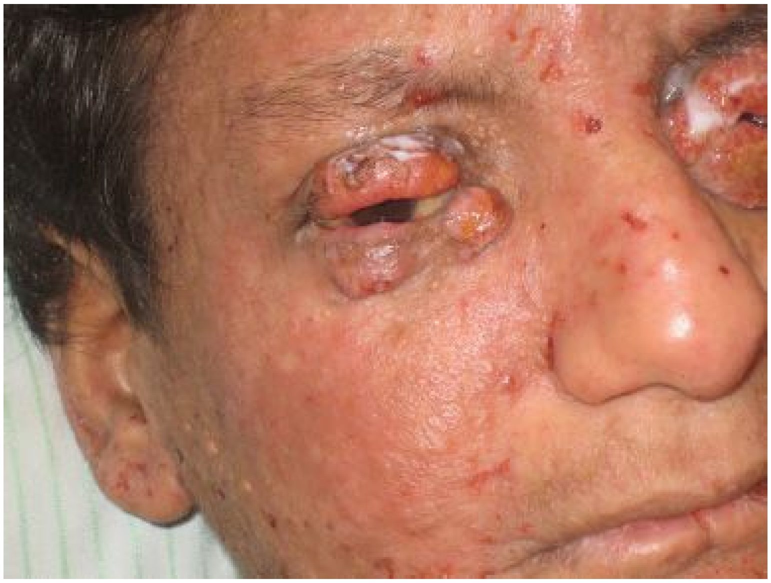

FIGURE 219-5 Severe viral infection of the eyelids in a patient with AR-Hyper IgE syndrome. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD*.)

- In toddlers and older children, immune deficiency syndromes have specific findings, which may help guide the diagnosis.
- Occurrence of atypical (opportunistic) infection, such as *Pneumocystis jirovecii* and mycobacteria, or unusually severe or complicated infections, may serve as clues to the underlying diagnosis.
- Neonatal eczema or Graft versus Host Disease (GvHD)—Skin rash may be present.

LABORATORY TESTING

- CBC and Fluorescence Activated Cell Sorting (FACS)—Combined deficiency should be immediately suspected if the total lymphocyte count is less than 2500/cubic mm or if the T cell percentage is <20 percent. Fluorescence Activated Cell Sorting (FACS) is a type of flow cytometry.
- A characteristic finding is the demonstration of highly activated (HLA $DR^+/CD45^+/RO^+$) maternal T-cells in the child's blood, that is, by HLA Typing
- Mitogen stimulation of lymphocytes showing a response of 10 percent of controls should prompt further evaluation.
- Specialized gene testing based on the clinical presentation should be done by a center, which specializes in congenital immune deficiencies.
- T cell receptor excision circles (Trec) newborn screening will detect many but not all combined immune deficiencies (see Table 219-2).

TABLE 219-2 Combined Immunodeficiencies, Their Characteristics, Clinical Findings, and Non-Infectious Complications

Syndrome	Special Physical Exam/Lab/ Radiology Findings	Serious Non-infectious Complications	Trec Newborn Screening
SCID	Failure to thrive Eczematous rash due to graft vs host disease from maternal immune cell engraftment	Malignancy Graft vs. host disease Exfoliative Dermatitis (**Figures 219-1**, **219-2**, **219-6** and **219-7**)	Will Detect
ZAP70 Deficiency	Normal Thymic Shadow, Normal or elevated lymphocyte count	Autoimmune disease such as colitis or cytopenias	Will Detect
Omenn Syndrome RAG1/ RAG2	Erythroderma Eosinophilia Lymphadenopathy Hepatosplenomegaly Expanded oligoclonal T cells	Malignancy	Will Detect
DNA Ligase IV Deficiency (**Figures 219-8**)	Microcephaly Narrow Bird like face Pancytopenia Photosensitivity Psoriasis	Developmental delay Radiosensitivity Photosensitivity Malignancy	Will Detect
Complete DiGeorge Syndrome	Low set and posteriorly rotated ears Ocular Hypertelorism Bulbous Nasal Tip Palate and Laryngeal defects	Conotruncal Cardiac Defects Hypocalcemia Autoimmunity	Will Detect
Nijmegen Breakage Syndrome	Microcephaly Narrow Bird like face Short Stature	Mild mental retardation Malignancy	Will Detect
AR HIES- DOCK8	No typical Physical exam findings as found in AD-HIES	Neurologic Complications Autoimmune disease	Will Detect
AD-HIES- STAT3 (**Figure 219-9**)	Broad nasal base and bridge Pneumatoceles Frontal bossing Coarse facies Retained primary teeth Scoliosis	Severe Atopic Dermatitis Bone fractures Vascular Abnormalities Lymphoma	Will Not Detect
Ataxia Telangiectasia (**Figures 219-10** and **219-11**)	Progressive cerebellar ataxia. Oculocutaneous telangiectasias	Radiosensitivity photosensitivity Diabetes Malignancy Bleeding	May Detect (3)
Hyper IgM Syndrome AID Deficiency	Lymphoid hyperplasia Varies based on defect May include Diarrhea, liver disease, cholangitis and cholangiocarcinoma	Autoimmune disease	Will Not Detect
Chronic Mucocutaneous Candidiasis (**Figure 121-8**)	Mucocutaneous fungal infection often extensive Onychomycosis Vitiligo Alopecia Areata	Autoimmune disease Endocrinopathy Malignancy	Will Not Detect
Wiskott-Aldrich Syndrome	Eczema Lymphadenopathy and Hepatospenomegaly Small Platelets	Autoimmune Disease Malignancy Bleeding	Will Not Detect

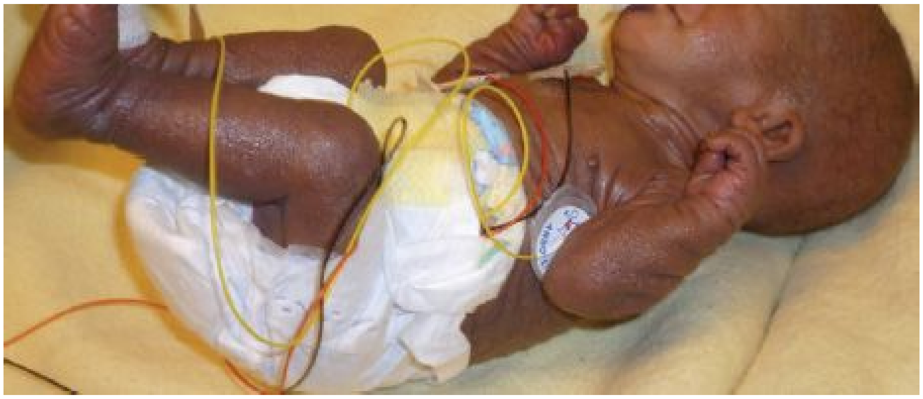

FIGURE 219-6 Severe exfoliative dermatitis in a 5-week-old infant highly suspected of having severe combined immunodeficiency in association with an unknown syndromatic disease. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD.*)

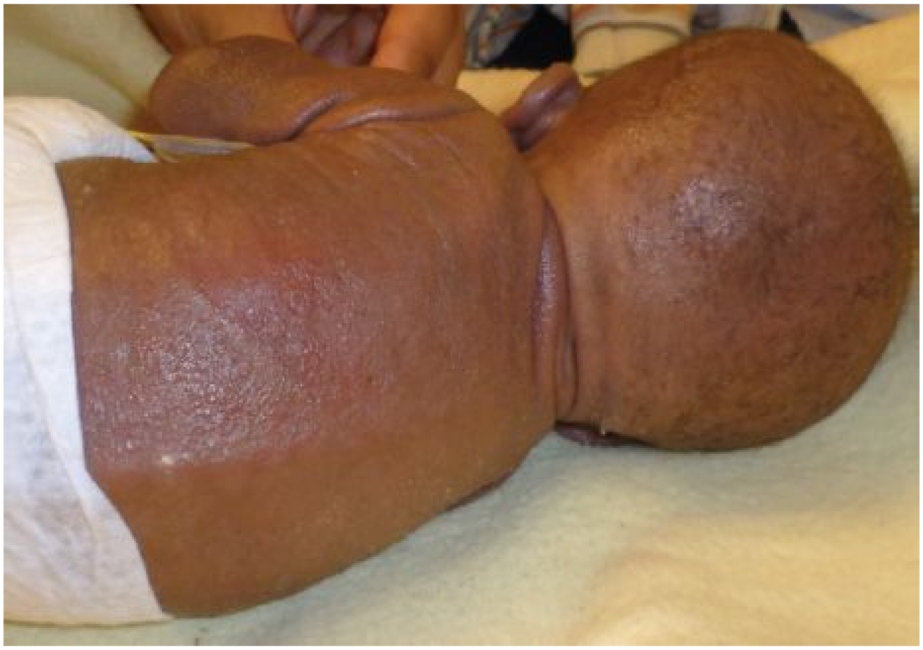

Figure 219-7 Exfoliative dermatitis on the back and scalp of the same infant as in **Figure 219-6**. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD.*)

IMAGING

- Chest x-ray may show a lack of a thymus as an early sign of a T cell immune deficiency and may show evidence of atypical pneumonia.
- Facial and bone changes may be found with specific immuno deficiencies.
- Care must be taken with radiology studies as some forms of SCID demonstrate increased radiosensitivity. x-ray imaging poses more risk for malignancy in these patients.

DIFFERENTIAL DIAGNOSIS

- Recurrent infections in otherwise healthy children can be evaluated with a CBC and differential to identify the T and B lymphocyte subset pattern.

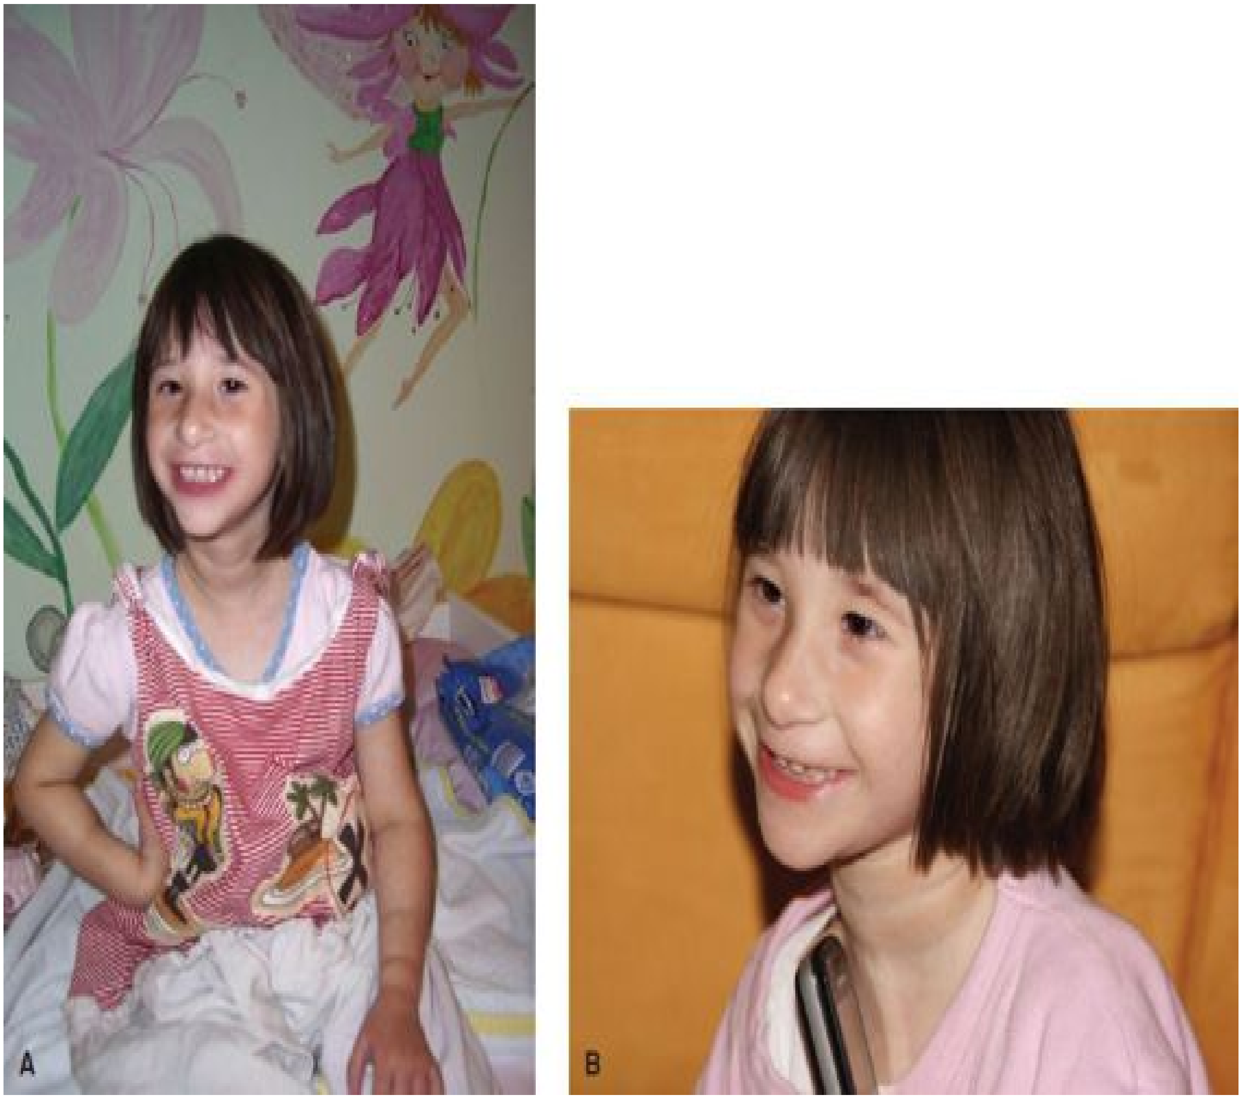

Figure 219-8 Microcephaly and narrow face in a patient with DNA Ligase IV deficiency on full (**A**) and close-up (**B**) views. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD. Reprinted from Wahn/Niehues Primäre Immundefekte, 2013, p. 22, with permission from Marseille Verlag.*)

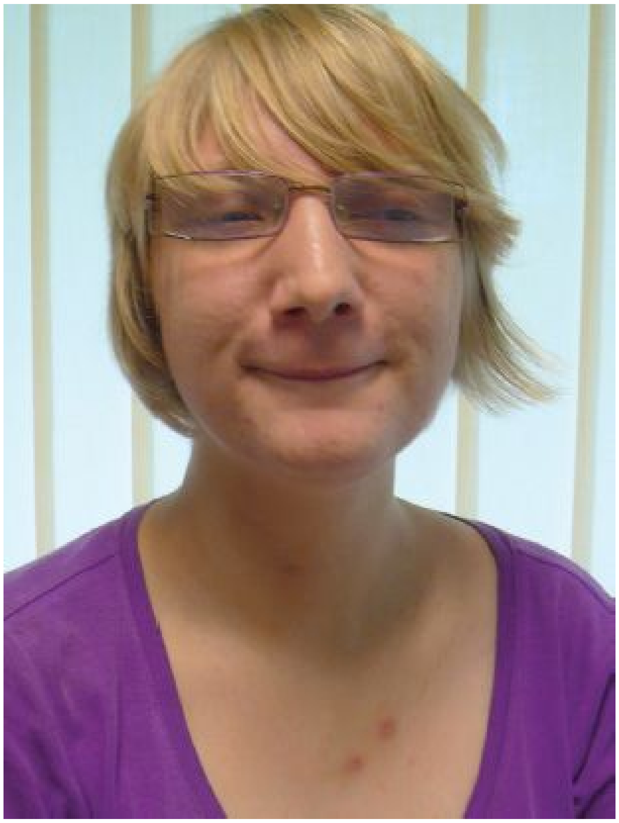

FIGURE 219-9 Characteristic facial features of broad nasal bridge, deep set eyes, eczematous lesions on the chest and coarsening of the facial skin in an 18-year-old woman with AD-Hyper IgE deficiency. (*Used with permission from Gregor Dückers, MD and Tim Niehues, MD*.)

- Serum Immunoglobulin levels are often helpful in determining the type and extent of involvement.
- Some diseases with chromosomal abnormalities (e.g., DiGeorge Syndrome or CHARGE) will show decreased but present numbers of T cells. These patients will have other characteristic congenital defects (e.g., skeletal and conotruncal abnormalities, or hypocalcemia. The diagnosis can be confirmed with appropriate genetic testing for 22q11 (see Chapter 216, DiGeorge Syndrome).
- Congenital humoral immune deficiency due to X-linked Agammaglobulinemia. These patients will have absent B cells and antibodies but normal T cell numbers, and usually present from 1to 2-years-old due to initial protection from maternal passively transferred antibodies (see Chapter 218, B Cell Immunodeficiencies).

- Failure to thrive and recurrent infections due to malnutrition or metabolic conditions (i.e., folate malabsorption; see Chapter 53, Failure to Thrive).

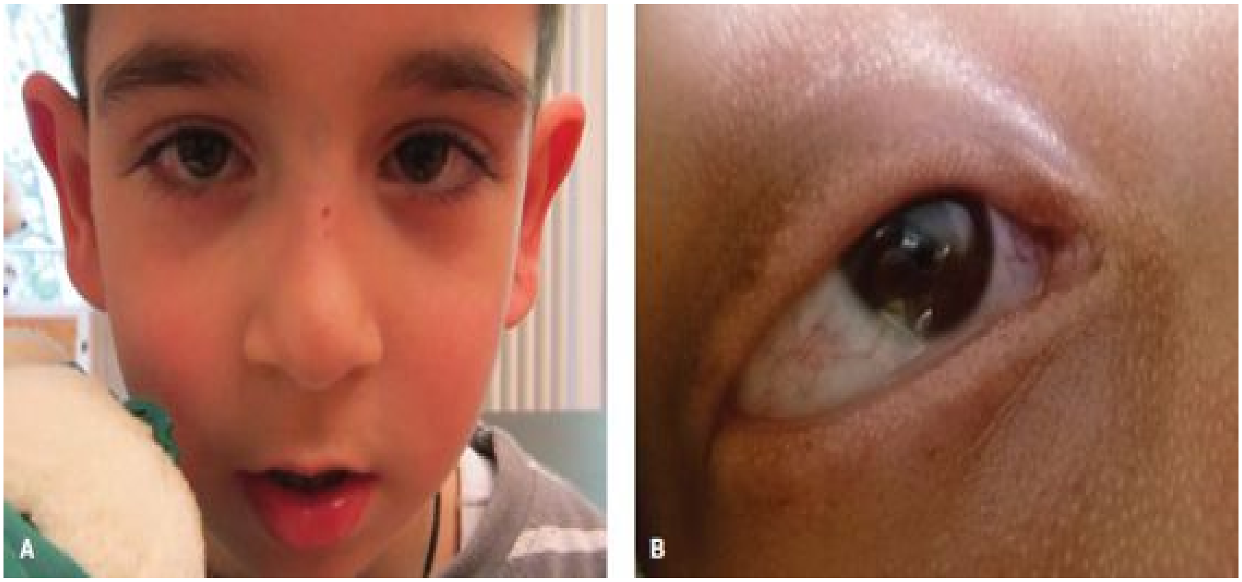

FIGURE 219-10 Characteristic bilateral (**A**) and right eye (**B**) conjunctival telangiectasias in a young boy with Ataxia Telangiectasia. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD.*)

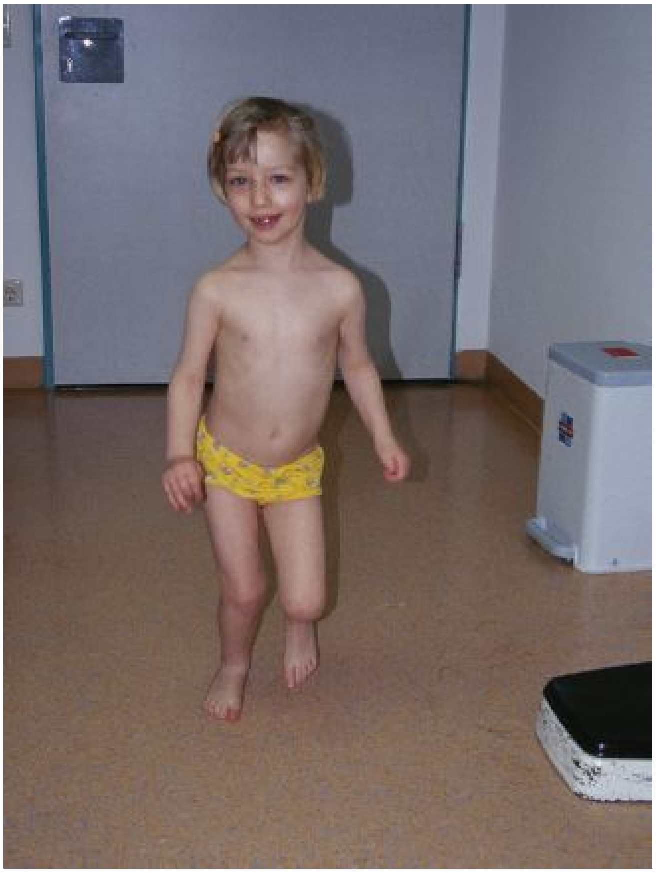

FIGURE 219-11 Gait changes in a young girl with Ataxia Telangiectasia. (*Used with permission from Tim Niehues, MD and Gregor Dückers, MD*.)

- HIV infection—These patients will have a normal thymic shadow and normal or increased immunoglobulin levels and usually a mother who is infected (see Chapter 182, Pediatric HIV Infection).
- Bone marrow failure due to secondary causes such as cancer.
- Intestinal lymphangiectasia—Can cause a severe protein losing enteropathy and loss of immunoglobulins.
- Congenital or acquired chylothorax with continuous drainage can lead to low immunoglobulins and lymphocyte counts.

MANAGEMENT

- Evaluation in a pediatric immunology center should occur immediately on suspicion of a combined immune deficiency.

NONPHARMACOLOGIC

- Protection of the patient from infections using contact and respiratory precautions should be considered.
- Avoid transfusion or if transfusion is indicated, use filter to delete residual lymphocytes entirely, because donor lymphocytes can cause fatal GvHD.
- Gene therapy has been tried in patients with certain types of immune defects (Adenosine Deaminase [ADA] deficiency, Il-2RG).[4,5] SOR Ⓐ
- Pegylated Adenosine Deaminase has been tried in ADA deficiency.[6] SOR Ⓐ

MEDICATIONS

- Early and aggressive diagnosis and treatment of infections.
- Based on the genetic defect, IVIG, *P jirovecii* prophylaxis, Stem cell transplant, and prophylactic antibiotics should be considered.
- Bone Marrow Transplantation is lifesaving and has been used successfully in many types of combined immunodeficiency.[7]

REFERRAL

Patients with combined immunodeficiencies should be immediately referred to an immunologist or a center specializing in immunodeficiency.

PREVENTION AND SCREENING

Many states and countries have begun universal newborn screening for combined and humoral immunodeficiencies using Trec and k- deleting recombination excision circles (Krec) respectively. This allows for early diagnosis and intervention before infections can begin.

PROGNOSIS

- The prognosis is based on the specific gene defect and the individual clinical situation.
- Without prompt recognition many patients will die due to complications of infection and inflammation.

FOLLOW-UP

The patients should be followed in centers, which have experience dealing with primary immune deficiencies.

220 CHRONIC GRANULOMATOUS DISEASE

Justin Greiwe, MD
Gregor Dückers, MD
Tim Niehues, MD
Brian Schroer, MD

PATIENT STORY

A 4-year-old boy presents with a recent history of persistent pneumonia. A detailed past medical history reveals several recurrent infections including pneumonia and lymph node abscesses growing *Staphylococcus aureus* and *Burkholderia cepacia*. His parents claim that he has been prescribed multiple courses of antibiotics over the last month with no improvement in his respiratory symptoms. There is no family history of immunodeficiency. Examination of the child revealed mild subcostal retractions and diffuse rales bilaterally. A chest x-ray demonstrated bilateral infiltrates of the upper and middle lung fields and a CT showed multifocal pneumonia (**Figure 220-1**). Diagnostic bronchoalveolar lavage and serological tests confirmed the presence of invasive pulmonary aspergillosis and the patient was placed on appropriate antifungal treatment. Because of the history and types of infection, a work-up for immunodeficiency was undertaken and the child was found to have chronic granulomatous disease.

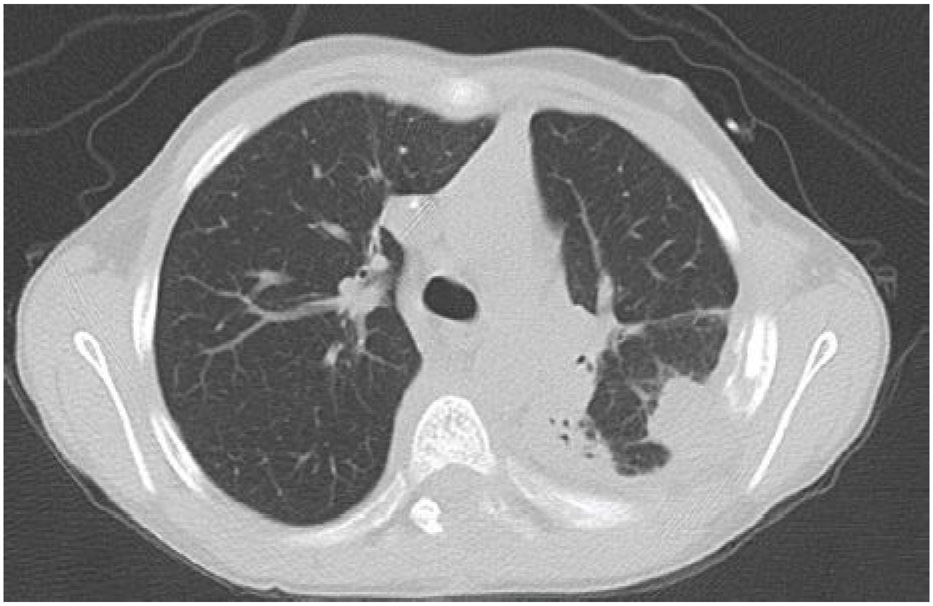

FIGURE 220-1 Multifocal pneumonia on CT scan in a young boy with chronic granulomatous disease. (*Used with permission from Alison Greiwe, MD*.)

INRODUTION

Chronic granulomatous disease (CGD) is the result of impaired intracellular microbial killing by phagocytes leading to formation of granulomata and recurrent infections with bacteria and fungi. Phagocytes are unable to kill the microbes they ingest secondary to a defect in a system of enzymes that produce reactive oxygen compounds. The most common and severe form of CGD is the X-linked type (~70% of all CGD cases) seen only in boys.

SYNONYMS

CGD, Chronic Dysphagocytosis, Chronic Familial Granulomatosis, Septic Progressive Granulomatosis, Fatal Granulomatosis of Childhood, Impotent

Neutrophil Syndrome, Congenital Dysphagocytosis, Bridges-Good syndrome, and Quie syndrome.

EPIDEMIOLOGY

- CGD affects around 1:200,000 people in the US.[1]
- The frequency of CGD is equal across ethnic and racial groups with disease presentation ranging from infancy into late adulthood.
- Most patients receive a diagnosis as toddlers.

ETIOLOGY AND PATHOPHYSIOLOGY

- Normal phagocytes utilize NADPH oxidase to generate reactive oxygen compounds like superoxide, which is essential for direct killing of certain catalase-positive bacteria and fungi.
- The enzyme that catalyzes the respiratory burst, NADPH oxidase, is a complex made up of subunits. One of 4 subunits may be defective in CGD.[2]
- Approximately 2/3 of CGD cases result from defects in the X-linked gene encoding the gp91phox subunit. The autosomal recessive forms of CGD are caused by mutations in the remaining subunits p22phox, p47phox, and p67phox. A recently discovered fifth subunit, p40phox, has been found to contribute to the autosomal recessive form of CGD as well.[3]
- Mutations leading to a loss or functional inactivation of one of these subunits leads to susceptibility of infection from any number of microorganisms (most commonly Staphylococci, *Aspergillus*, *Serratia*, *Nocardia*, and *Burkholderia*).

RISK FACTORS

The following factors increase the risk of developing CGD:

- Parents who are carriers of the recessive gene and thus can transmit the gene to their offspring in an autosomal recessive manner.
- Male gender, as most mutations are X-linked.
- A family history of unexplained recurrent or chronic infections.
- Rare cases may be due to spontaneous mutations.[4]

DIAGNOSIS

- Median age at diagnosis is 2.5 to 3 years.[5]
- Diagnosis may be delayed as a result of broad spectrum antibiotic use or if the manifestations are less severe (as in the autosomal recessive forms of the disease).
- Carrier females can exhibit some symptoms due to high degree of lyonization of the functional gene creating a mosaic pattern. This can create a discoid lupus appearance (**Figure 220-2**).[6] Most female carriers are asymptomatic.

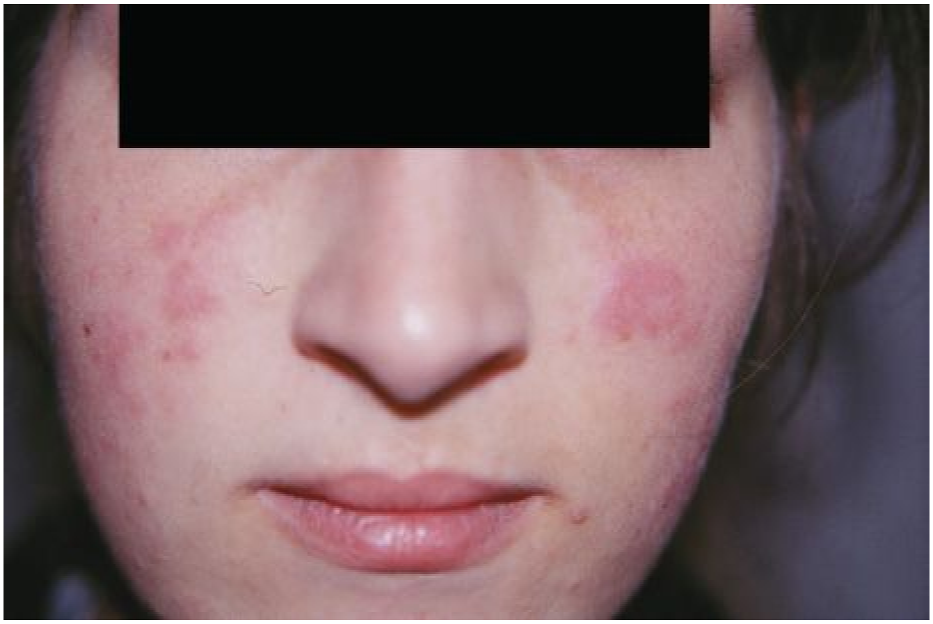

FIGURE 220-2 Lupus exanthema in the mother of a patient with chronic granulomatous disease, exemplifying the concept of lionization of the functional gene in carriers. (*Used with permission from Gregor Dückers, MD, and Tim Niehues, MD.*)

CLINICAL FEATURES

▶ Infection

- Recurrent or unusually severe bacterial and fungal infections most often manifesting as pneumonia, abscesses, suppurative adenitis (**Figure 220-3**), osteomyelitis (**Figure 220-4**), bacteremia/fungemia, superficial skin infections, and organ abscesses (liver, spleen, brain; **Figure 220-5**).

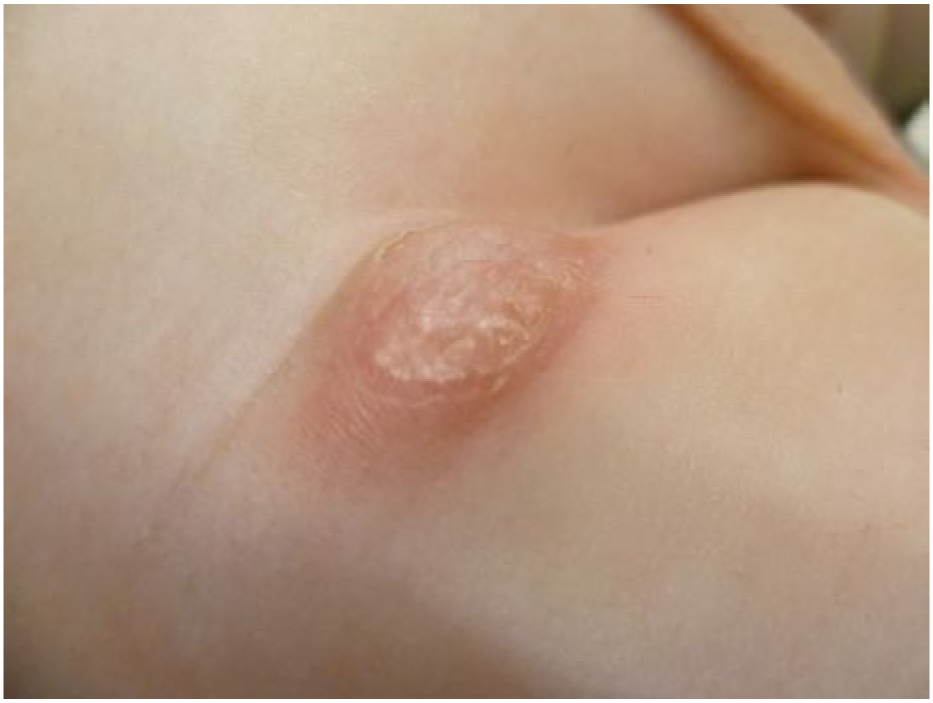

FIGURE 220-3 Fluctuant inguinal lymphadenitis in a young patient with chronic granulomatous disease. (*Used with permission from Gregor Dückers, MD and Tim Niehues, MD*.)

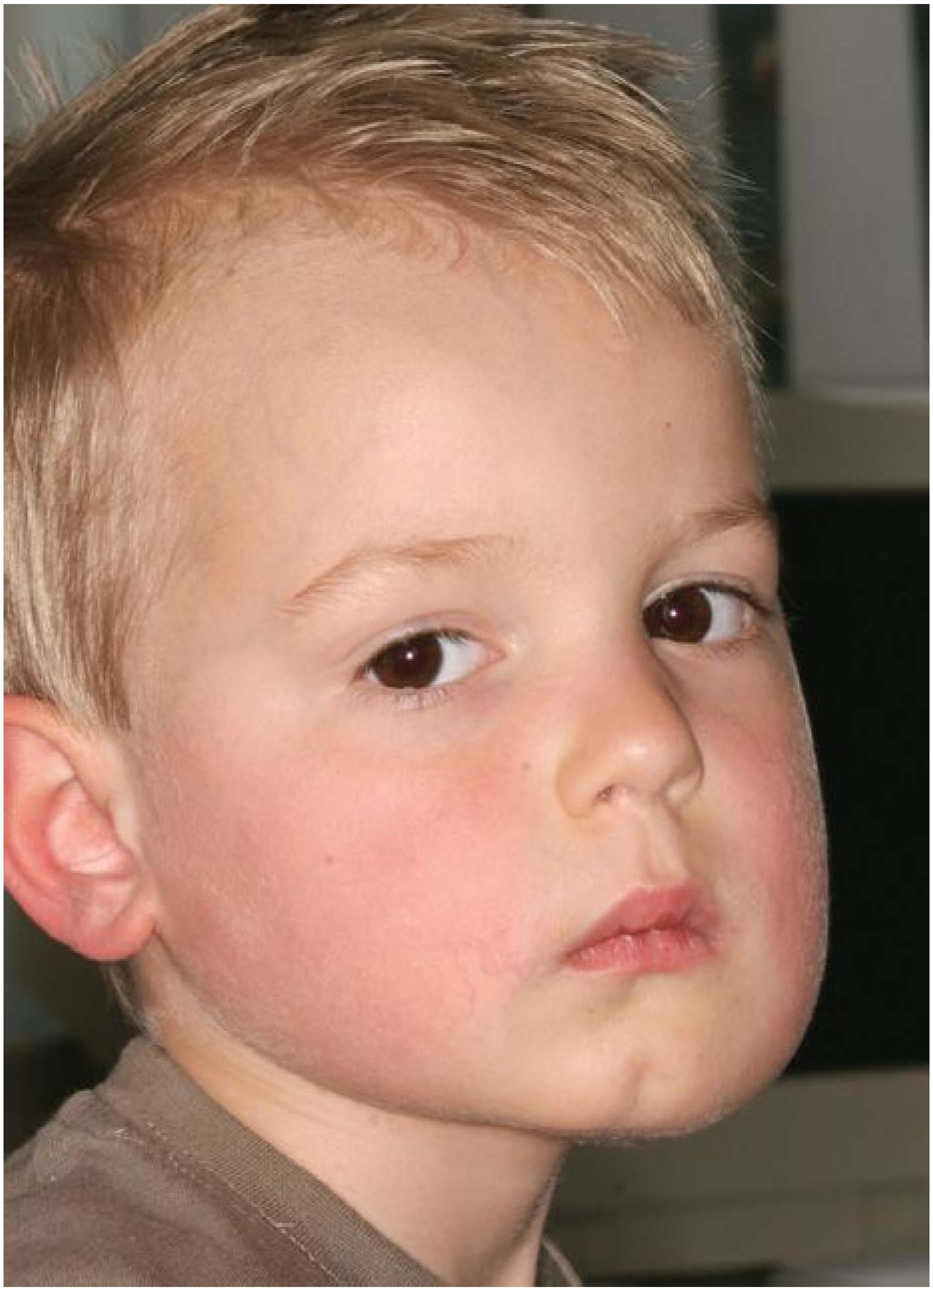

FIGURE 220-4 Osteomyelitis of the left mandible in a young boy with chronic granulomatous disease. (*Used with permission from Gregor Dückers, MD and Tim Niehues, MD*.)

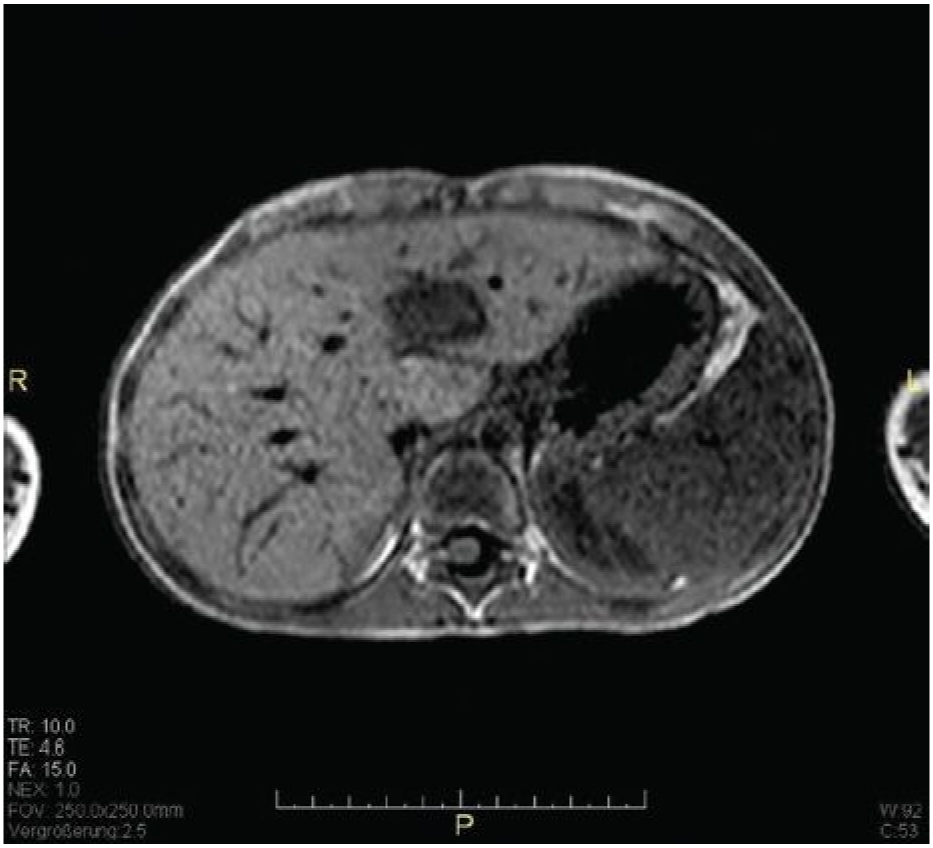

R

C:53

FIGURE 220-5 Hepatic abscess in liver, as a manifestation of chronic granulomatous disease in a young patient. (*Used with permission from Gregor Dückers, MD and Tim Niehues, MD.*)

- Typical bacteria found in US and European patients include *S. aureus* and *Burkholderia*. Fungi isolated in CGD are *Aspergillus* and *Nocardia* species.[7]

▶ Inflammation

- Recurrent fever or fever of unknown origin.
- Diffuse granulomas that affect a number of different systems including the gastrointestinal, genitourinary, pulmonary, and central nervous systems.
- Abnormal wound healing (**Figure 220-6**).

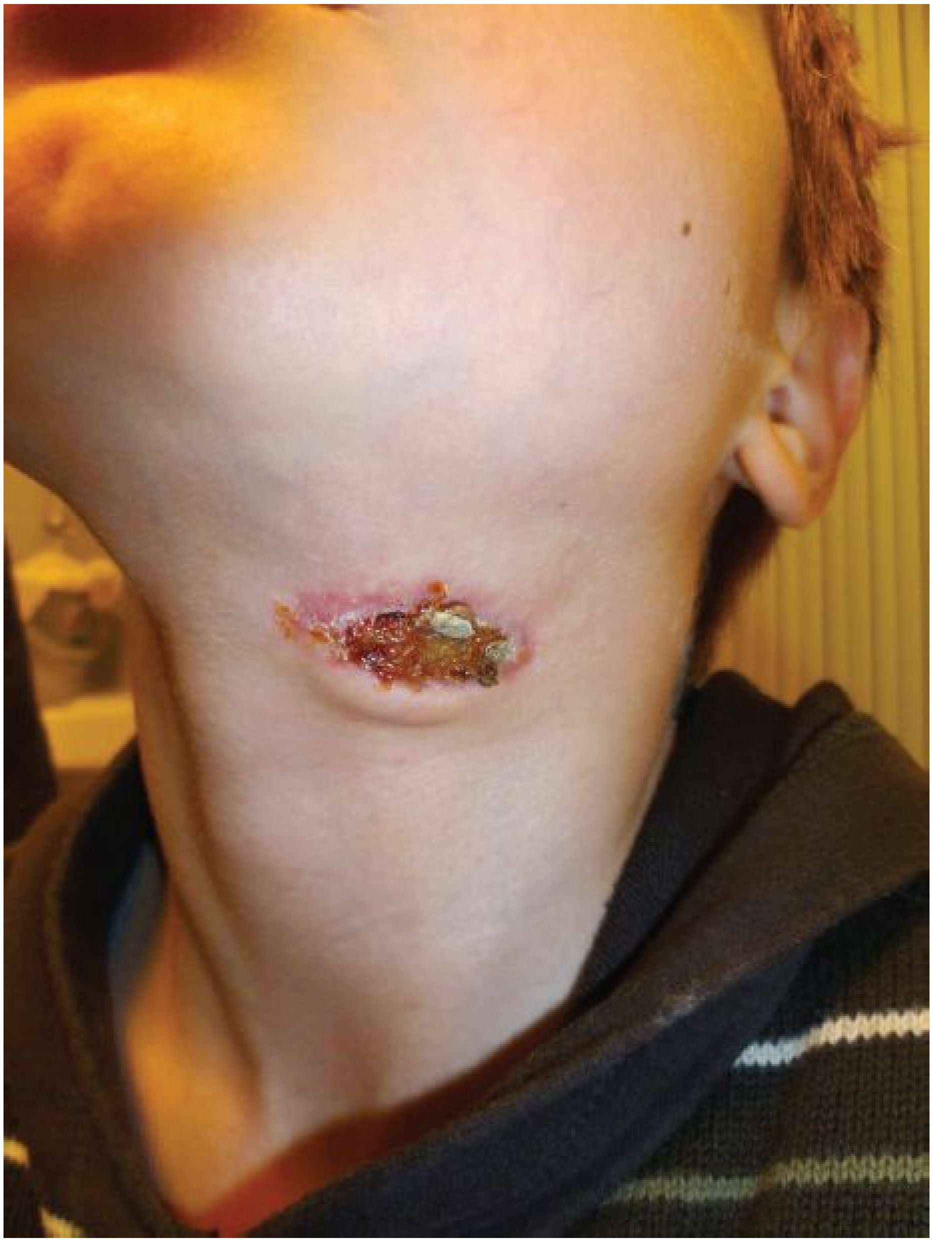

FIGURE 220-6 Impaired wound healing after incision and drainage of an infected lymph node in a child with chronic granulomatous disease. (*Used with permission from Gregor Dückers, MD and Tim Niehues, MD*.)

- Patients with CGD may have features that may mimic the clinical picture of inflammatory bowel disease.[8]

PHYSICAL FINDINGS

- Growth failure/short stature.
- Lymphadenopathy.
- Hepatosplenomegaly.
- Cutaneous abscesses.

LABORATORY TESTING

- Dihydrorhodamine (DHR) test—This has replaced Nitro blue tetrazolium as a more effective screening tool because it is easier to use, more objective and more accurate.[9]
- Genetic mutation analysis: This may help to verify the diagnosis, establish an inheritance pattern, and provide valuable information for family counseling.
- An aggressive search for unusual and rare pathogens is necessary (**Figure 220-7**). This requires help from an experienced microbiology lab.

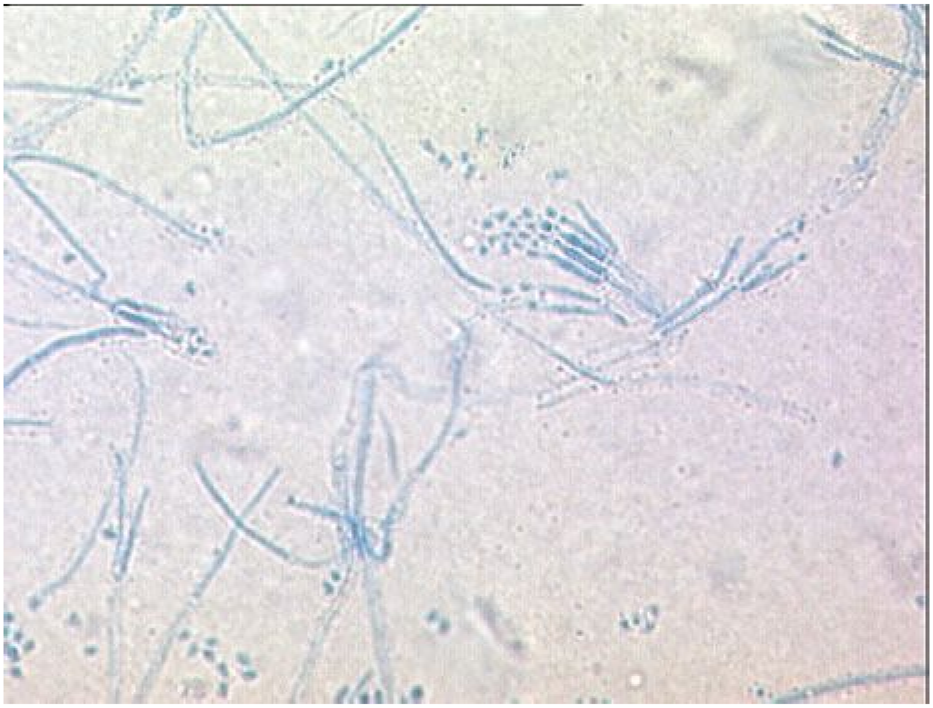

FIGURE 220-7 *Geosmithia* fungus isolated from a patient with osteomyelitis and chronic granulomatous disease. (*Used with permission from Gregor Dückers, MD, and Tim Niehues, MD*.)

IMAGING

- X-rays may be helpful in diagnosing pneumonia.
- CT imaging is useful at evaluating the size, number, and location of abscesses in the lung, spleen, or liver (**Figure 220-5**).

DIFFERENTIAL DIAGNOSIS

- Severe and/or recurrent infections with catalase-positive microorganisms can be caused by any of the following and should be considered when working up a child for CGD:
  - Other primary immunodeficiencies (B-cell deficiency, Hyper-immunoglobulin E syndrome (HIES), leukocyte adhesion deficiency, complement deficiencies, Myeloperoxidase deficiency)—See Chapters 218, B Cell Immunodeficiencies and 219, T- and B-cell Immunodeficiencies.
  - Secondary immunodeficiencies, that is, Human Immunodeficiency Virus (HIV/AIDS)—See Chapter 182, Pediatric HIV Infection.
  - Metabolic disorders (cystic fibrosis, G6PD deficiency)—See Chapter 51, Cystic Fibrosis.

Inflammatory disorders (Crohn disease)—See Chapter 59, Inflammatory Bowel Disease.

MANAGEMENT

- As with other primary immunodeficiencies, the diagnosis and treatment of infections in CGD must be early and aggressive.

NONPHARMACOLOGIC

- Standard infection prevention measures include good hand hygiene for the patient, family, and close contacts.
- Avoidance of sick contacts when possible.
- All immunizations are safe for these children and should be given on time as per the standard schedule. They may receive live virus vaccines.
- Experimental gene therapy trials for CGD are currently underway and may be appropriate in refractory or life-threatening infections. Gene therapy as a cure is still far from becoming a reality.[10]

MEDICATION

- Prophylactic regimens of antimicrobials and antifungals like trimethoprim-sulfamethoxazole and itraconazole remain first-line therapy and are commonly used.[10] SOR Ⓒ
- Immunomodulatory treatment. In one placebo trial, patient who received subcutaneous interferon (IFN)-gamma had significant reductions in the number of serious infections.[11] SOR Ⓑ The potential drawbacks for IFN-gamma include adverse side effects (fever/myalgias), time commitment (injections 3 times/week), and cost.

Treatment of infections

- Starts with an aggressive diagnostic approach (cultures, open biopsies) and targeted treatment (parenteral, several weeks duration). SOR Ⓒ
- WBC transfusions during infections may be of benefit but should be performed only in specialized centers who are experienced with CGD. SOR Ⓒ

Treatment of inflammation

- Obstructive or painful granulomas that impinge on nearby organs like the stomach, ureters, or urinary bladder can be relieved by short-term steroid therapy. SOR Ⓒ

SURGERY

- Liver and lymph node abscesses and obstructive or painful granulomas are very often drained or removed surgically, if steroid therapy fails. SOR Ⓒ

▶ Curative treatment

- Stem cell transplantation (SCT) results have improved significantly. SCT is a good option for children who suffer from serious infections despite prophylaxis.[12] SOR Ⓒ
- Gene therapy has been tried but the long-term efficacy and risks remain to be determined. SOR Ⓒ

REFERRAL

- Immunology referral should be made in all patients who are suspected to have an immunodeficiency.
- Referral to an infectious disease specialist is necessary to help with treatment for fungal or severe bacterial infections.
- Surgical referral should be made if there is pain or organ dysfunction as a result of granuloma formation.
- Referral to a geneticist is useful for the family of a newly diagnosed patient. Family members will receive counseling about the benefits and risks of testing for the carrier state. As the patient gets older, he or she may want to discuss the issues of childbearing and the risk of passing on CGD to their offspring.

PREVENTION AND SCREENING

- CGD is an inherited disease and therefore cannot be prevented.
- If there is a known family history of CGD, genetic counseling may be beneficial prior to conception.
- Patients with CGD should avoid construction sites and long-term travel in tunnels due to the risk of exposure to *Aspergillus* spores/conidia.

PROGNOSIS

- Patients with the more severe X-linked form of CGD suffer from increased morbidity and mortality in their early teen years.
- Mainly due to effective, intracellular active anti-bacterial and antifungal prophylaxis as well as more successful stem cell transplantation, prognosis of patients with CGD has significantly improved over the past two decades.

FOLLOW UP

- Frequent follow-up in a specialized institution is necessary for patients with CGD because early and aggressive treatment of infections and inflammation is essential to prevent severe complications.

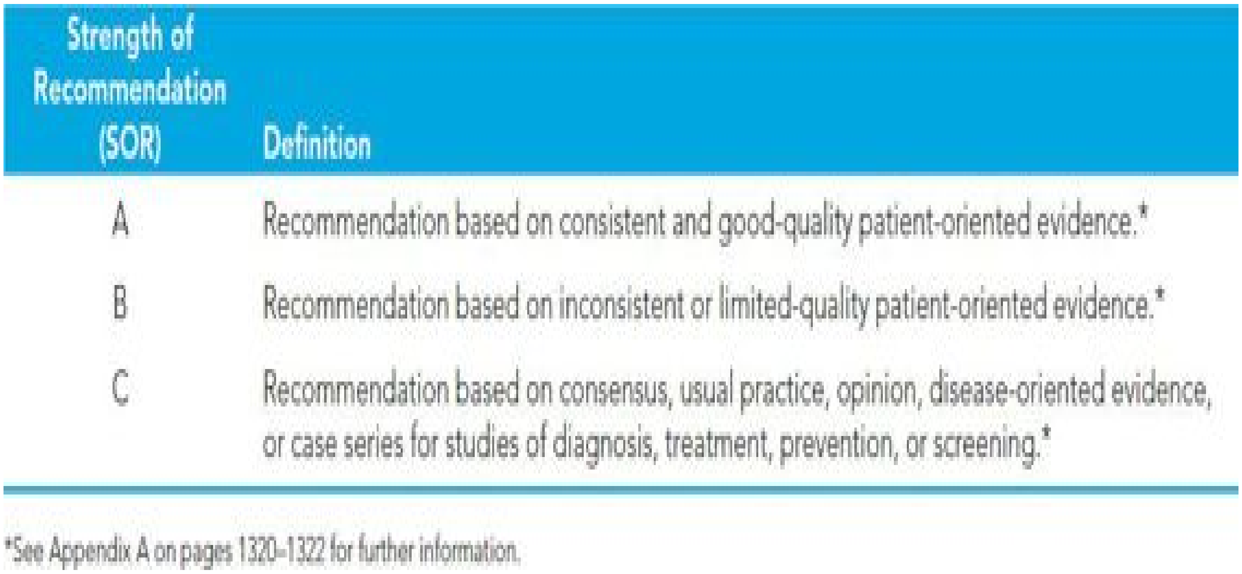
PART 21

GENETIC DISORDERS



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

221 DOWN SYNDROME

Di Sun, BS, MPH
Elumalai Appachi, MD, MRCP

PATIENT STORY

A 2-day-old baby boy is brought to the emergency department for vomiting. The patient's mother is a 25 year-old single parent who did not receive prenatal care, and the baby was born at home via vaginal delivery at 39 weeks gestation. The mother reports that the baby vomits whenever she tries to breastfeed him and that the emesis appears green and thick. The infant is noted to have epicanthal folds, upward-slanting palpebral fissures, flat nasal bridge, a single transverse palmar (simian) crease, and small ears (**Figures 221-1** and **221-2**). The examining physician suspects the child has Down syndrome and orders an abdominal x-ray, which reveals a "double-bubble," consistent with duodenal atresia, and is associated with Down syndrome. (**Figure 221-3**). The baby undergoes surgical correction of the atresia and recovers completely. A chromosomal analysis confirms the diagnosis of Down syndrome.

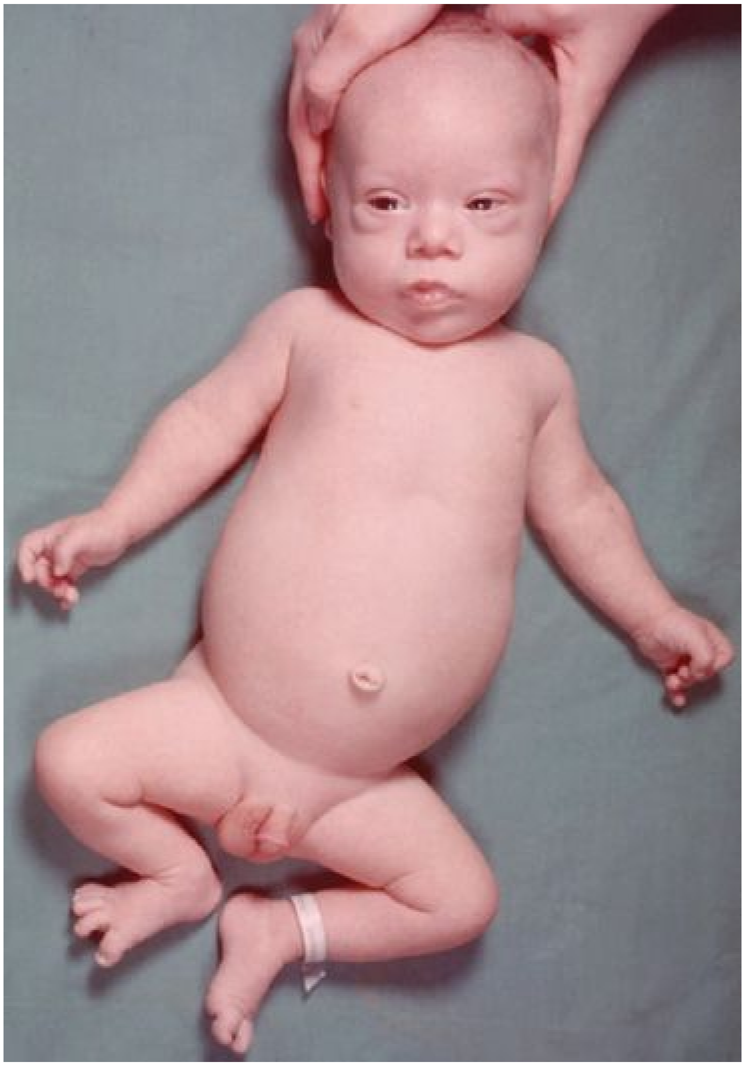


FIGURE 221-1 Epicanthal folds, upslanting palpebral fissures, flat nasal bridge, and wide gap between the first and second toe in an infant with Down syndrome. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

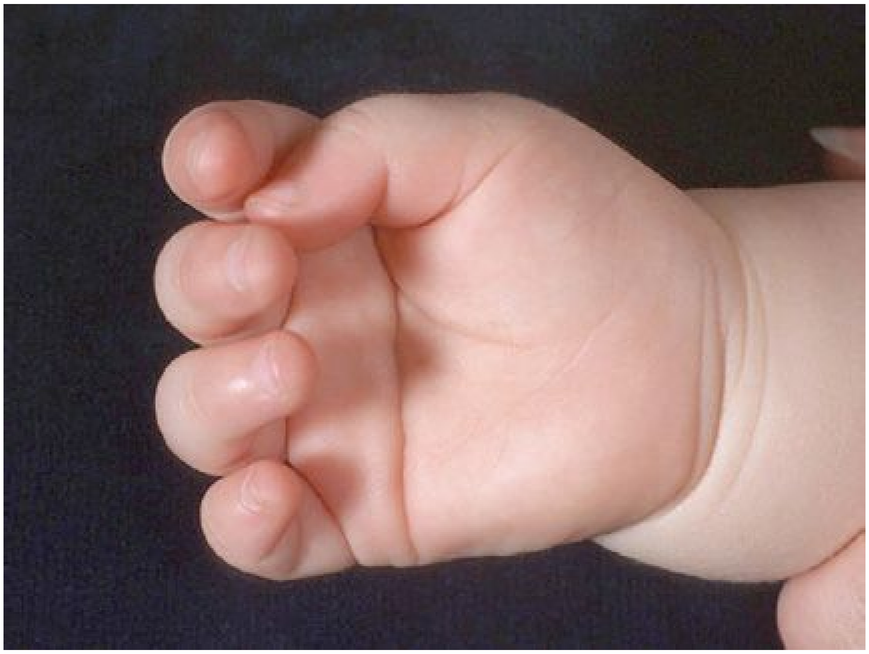

FIGURE 221-2 Single transverse palmar crease in an infant with Down syndrome (simian crease). This is seen in about 50 percent of infants with Down syndrome and can be seen in infants and children who do not have Down syndrome. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

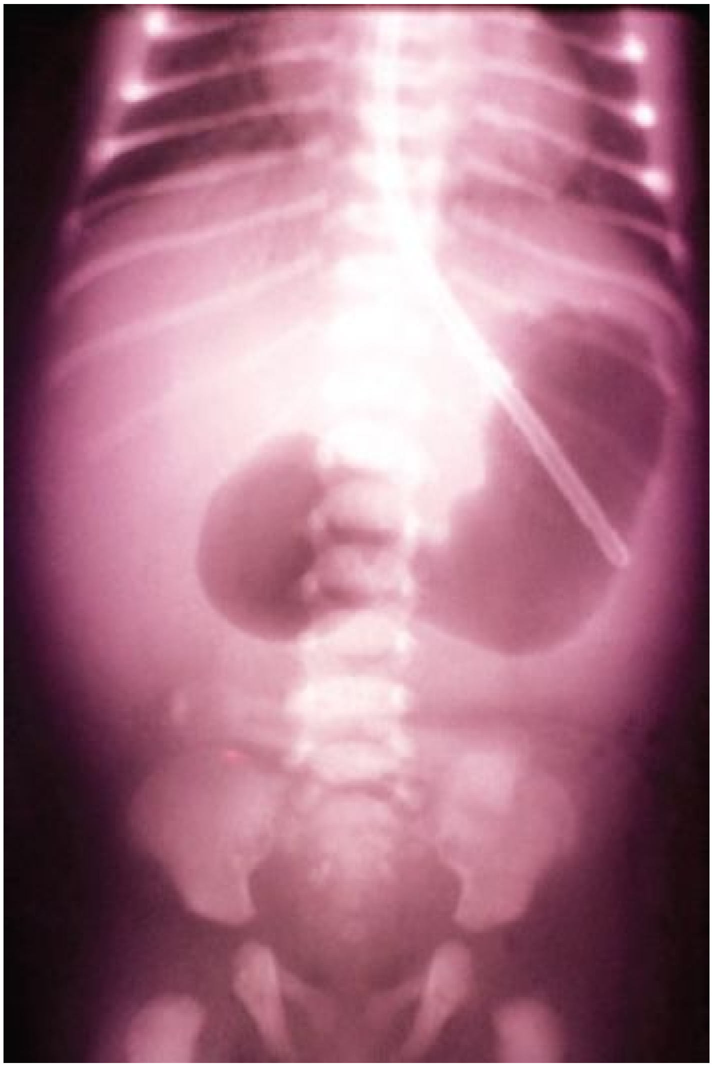

FIGURE 221-3 “Double bubble” sign of duodenal atresia on plain x-ray in a child with Down syndrome. Infants with Down syndrome have an increased incidence of intestinal atresias. (*Used with permission from Elumalai Appachi, MD.*)

INTRODUCTION

- Down syndrome (DS) is an aneuploidy that develops from excess genetic material on chromosome 21, and results in a distinctive phenotypic appearance.[1,2] Children commonly present with congenital cardiac, hematologic, musculoskeletal, visual, and/or auditory defects.[3] The incidence of DS increases with maternal age.[4]

SYNONYMS

Trisomy 21.

EPIDEMIOLOGY

- DS is the most commonly occurring genetic disorder among live births, occurring in 1 in 691 of all live births in the US.[5]
- The risk of having a prenatal diagnosis for DS is thought to be higher since it is estimated that 67 percent women (range 61% to 93%) in the US with a fetus demonstrating trisomy 21 will terminate the pregnancy.[6]
- Compared to Caucasian mothers, the prevalence ratio of trisomy 21 live births was 0.77 among African American mothers and 1.12 among Hispanic mothers. These differences could reflect ethnic differences in accessibility to prenatal screening, variation in the decision to terminate the pregnancy, or reporting bias inherent to the design of the study.[7]
- Although the risk of DS increases with increasing maternal age, approximately 80 percent of babies with DS are born to women <35 years of age.[4]

ETIOLOGY AND PATHOPHYSIOLOGY

- Ninety-five percent of DS cases arise from nondisjunction of chromosome 21, resulting in 3 complete copies of chromosome 21.[2]

  - In 86 percent of these cases, the extra chromosome originated from the mother due to nondisjunction during meiosis II (75%) rather than meiosis I (25%). Nine percent of complete trisomy 21 is derived from the father. Less than 5 percent of complete trisomy 21 is due to mitotic errors.[1]
  - These nondisjunction events are associated with increasing maternal age, which is correlated with a decrease in genetic recombination.[1]
- Three to four percent of DS cases occur due to chromosome 21 translocations, including balanced Robertsonian translocations of chromosome 21q paired most commonly with chromosome 14q. In patients with balanced translocations, parents should be screened to ensure that one of them is not a phenotypically normal carrier of a balanced translocation.[1]
- One to two percent of DS cases are due to mosaicism in which two cell lines are expressed, one with trisomy 21 and the other with normal cytogenetics.[1]
- The extra genetic materials lead to the characteristic DS phenotype, the best studied of which being the central nervous system manifestations. On histopathological studies, DS patients have decreased numbers of cortical neurons, stagnation of dendritic tree development at 4 months of age, decreased number of synapses, and delayed myelination when compared to normal subjects.[1]

RISK FACTORS

- Increasing maternal age is the single risk factor most associated with nondisjunction errors hypothesized to be secondary to accumulation of environmental insults to the oocyte and/or gradual attrition of the meiotic machinery.[1]
- Altered recombination pattern during meiosis, characterized by decreased recombination or pericentromeric exchange, will increase risk of DS.[1]

- Other environmental factors implicated in DS include maternal alcohol use, maternal irradiation, and low socioeconomic status. However, these associations have not been confirmed.[7]

DIAGNOSIS

CLINICAL FEATURES

Typical physical findings characteristic of DS are:

- Hypotonia (**Figure 221-1**).
- Wide gap between first and second toes (**Figure 221-1**).
- Clinodactyly (bend or curvature of one finger toward the other fingers, most commonly the fifth finger toward the other four fingers; **Figure 221-4**).

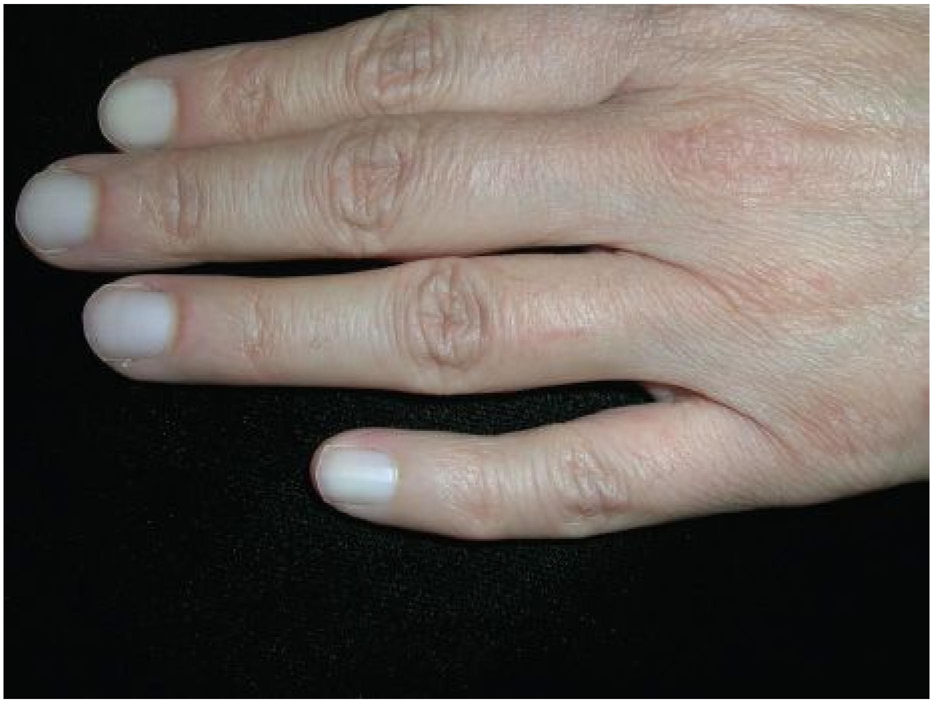

FIGURE 221-4 Clinodactyly (curvature of one finger toward the other fingers) is commonly seen in Down syndrome. (*Used with permission from*

Richard P. Usatine, MD.)

- Simian crease (**Figure 221-2**).
- Craniofacial abnormalities such as brachycephaly.
- Small and low-set ears (**Figure 221-5**).

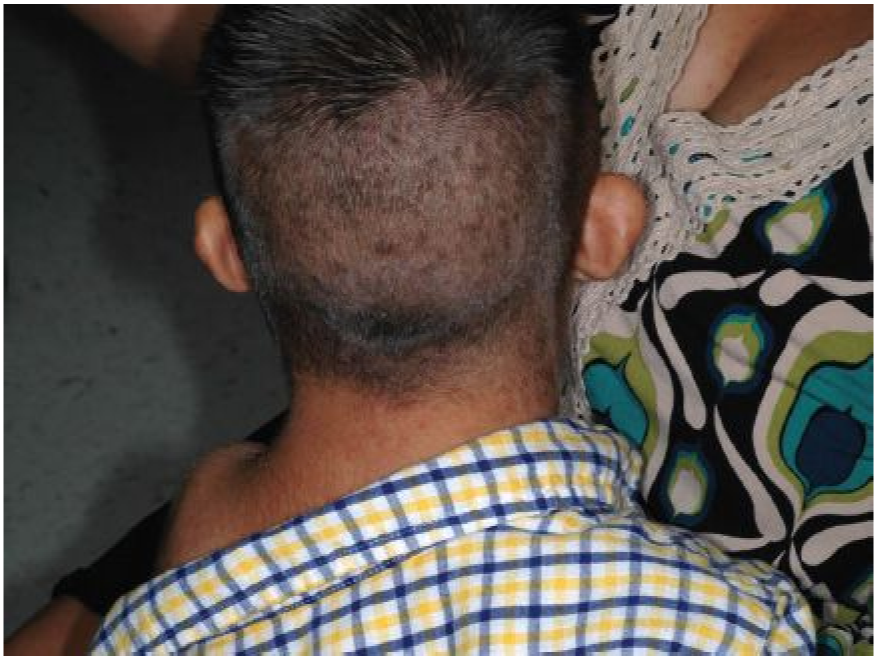

FIGURE 221-5 Small, low-set ears in a boy with Down syndrome. This boy also has crusted scabies, visible on his scalp and neck. (*Used with permission from Richard P. Usatine, MD*.)

- Epicanthal folds, upward-slanting palpebral fissures (**Figures 221-6** and **221-7**).

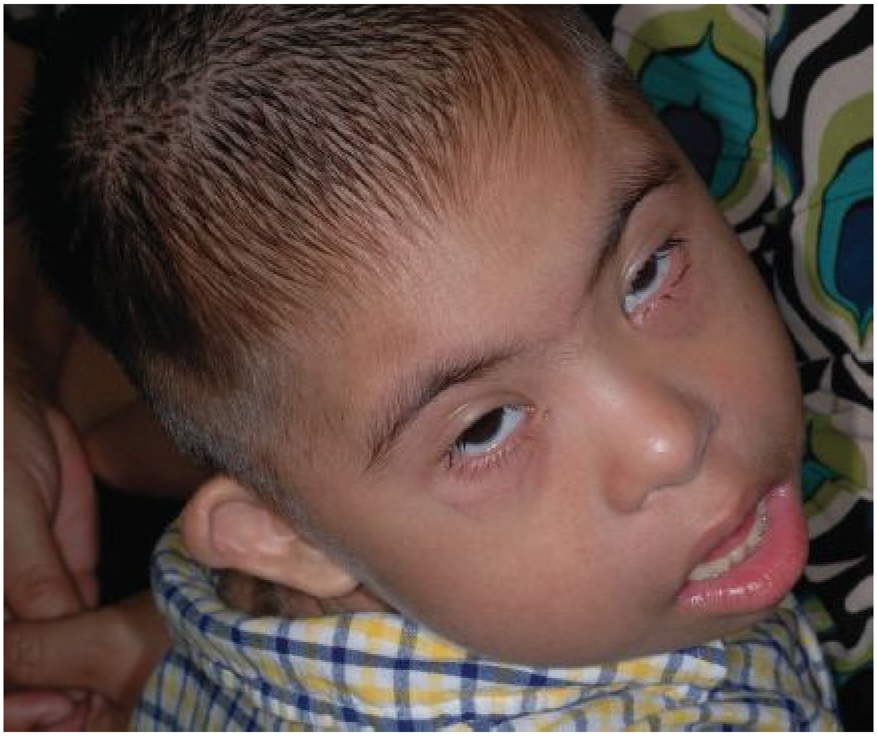

FIGURE 221-6 Epicanthal folds, upward slanting palpebral fissures and flat nasal bridge in the same boy as in **Figure 221-5**. (*Used with permission from Richard P. Usatine, MD*.)

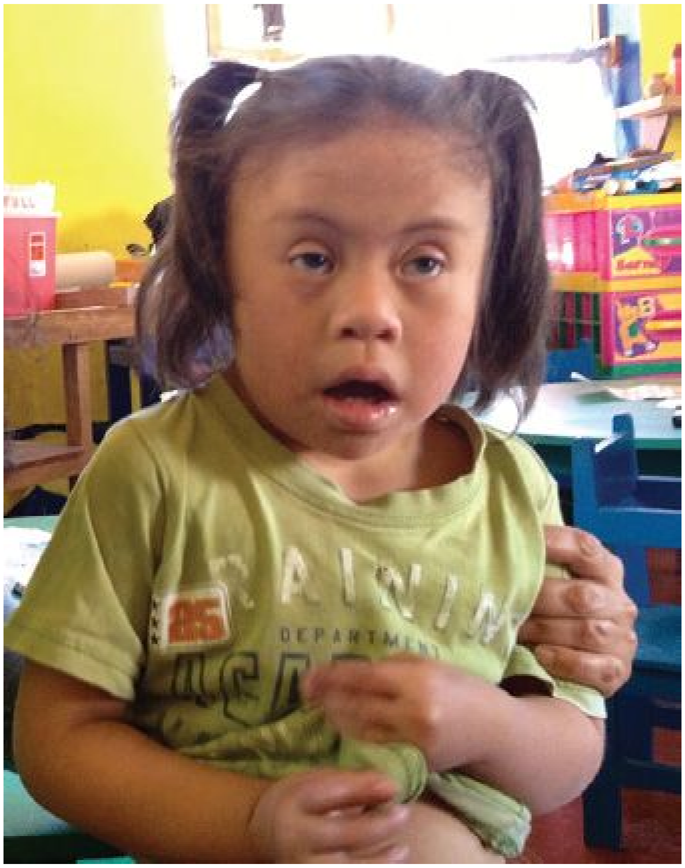

FIGURE 221-7 Epicanthal folds, upward-slanting palpebral fissures, and flat nasal bridge in a 3-year-old girl with Down syndrome. This girl was living in shelter for children with disabilities in a remote part of Peru and was found to have a grade 4 pansystolic murmur and signs of congestive heart failure, likely from an undiagnosed ventricular septal defect. (*Used with permission from Sangeeta Krishna, MD.*)

- Flat nasal bridge (**Figures 221-6** and **221-7**).
- Brushfield spots (speckled white spots on the iris; **Figure 221-8**).

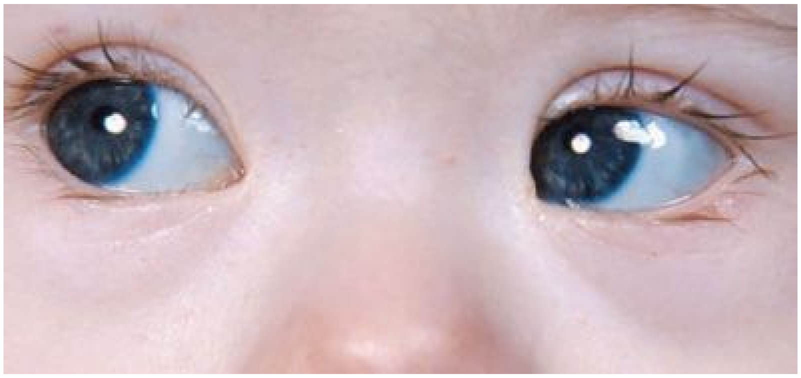

FIGURE 221-8 Speckled white spots on the iris (Brushfield spots) in an infant with Down syndrome. These are present in 90 percent of infants with Down syndrome but are also seen in infants without Down syndrome. (*Used with permission from Cleveland Clinic Children’s Hospital Photo Files*.)

Patients can also have maxillary and pharyngeal hypoplasia, which can lead to hearing loss and nasal obstruction.[2,3]

In early development, children with DS will demonstrate achievement of normal milestones in the low-normal timeframe, but their cognitive function stops developing in adolescence. Alzheimer’s is present in 75 percent patients with DS who are over 60 years of age.[3]

- DS is associated with many other medical conditions:
  - Hearing loss (75%).
  - Eye disease (60%) including cataracts, strabismus, and refractive errors.
  - Congenital heart disease (50%) with the most common being atrioventricular septal defect (see Chapter 47, Syndrome Associated with Heart Disease).
  - Gastrointestinal atresia (12%; **Figure 221-3**).
  - Thyroid disease (4 to 18%).
  - Polycythemia (18 to 64%).
  - Seizures (1 to 13%).
  - Transient myeloproliferative disorder (10%).
  - Celiac disease (5%).
  - Leukemia (1%).
  - Atlantoaxial instability (1 to 2%).
  - Autism (1%).
  - Hirschsprung (<1%).[3]
  - Behavioral disorders, including attention deficit hyperactivity disorder (6.1%), conduct disorder (5.4%), or aggressive behavior (6.5%). Many adults with DS will also have major depressive disorder (6.1%).[3]

LABORATORY TESTING

- In a newborn with no prenatal testing, if clinical exam is suspicious for DS (hypotonia, craniofacial abnormalities, etc.), a blood sample should be sent for fluorescent in situ hybridization (FISH), which detects trisomy 21 and is available within 1 to 2 days. A positive test requires confirmation with a complete cytogenetic analysis which detects translocations.[2]
- Once the diagnosis of DS is established, the newborn should receive a thorough physical exam evaluating for duodenal and anorectal atresia, problems with feeding, stridor/wheezing, congenital cataracts using red reflex testing, and hearing loss via brainstem auditory evoked response.[2]
- A CBC should be obtained to assess for hematologic abnormalities including transient myeloproliferative disorder, which increases the risk for later development of leukemia and polycythemia. TSH and free thyroxine should also be drawn to screen for congenital hypothyroidism.[2]

IMAGING

- All infants with DS should receive an echocardiogram to evaluate for congenital heart disease.[2]
- If clinically indicated, a swallow study can assess for feeding difficulties, laryngoscopy can assess for airway abnormalities, and abdominal x-ray can diagnose duodenal atresia (**Figure 221-3**).[2]

DIFFERENTIAL DIAGNOSIS

- Physical exam findings in isolation, such as simian crease, epicanthal folds, etc., may be variants of normal and may not indicate DS. Rely on clinical suspicion to judge whether or not cytogenetic testing may be useful.

- Other conditions to consider in the differential are trisomy 18 which presents with typical clinical features including rocker bottom feet and severe neurodevelopmental delay.
- Zellweger syndrome, a peroxisomal disorder, presents with hypotonia and abnormal elevation of very long chain fatty acids, especially those with 26 carbon atoms, and an increased ratio of C26 to C22 fatty acids in the plasma, as well as fibroblasts and amniocytes.

MANAGEMENT

- Management of a patient with DS should focus on education of the family, early screenings to allow for early interventions for any anomalies associated with DS, and routine follow-up at well-child visits to screen for conditions associated with DS.

NONPHARMACOLOGIC

- Parents should be educated about what to expect in their child. Children with DS are at risk for increased susceptibility for respiratory tract infections. Those with hemodynamically significant congenital heart lesions or comorbid conditions should receive respiratory syncytial virus prophylaxis between birth and 12 months old.[2] SOR Ⓐ
- All parents should be educated about atlantoaxial instability and should warn providers to avoid excessive extension or flexion of the cervical spine during procedures.[2]
- At annual appointments, parents should be asked whether their children have frequent ear infections, drainage from the ear, or hearing loss. Patients should be referred to otolaryngology as necessary.[2]
- Annually, parents should also be asked about presence of obstructive sleep apnea. A sleep study can be ordered for symptomatic patients but it is recommended that all patients undergo a sleep study by 4 years of age.

Patients found to have obstructive sleep apnea should be referred to otolaryngology and/or pulmonology.[2]

- Parents should also be asked whether their child has seizures with referral to neurology as needed.[2]
- Refer children with DS to ophthalmology within 6 months of age to evaluate for strabismus or cataracts. Ensure that patients follow-up with ophthalmology since 50 percent patients will develop refractive errors leading to amblyopia at <5 years of age.[2]
- At well-child visits, patients should also be screened for any indications of heart failure including failure to thrive, feeding difficulties, or tachypnea and asked about seizures.[2]
- Annual labs should include TSH to screen for thyroid dysfunction and CBC and reticulocyte hemoglobin (CHr) concentrations to monitor for iron-deficiency anemia. In children with DS, mean corpuscular volume is elevated in up to 45 percent of patients, and serum ferritin may be elevated from chronic inflammation. Thus, neither of these are useful screening tools for iron deficiency.[2]
- Assess patients for behavioral or social issues. Refer to child psychiatry if there is high suspicion for autism or attention-deficit/hyperactivity disorder, for early intervention.[2]
- Parents should be referred to support groups and given resources to help with behavioral and neurocognitive development of the patient.[2]

MEDICATIONS

- There are no specific medications for DS. Treat associated conditions with medications specific to the condition.

SURGERY

- Children with cataracts may undergo cataract surgery; those with congenital heart disease may require surgical correction; those with intestinal atresia require abdominal surgeries.

- Atlantoaxial subluxation poses an extra anesthetic risk during elective surgeries, especially during intubations, and should be kept in mind.

REFERRAL

- By 6 months of age, all children with DS should be referred to ophthalmology for evaluation of strabismus, cataracts, and amblyopia.
- By 4 years of age, all children with DS should have obtained a sleep study to assess for obstructive sleep apnea.
- For abnormalities detected on echocardiogram, children with DS should be referred to cardiology.
- Children with elevated white blood cell count or hemoglobin/hematocrit should be referred to hematology/oncology.
- For children with stridor/wheezing or signs of obstructive sleep apnea, refer to pulmonology.
- Children with recurrent otitis media should be referred to otolaryngology.
- Children with gastrointestinal atresia should be referred to general surgery.
- Children who have difficulty swallowing or are suspected of having aspiration pneumonia should be referred to pulmonology and may require gastrostomy tube placement by surgery to maintain feeds.

PREVENTION AND SCREENING

- Screening for DS is routine in prenatal care and is offered to women of all ages.
- The first trimester screen examines—Nuchal translucency on ultrasound and maternal serum levels of β-hCG and pregnancy associated plasma protein (PAPP-A). Increased nuchal translucency, high β-hCG, and low

PAPP-A are associated with DS. Taking these factors and maternal age into account, the risk of the fetus having DS is calculated. This screen has a sensitivity of 82 to 87 percent. False positive rates are higher with increasing maternal age.[6,8]

- Mothers at increased risk for having a child with DS can choose to have diagnostic testing via chorionic villus sampling in the first trimester or can proceed with the quad screen (maternal serum levels of b-hCG, unconjugated estriol, alpha-fetoprotein, and inhibin A) for a revised risk assessment.[6,8]
- Mothers who missed the first trimester screen or would like a final risk assessment can undergo the quad screen in the second trimester. DS fetuses tend to have decreased alpha-fetoprotein and estriol and increased inhibin A and β-hCG. Similar to the first trimester screen, the patient's risk of having a baby with DS is calculated based on this data and patient data. The quad screen alone has a sensitivity of 80 percent, but when combined with first semester screen, the two tests have a sensitivity of 95 percent with a 5 percent false positive rate.[6,8]
- Mothers with a risk of having a DS baby exceeding 1 in 270 (the risk of miscarriage with diagnostic testing) and who desire a definitive diagnosis can proceed with amniocentesis during the second trimester. Amniocentesis allows for definitive chromosomal analysis.[6,8]

PROGNOSIS

- With routine care and behavioral support, most individuals with DS without severe neurocognitive deficits can participate in normal activities of daily living.[9]
- Individuals with DS have a decreased lifespan (50 to 60 years) with an increased susceptibility for earlier development of Alzheimer's.[3]
- Through childhood (infancy to age 20 years), the risk for mortality was highest among patients with congenital heart disease both in the immediate post-natal period and through age 20 years.[9]

- Survival of non-Hispanic Caucasian children who have DS is higher than non-Hispanic African American children with DS in the postnatal period and through age 10 years.[9]

FOLLOW-UP

- Children with DS should follow routine well-child visits and see their pediatricians at least annually.
- Children with DS should follow-up with pediatric specialties as determined by the individual specialty depending on patient situation.

PATIENT EDUCATION

- Educate parents about what to expect with their child—Hypotonia, delayed teething, and lower intelligence quotients. All parents should understand the importance of warning other providers about possible atlantoaxial instability during procedures.
- Patients and their families should be educated on signs to watch out for that may indicate development of conditions associated with DS—Hypothyroidism, hearing loss, or middle ear disease, obstructive sleep apnea, heart failure, vision problems, and hematologic derangements including anemia and lymphoproliferative disorders.
- Taking care of a child with disabilities, while rewarding, can often be very taxing on the family. Ensure that the family is in touch with resources/support groups that can help parents.

222 TURNER SYNDROME

Elumalai Appachi, MD, MRCP

PATIENT STORY

A 6-year-old girl is brought to the pediatrician because of swelling in her lower legs that was noted by her mother over the past few weeks. The child has otherwise been well. Review of the growth parameters showed the girl to be at less than the 5th percentile for height. The girl exhibited edema of the lower extremities (right > left), low set ears, ptosis, and mild micrognathia (**Figures 222-1** and **222-2**). The pediatrician suspected Turner syndrome and referred the child to a pediatric endocrinologist, who confirmed the diagnosis with a karyotype (45, XO pattern). The child and family received counseling and education, and the girl was treated with growth hormones and has done well. Screening tests for renal and cardiac abnormalities were normal.

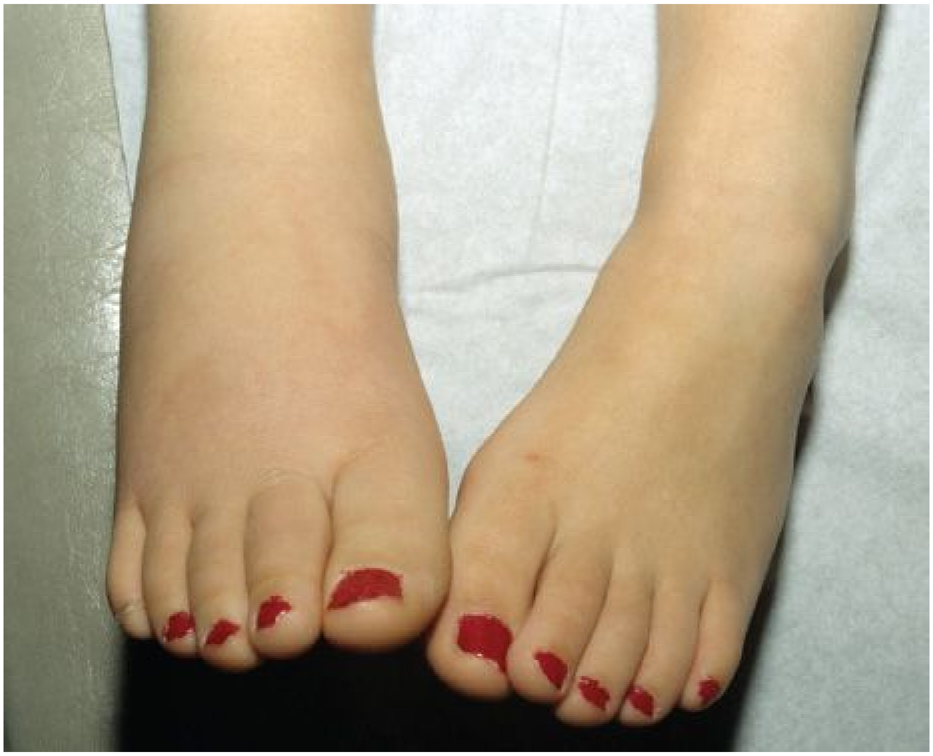

FIGURE 222-1 Lymphedema in the lower extremities, which is especially prominent on the right, in a 6-year-old girl with Turner syndrome. This was the presenting feature of this syndrome in this girl. (*Used with permission from Camille Sabella, MD*.)

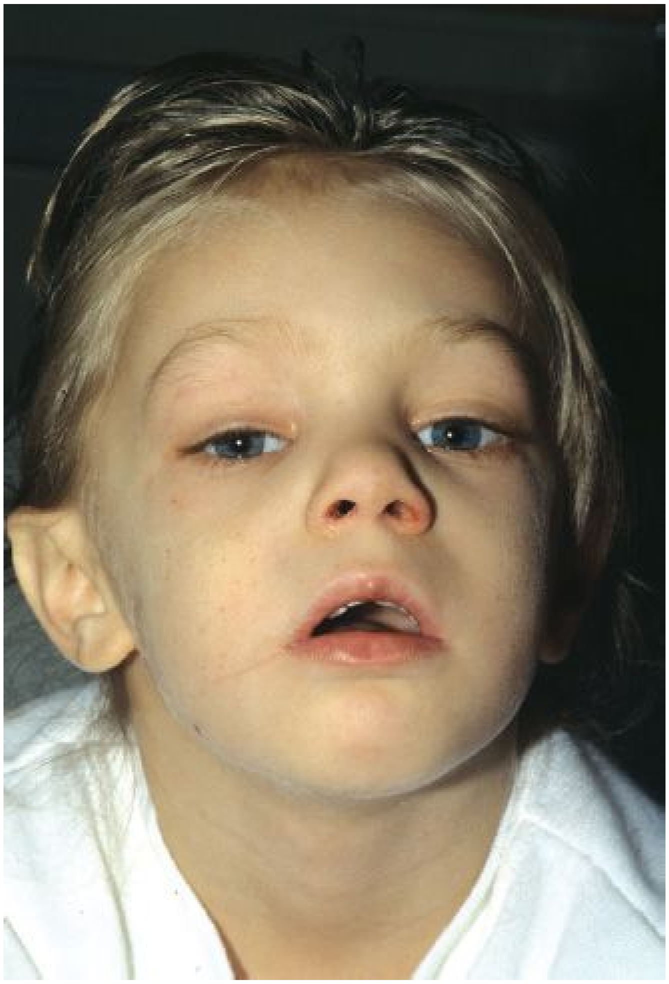

FIGURE 222-2 Low set ears, low hairline, mild ptosis, and small lower jaw in the same 6-year-old girl in Figure 222-1. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

Turner syndrome is an absence of one of the X chromosome (partial or complete) with a resultant female phenotype of short stature, lack of normal sexual maturation, and diverse somatic findings.

SYNONYMS

Gonadal dysgenesis, Haploinsufficiency of the X chromosome (45, XO karyotype), Bonnevie-Ullrich syndrome, and monosomy X.

EPIDEMIOLOGY

- Turner syndrome is the most common sex-linked chromosomal abnormality.
- Turner syndrome is a common cause of first-trimester spontaneous abortions, accounting for approximately 20 percent of the spontaneous abortions caused by chromosomal defects.
- Incidence is 1/2,500 to 1/5,000 live births; only 5 to 10 percent of affected fetuses survive to birth.[1]
- There are roughly 50,000 to 75,000 cases total in the US

ETIOLOGY AND PATHOPHYSIOLOGY

- Turner syndrome is a chromosomal abnormality caused by complete or partial absence of the second sex chromosome in a woman (most common karyotype is 45, XO) or mosaicism (e.g., karyotype 46, XX/45, XO or 46, XY/45, XO).
- Not related to maternal age.

DIAGNOSIS

The diagnosis of Turner syndrome is suspected on clinical features and confirmed by chromosomal analysis. Any girl with pathological short stature should have a karyotype performed to rule out Turner syndrome.[2,3]

CLINICAL FEATURES

- Can be identified at birth by the presence of lymphedema and excessive skin folds in the neck—Present in 30 percent of cases (**Figures 222-3** and **222-4**).[4]

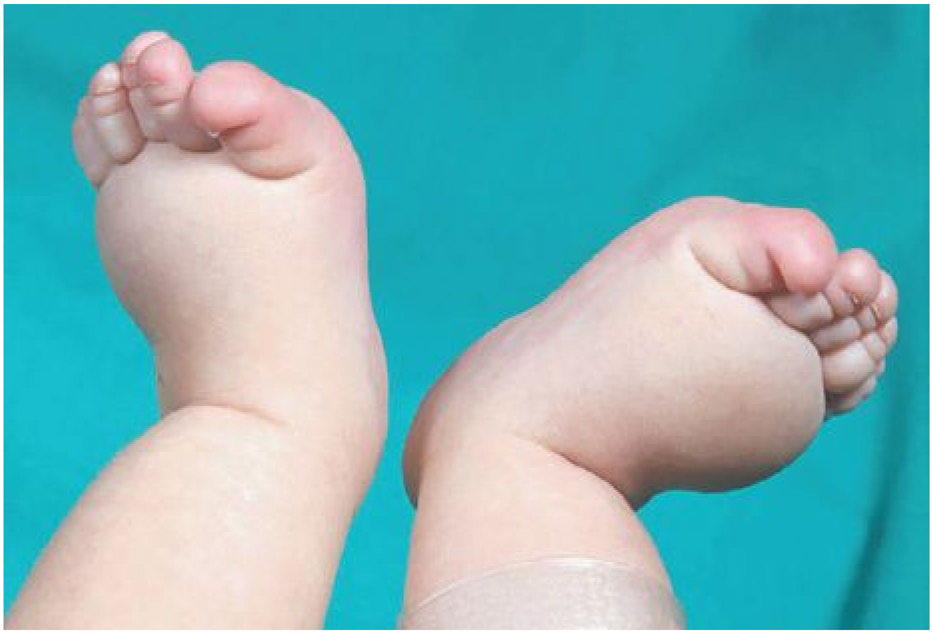

FIGURE 222-3 Lymphedema in a newborn infant who was found to have Turner syndrome. Thirty percent of infants with Turner syndrome will have lymphedema at birth. (*Used with permission from Cleveland Clinic Children’s Hospital Photo Files*.)

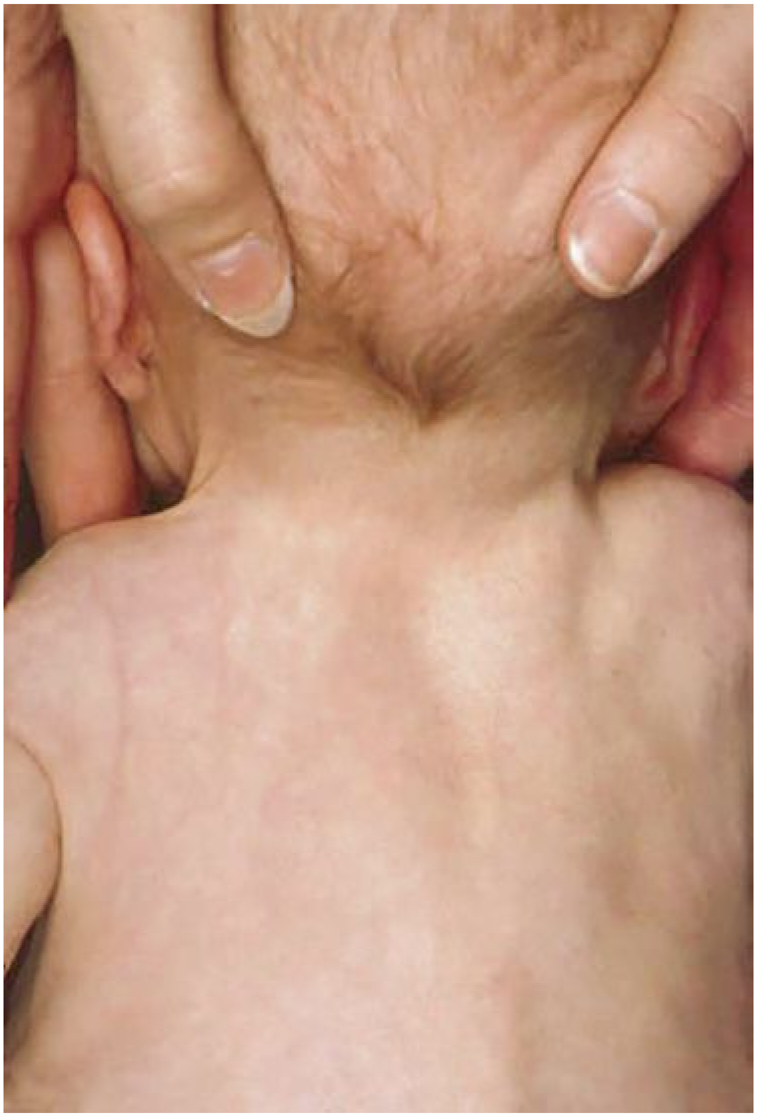

FIGURE 222-4 Loose skin folds and webbing of the neck in a newborn with Turner syndrome. (*Used with permission from Cleveland Clinic Children’s Hospital Photo Files*.)

- Growth failure and short stature.[2]
- Lymphedema of the limbs and neck usually occurs during infancy but may occur later, including during adolescence (**Figures 222-1**, **222-3**, and **222-4**).
- Loose skin folds and webbing of the neck (**Figure 222-5**).

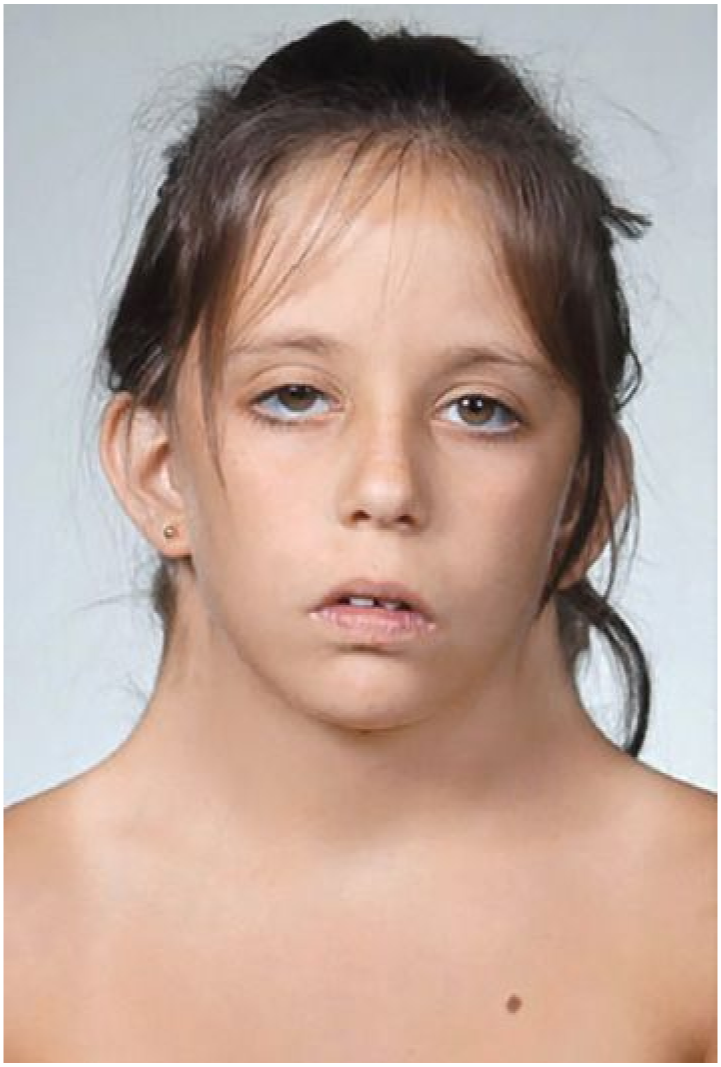

FIGURE 222-5 Prominent webbing of the neck in an adolescent with Turner syndrome. Also note the low set ears, low hairline, and mild ptosis. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Broad, shield-like chest and wide spaced nipples (**Figures 222-6** and **222-7**).

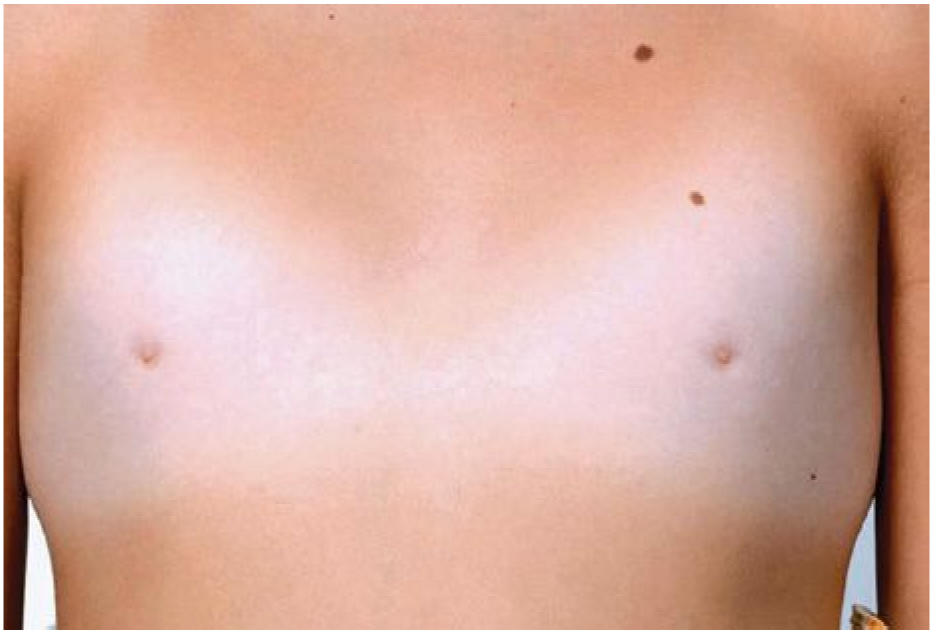

FIGURE 222-6 Wide spaced nipples and broad, shield-like chest, in the same girl with Turner syndrome in Figure 222-5. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

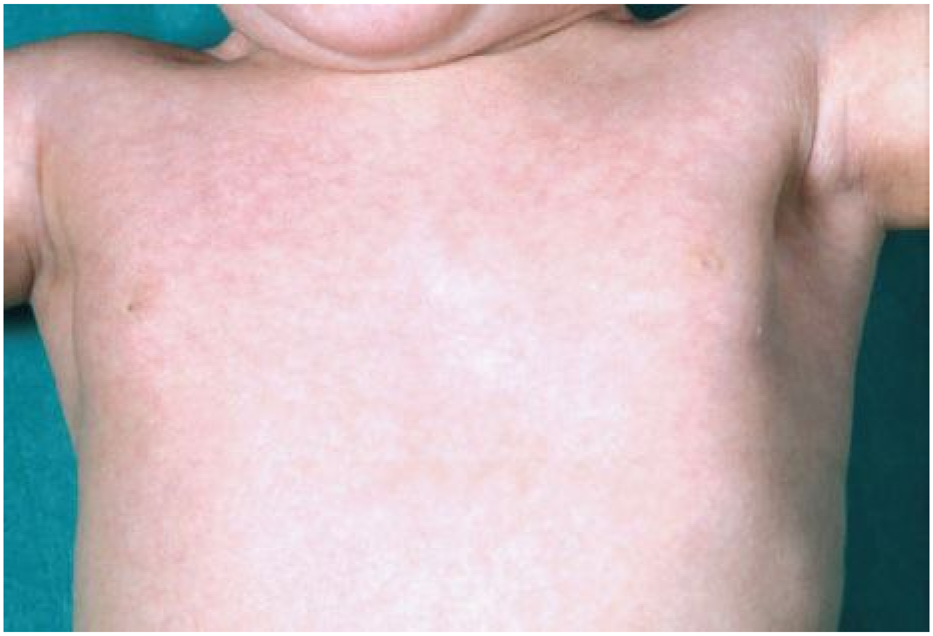

FIGURE 222-7 Wide-spaced nipples and loose skin folds in the neck visible in an infant with Turner syndrome. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Shortened fourth and fifth metacarpals and metatarsals—Found in 50 percent of patients.
- Atypical facies that may include prominent or low-set ears, low hairline, ptosis, and hypertelorism (**Figures 222-2** and **222-5**).
- Cardiovascular abnormalities, such as bicuspid aortic valve, dilated aortic root, or coarctation of aorta (50%), especially if there is presence of webbed neck.[5]
- Early menopause.
- Renal anomalies, such as horseshoe kidneys, pelvic kidney, UPJ obstruction, idiopathic hypertension, and renal infections.
- Recurrent otitis media (75%) mild neurological problems.
- Hearing defects.[6]
- Bone abnormalities.
- Feeding problems.
- Hypothyroidism and thyroiditis.
- Delayed onset of menstruation.
- Infertility.
- Learning problems.

LABORATORY TESTING

- Karyotype should be performed to confirm the diagnosis.
- Thyroid function tests should be obtained to screen for thyroid dysfunction.
- Audiology screening should be performed in all patients with Turner syndrome.

IMAGING

- Echocardiogram should be done to screen for cardiovascular abnormalities.
- Renal ultrasound should be done to screen for renal anomalies.

DIFFERENTIAL DIAGNOSIS

- Noonan Syndrome—Mainly seen in males who have a similar phenotype to Turner syndrome. It can be seen in females (see Chapter 226, Noonan Syndrome).
- Congenital lymphedema—Findings present at birth, but not associated with other features of Turner syndrome and associated with a normal karyotype.

MANAGEMENT

NONPHARMACOLOGIC

- Audiology screening and subsequent hearing aids may be necessary for hearing defects.
- Counseling and monitoring of the child and the family is a vital part of the management.

MEDICATIONS

- Growth hormone therapy is indicated for all patients and should be instituted in early childhood to maximize growth potential.[7–12] SOR A
- Hormone replacement therapy with estrogen should be started in adolescence when follicle-stimulating hormone and luteinizing hormone

levels are increased; preferably, therapy should not begin until age 13 to 15 years of age to maximize the linear growth.[13–15] SOR A

- During adolescence, estrogen is cycled with progesterone to achieve sexual maturity and to maximize bone development, including the prevention of osteoporosis.
- Treatment with thyroid hormone replacement may be required for hypothyroidism.
- Treatment for obesity may be required, and lifestyle education with advice on diet and exercise must be included to prevent complications such as diabetes, osteoporosis, and hypertension.

SURGERY

- Gonadectomy (gonadal ablation) may be indicated for patients with Turner syndrome who have Y chromosomal mosaicism, to eliminate the risk of malignancy in the streak gonad.
- Patients who have coarctation of the aorta or bicuspid aortic valve may need surgical repair.

REFERRAL

- A multidisciplinary team approach, including endocrinologists, geneticists, and nutritionists, is recommended for the management of patients with Turner syndrome.
- Appropriate referral is made based on the age at presentation.

PREVENTION AND SCREENING

- Turner syndrome may be suspected during prenatal ultrasound if there is a cystic hygroma or edema of the limbs.

- Prenatal diagnosis to confirm the diagnosis can be made by chorionic villus sampling or amniocentesis.

PROGNOSIS

- Normal life expectancy.
- Adult height is well below the average even with growth hormone therapy.[16,17]
- The majority of patients with Turner syndrome are infertile, although pregnancy has been achieved with the use of assisted reproductive techniques.

FOLLOW-UP

- Patients need speech evaluation especially when presented with hearing defects.
- Cardiology follow up with echocardiography should be done annually or twice a year.
- Thyroid function should be checked annually or twice a year.
- Regular follow up with endocrinologist and regular monitoring of follicle-stimulating hormone and luteinizing hormone levels should be performed at 10 years of age onward.
- Evaluate for secondary sexual development at adolescence.
- Discuss social adaptation, and provide support group contacts.

223 MARFAN SYNDROME

Elumalai Appachi, MD, MRCP

PATIENT STORY

A 14-year-old girl is brought to her pediatrician for a routine health maintenance visit. The pediatrician notes that she is tall for her age, has long, slender fingers, hypermobile joints, and that her arm span is longer than her body span (**Figures 223-1** to **223-3**). She also has a high arched palate and a systolic murmur. The pediatrician refers the girl to a cardiologist, who performs an echocardiogram, which reveals mitral valve prolapse without regurgitation, and dilatation of the aortic root. The pediatrician and cardiologist suspect that the child has Marfan syndrome and order a test for fibrillin 1 mutation, which confirms the diagnosis. Her pediatrician plans a multidisciplinary team for the girl, including baseline and follow-up ophthalmology examinations, and close follow-up visits with the cardiologist, orthopedist, and geneticist.

INTRODUCTION

Marfan syndrome (MFS) is a heritable disorder of connective tissue resulting from mutations in the gene encoding the extracellular matrix protein fibrillin 1(FBN1). Individuals with MFS manifest variable clinical features, which often involve the skeletal, cardiovascular, and ocular systems.

EPIDEMIOLOGY

- The incidence of this disorder is about 1 per 5,000 to 10,000 births.[1]
- MFS is inherited in an autosomal dominant manner; thus, there is a 50 percent chance of an offspring inheriting the condition from the affected parent.
- Approximately 1/3 of cases are sporadic due to *de novo* mutations; new mutations are often associated with advanced paternal age.

ETIOLOGY AND PATHOPHYSIOLOGY

- MFS is associated with abnormal biosynthesis of fibrillin-1, which is the major constituent of microfibrils. Mutations in FBN1 are found in about 95 percent of patients who meet the diagnostic criteria for Marfan syndrome.[2,3]
- The FBN1 locus resides on the long arm of chromosome 15 (15q21) and the gene is composed of 65 exons. More than 1,000 mutations distributed throughout FBN1 have been identified, many being unique to a given family.[4,5]
- The condition results from a structural deficiency of connective tissues. The decreased fibrillin-1 leads to a primary derangement of elastic fiber

deposition, along with elastic fiber fragmentation. The decreased elastin in the aorta, skin, and other connective tissue is responsible for accelerated degeneration of tissue resulting in the clinical manifestations.

- Mutations in FBN1 are associated with a wide phenotypic spectrum ranging from severe rapidly progressing neonatal manifestations, manifestations that present in childhood and early adulthood, to isolated features such as ectopia lentis or skeletal manifestations.

DIAGNOSIS

- The diagnosis of MFS is based on well-defined clinical criteria. Genetic testing of FBN1 should be reserved for those patients in whom there is strong suspicion of the diagnosis, or for patients who are suspected of having the disorder but who may not meet full clinical criteria.[6]
- The revised Ghent diagnostic criteria[7] outlines a *definitive* diagnosis of MFS when any of the following are present:
    - Aortic root dilation (≥2 z score) and ectopia lentis (z score is a standard measure of aortic root diameter at the sinus of Valsalva based on body surface area).
    - Aortic root dilation (≥2 z score) and FBN1 mutation.
    - Aortic root dilation (≥2 z score) and systemic score ≥7 (see the following for scoring system).
    - Ectopia lentis and FBN1 mutation known to be associated with Marfan syndrome.
    - Positive family history of Marfan syndrome and ectopia lentis.
    - Positive family history of Marfan syndrome and systemic score ≥7.
    - Positive family history of Marfan syndrome and aortic root dilation (≥3 z score) in those <20 y of age or ≥2 z score in those >20 y of age.
- A *potential* diagnosis is made when there is an FBN1 mutation with aortic root dilation with a z score <3 in those <20 years of age.
- The systemic scoring system used for the diagnosis of MFS includes:
    - Wrist and thumb sign (3 points; **Figures 223-4** and **223-5**).

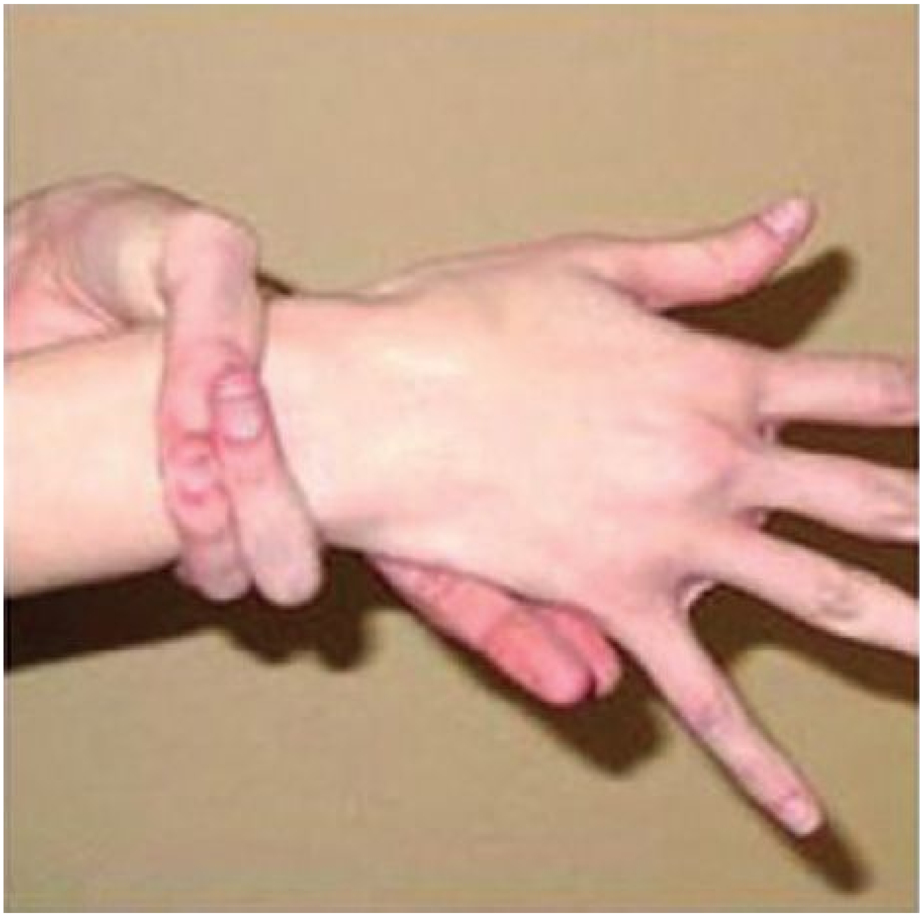

FIGURE 223-4 “Wrist” sign, which is a full overlap of the distal phalanges of the thumb and fifth finger when wrapped around the contralateral wrist, in a patient with Marfan syndrome. (*Used with permission from Rudolph CD, Rudolph AM, Lister G, First LR, Gershon AA: Rudolph’s Pediatrics, 22nd edition. www.accesspediatrics.com. Figure 181-1B, New York: McGraw-Hill*.)

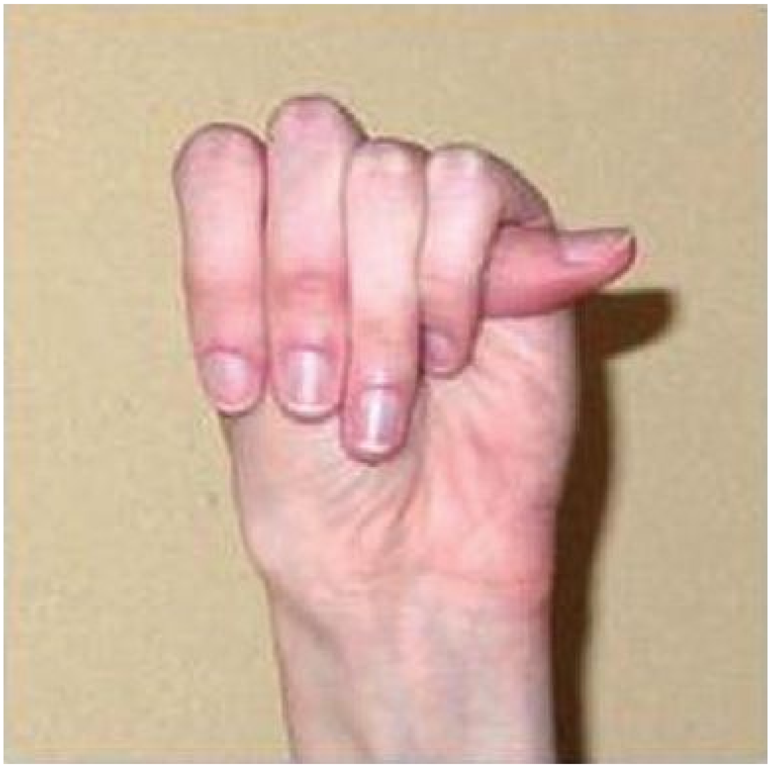

FIGURE 223-5 “Thumb” sign, the distal phalanx of the thumb fully extending beyond the ulnar border of the hand when folded across the palm, in a patient with Marfan syndrome. (*Used with permission from Rudolph CD, Rudolph AM, Lister G, First LR, Gershon AA: Rudolph’s Pediatrics, 22nd edition. www.accesspediatrics.com. Figure 181-1C, New York: McGraw-Hill.*)

- Wrist or thumb sign (1 point).
- Pectus carinatum (2 points; **Figure 223-6**).

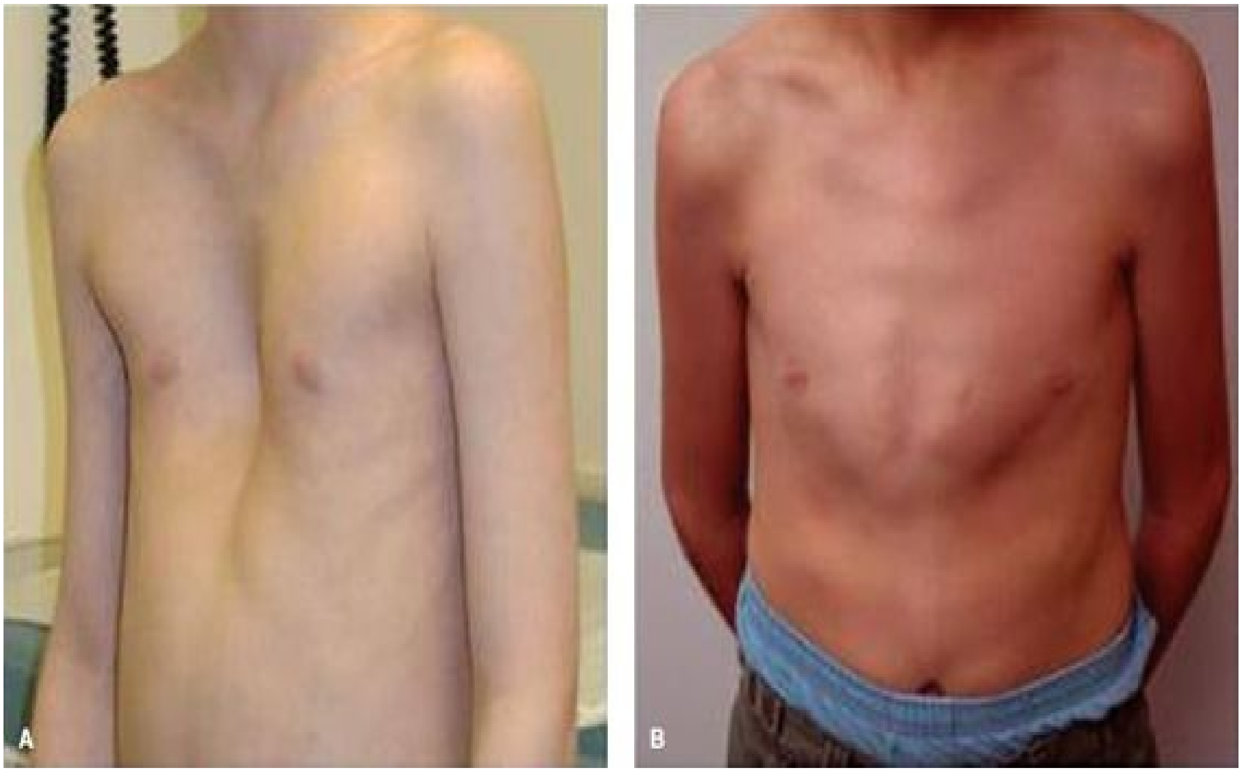

FIGURE 223-6 Pectus excavatum (**A**) and pectus carinatum (**B**) resulting from overgrowth of the ribs in two patients with Marfan syndrome. (*Used with permission from Rudolph CD, Rudolph AM, Lister G, First LR, Gershon AA: Rudolph's Pediatrics, 22nd edition. www.accesspediatrics.com. Figure 181-1 D and E, New York: McGraw-Hill.*)

- Pectus excavatum (1 point; **Figure 223-6**).
- Hindfoot deformity (2 points).
- Pes planus (1 point; **Figure 223-7**).

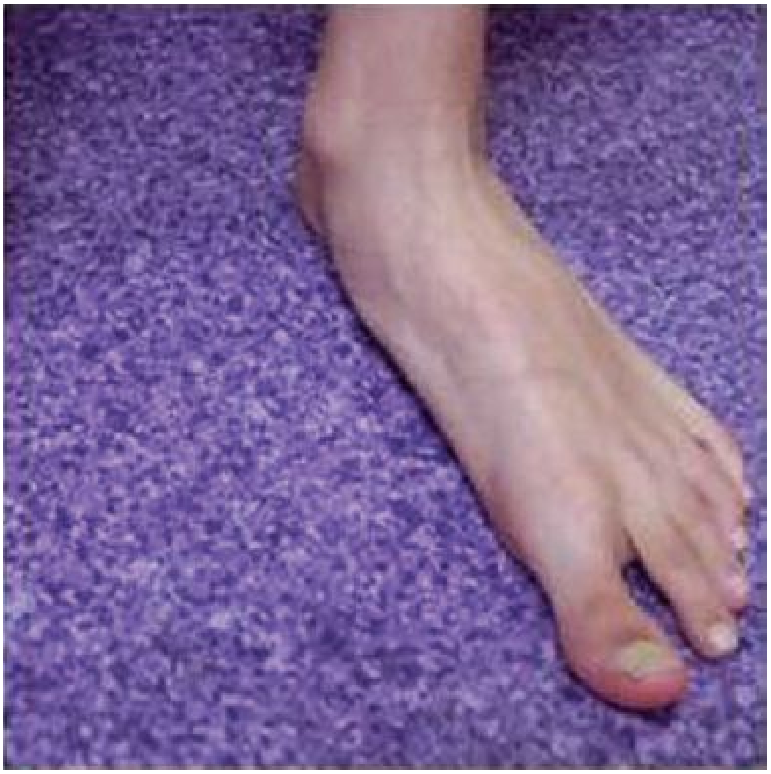

FIGURE 223-7 Pes planus (flat foot) in a patient with Marfan syndrome. (*Used with permission from Rudolph CD, Rudolph AM, Lister G, First LR, Gershon AA: Rudolph's Pediatrics, 22nd edition. www.accesspediatrics.com. Figure 181-1 F, New York: McGraw-Hill.*)

- Pneumothorax (2 points).
- Dural ectasia (2 points).
- Protrusio acetabulae (2 points).
- Reduced upper to lower segment ratio and increased arm-span-to-height ratio (1 point; **Figure 223-1**).
- Scoliosis or thoracolumbar kyphosis (1 point; **Figure 223-8**).

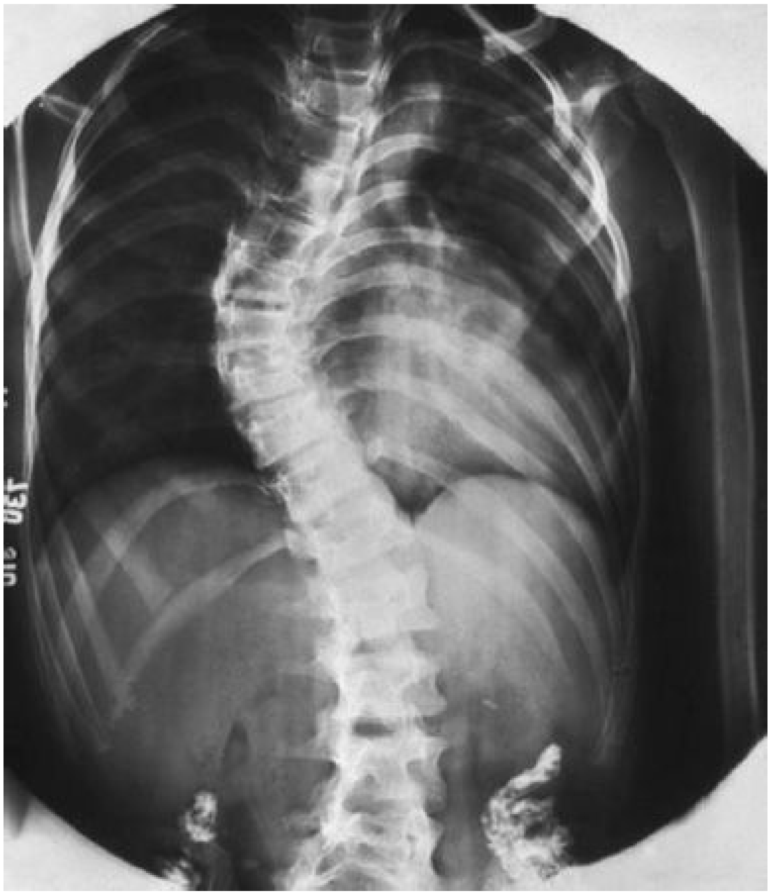

FIGURE 223-8 Severe scoliosis in a patient with Marfan syndrome. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Reduced elbow extension (1 point).
- Craniofacial features such as dolichoencephaly, downward-slanting palpebral fissures, endophthalmos, retrognathia, and malar hypoplasia (1 point if at least 3 of these are present).
- Skin striae (1 point; **Figure 223-9**).

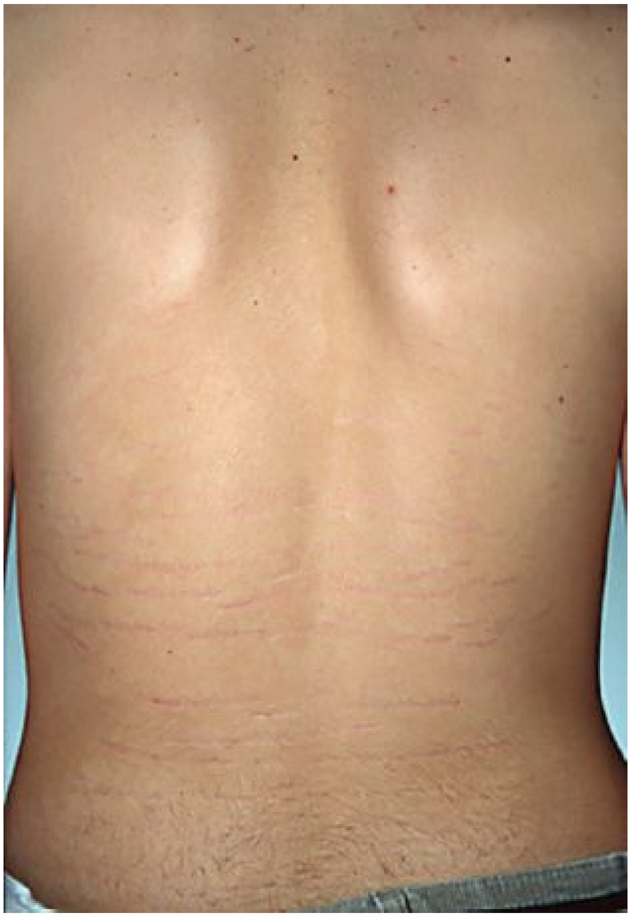

FIGURE 223-9 Horizontal skin striae in a patient with Marfan syndrome. These are a result of rapid growth and typically perpendicular to the growth axis. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

  - Myopia (1 point).
  - Mitral valve prolapse (1 point).

CLINICAL FEATURES

▸ The skeletal system

- Excessive growth of long bones is common, typically resulting in tall stature.
- Disproportionate growth of skeletal systems results in an arm span >1.05 times the height, or a reduced upper to lower segment ratio (in the absence

of severe scoliosis; **Figure 223-1**).

- Arachnodactyly (long spider like fingers) is generally a subjective finding (**Figure 223-2**). The combination of long fingers and loose joints leads to the characteristic:
    - Walker-Murdoch or “Wrist” sign—Full overlap of the distal phalanges of the thumb and fifth finger when wrapped around the contralateral wrist (**Figure 223-4**).
    - The Steinberg or “Thumb” sign—Distal phalanx of the thumb fully extends beyond the ulnar border of the hand when folded across the palm, with or without active assistance by the patient or examiner (**Figure 223-5**).
- Patients may have overgrowth of the ribs, pushing the sternum anteriorly (pectus carinatum) or posteriorly (pectus excavatum; **Figure 223-6**).
- Thoracolumbar scoliosis is present in about half of individuals with MFS and can range from mild to severe and can be progressive (**Figure 223-8**).
- Pes planus (flat feet) is commonly present and varies from mild and asymptomatic to severe deformity (**Figure 223-7**).

► Cardiac system

- Involvement of the cardiovascular system is the major cause of morbidity and mortality in MFS.
- Aortic aneurysm and dissection remain the most life-threatening manifestations. This finding is age dependent, prompting life-long monitoring by echocardiography or other imaging modalities.
- The aortic dilation is progressive over time, with the majority of cases becoming evident before 18 years of age.
- Aortic valve dysfunction is generally a late occurrence, attributed to stretching of the aortic annulus by an expanding root aneurysm.
- Atrioventricular (AV) valves are most often affected. Thickening of the AV valves is common and often associated with prolapse of the mitral and/or tricuspid valves. Variable degrees of regurgitation may be present.

- Other cardiovascular manifestations include ventricular and supraventricular arrhythmias and dilated cardiomyopathy. Patients may present with heart failure, pulmonary hypertension or sudden death.

▶ Ocular system

- Myopia is the most common ocular feature and can progress rapidly early during childhood.
- Ectopia lentis (dislocation of the lens) occurs in 70 percent of patients (**Figure 223-10**). This is often the presenting feature of MFS and occurs commonly before 10 years of age. A slit lamp examination after full pupillary dilation is the most reliable method to appreciate this finding.

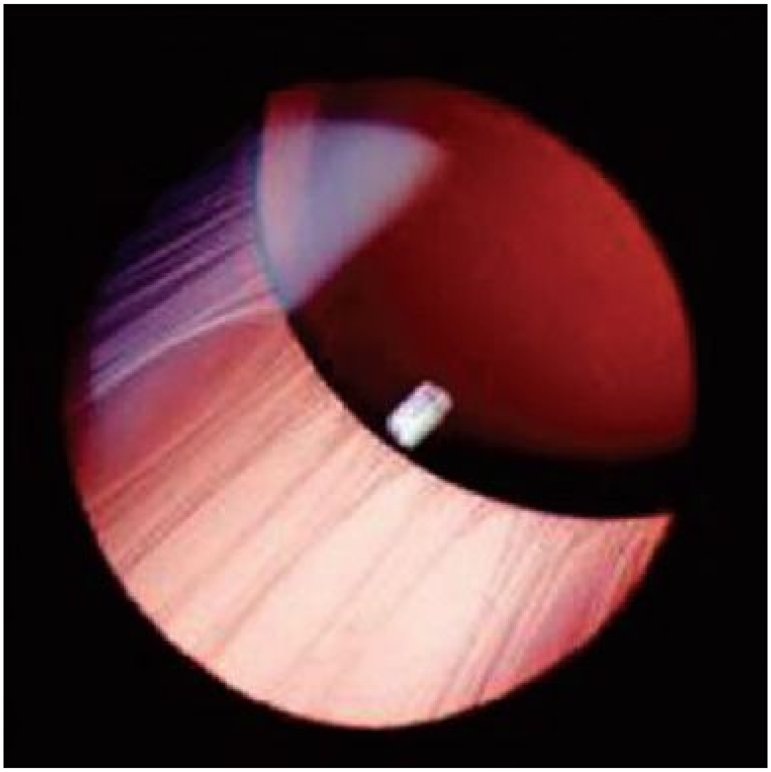

FIGURE 223-10 Ectopia lentis (dislocation of the lens) in a patient with Marfan syndrome. (*Used with permission from David Dreis, MD, in Rudolph CD, Rudolph AM, Lister LE, First LR, Gershon AA: Rudolph's Pediatrics, 22nd edition. www.accesspediatrics.com. Figure 181-1H, New York: McGraw-Hill.*)

- Other manifestations include a flat cornea, retinal detachment, and glaucoma.

▶ Pulmonary system

- Pectus and scoliosis can cause restrictive lung disease.
- Widening of the distal airspaces with or without discrete bullae or (often apical), blebs can predispose to spontaneous pneumothorax, which occurs in up to 15 percent of patients.

▶ Integument

- Skin striae, which are signs of rapid growth, are commonly apparent; these are typically horizontal and located across the lower back and inguinal and axillary regions (**Figure 223-9**).
- Patients with MS have an increased incidence of inguinal and other hernias, which may be apparent at birth or acquired during adolescence. These may be require surgical correction and may recur.

LABORATORY TESTING

- Molecular analysis for an identifiable FBN1 mutation is important in confirming the diagnosis.
- Echocardiogram of the heart to evaluate for cardiovascular manifestations should be performed in all patients at diagnosis.
- A urine cyanide nitroprusside test or a serum homocysteine level should be performed to exclude homocystinuria, which may have similar clinical findings.

DIFFERENTIAL DIAGNOSIS

- Ehlers-Danlos syndrome can have similar clinical features, such as mitral valve prolapse, thin atrophic scars, joint hypermobility, and rupture of hollow organs (see Chapter 223, Ehlers-Danlos Syndrome).
- Homocystinuria may have similar clinical features such as ectopia lentis and skeletal abnormalities. This entity is inherited in an autosomal recessive manner, associated with variable cognitive defects, and increased risk for thromboembolism. The plasma homocystine levels will be elevated.
- Loeys-Dietz syndrome—Affected patients show malar hypoplasia, arched palate, retrognathia, pectus deformity, scoliosis, joint laxity, dural ectasia, and aortic root aneurysms and dissection. Although their fingers tend to be long, overgrowth of the long bones is subtle or absent and ectopia lentis is not a feature.

MANAGEMENT

- A multidisciplinary team approach is required to screen and prevent complications and to provide ongoing support for the patient and the family.
- The aim of management is to diminish aortic complications. This can be accomplished by paying close attention to the need for activity restrictions, surgery, and pharmacologic therapy.

NONPHARMACOLOGIC

- Although physical activity is encouraged for all patients to promote overall health, skill development, coordination, musculoskeletal health, and socialization, these patients are at significant risk of physical injury and complications.[6]
- Limitations on strenuous exercise or sport activities to decrease the risk of aortic dissection or retinal detachment are often recommended.

- In general, patients with MFS who do not have aortic dilation or significant valvular problems are encouraged to participate in competitive and noncompetitive activities, as tolerated.

MEDICATIONS

- β-blockers, based on their ability to reduce hemodynamic stress on the aortic wall, have traditionally been considered the standard of care for patients with MFS. SOR Ⓒ However, there is insufficient evidence to support their routine use.[8]
- Losartan, an angiotensin II receptor type 1 blocker, has been shown to prevent pathologic aortic root growth and to normalize both aortic wall thickness and architecture in a small group of patients.[9]Randomized controlled trials using losartan for MFS are ongoing.

SURGERY

- Successful surgical repair of aortic root aneurysms may be the single most important cause of improvement in life expectancy.
- Surgical repair of the aorta is indicated once:[10]
    - The maximal aortic root measurement exceeds 5 cm.
    - The rate of increase of the aortic diameter approaches 1 cm per year.
    - There is progressive aortic regurgitation.

REFERRAL

- A multidisciplinary team approach is important for the long-term management of these patients and should include a cardiologist, ophthalmologist, orthopedic surgeon, and geneticist.

PREVENTION AND SCREENING

- Prenatal diagnostic testing is available if a disease causing mutation has been identified in the family. As the severity of the condition is unpredictable, analyses and planning should ideally be done prior to conception.
- Prevention of cardiac morbidity is critical and patients require close monitoring by a cardiologist.
- Annual echocardiogram is recommended for all patients with MFS, as long as aortic dimensions are low and the rate of dilation is low.[6] More frequent studies are needed when abnormalities are noted.

PROGNOSIS

- The prognosis is variable based on the clinical manifestations and ongoing care.
- Aortic dissection is exceedingly rare in early children.
- Generally, a normal life expectancy is possible, especially after aortic root repair.

FOLLOW-UP

- It is important for these patients to have a medical home to assure that there coordination of care with the various specialists and to offer psychosocial support.
- Close follow-up with a cardiologist, along with annual echocardiography, is mandatory.
- Annual ophthalmology exam is recommended for all patients with MS.
- Screening for scoliosis is recommended yearly until 6 years of age, every 6 months between 6 to 18 years of age, and yearly after age 18 years.

224 EHLERS–DANLOS SYNDROMES

Elumalai Appachi, MD, MRCP

PATIENT STORY

A 12-year-old boy presents to his pediatrician with pain in his knees while walking. On physical examination, he is noted to be short, has hyperextensibility of the skin, and hypermobile joints (**Figures 224-1** and **224-2**). His mother mentions that there are family members who have hypermobile joints, and who have had problems with dislocation and sprains of their joints. The pediatrician makes a clinical diagnosis of Ehlers-Danlos Syndrome and orders an echocardiogram, which is normal.

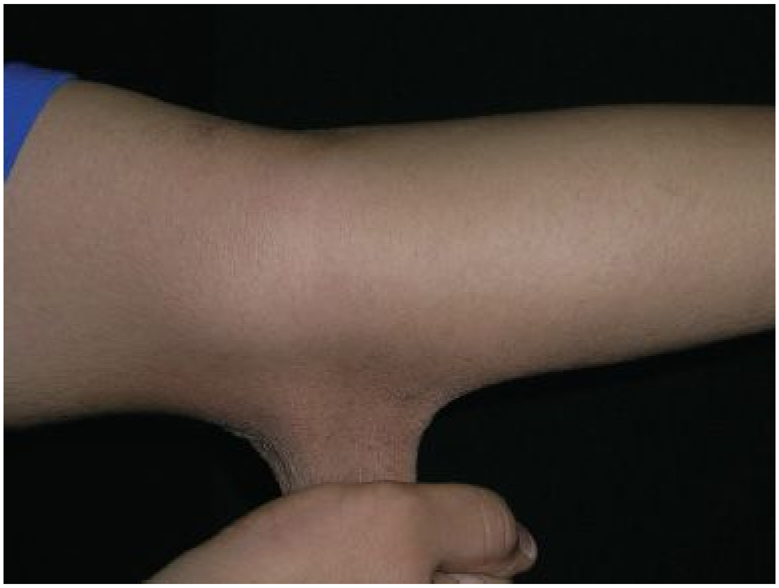

FIGURE 224-1 Hyperextensibility of the skin in a boy with proven Ehlers-Danlos syndrome. (*Used with permission from Richard P. Usatine, MD.*)

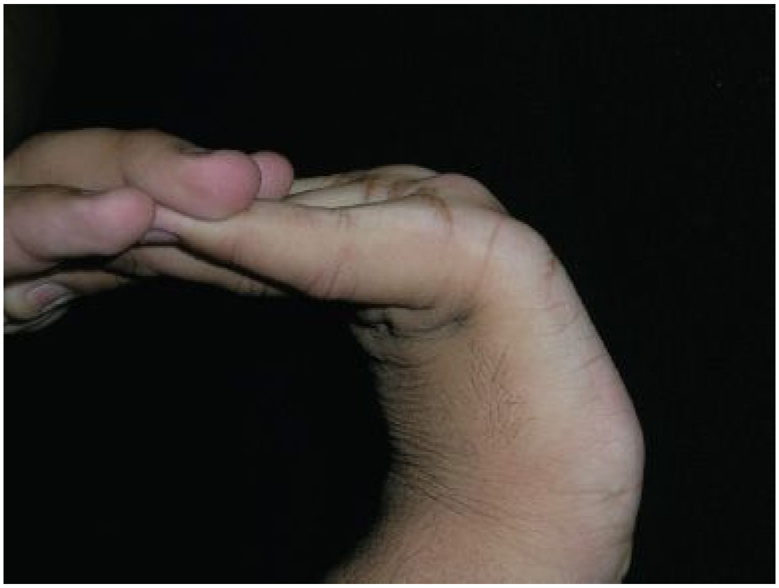

FIGURE 224-2 Hypermobility of the fingers in the same boy with Ehlers-Danlos syndrome. (*Used with permission from Richard P. Usatine, MD*.)

INTRODUCTION

The Ehlers–Danlos syndromes (EDS) constitute a genetically heterogeneous group of conditions, characterized by fragility of the connective tissues, resulting in skin, ligament, joint, blood vessels, and visceral organ manifestations. The clinical spectrum ranges from mild skin and joint hyperlaxity to severe physical disability and life-threatening vascular complications.

SYNONYMS

Hereditary collagen dysplasia.

EPIDEMIOLOGY

- The prevalence of EDS (all types) is estimated to be approximately one in 5,000 individuals.[1]
- The most recent classification of EDS relies on clinical and biochemical criteria.[2]
- Classification of the EDS types and prevalence:
  - Classic type—Affects 1 in 20,000 to 40,000 individuals.
  - Hypermobility type—Affects 1 in 10,000 to 15,000 individuals.
  - Vascular type—Affects 1 in 250,000 individuals. Accounts for about 5 percent of cases of EDS. Not often diagnosed until adulthood.
  - Kyphoscoliosis type—Very rare.
  - Arthrochalasia type—Very rare.
  - Dermatosparaxis type—Very rare
- The vascular form of EDS is the most dangerous, because it is associated with spontaneous rupture of medium and large-sized arteries and hollow organs, especially the large intestine and uterus; vascular events typically occur between the third and fifth decade.

ETIOLOGY AND PATHOPHYSIOLOGY

- Mode of inheritance is autosomal dominant for all forms of EDS except the kyphoscoliosis and dermatosparaxis types (recessive mode), and an unclassified X-linked form which is extremely rare.
- Abnormalities of mature collagen structure in extracellular matrices of multiple tissues (skin, tendons, blood vessels, and viscera) are common to all forms of EDS.
- Classic EDS is associated with defects in type V collagen, corresponding to mutations of COL5A genes, as well as type I collagen (COL1A1).
- The precise etiology for the hypermobility form has not been identified.
- Vascular EDS involves a deficiency in type III collagen and several studies suggest that mutations of gene COL3A1 lead to this deficiency.[3]

- The kyphoscoliotic type of EDS is caused by a deficiency of lysyl hydroxylase (PLOD), a collagen modifying illness.
- The arthrochalasia form of EDS results from a defect in type I collagen, caused by mutations in the COL1A2 genes.

RISK FACTORS

- Family history.

DIAGNOSIS

- The diagnosis of EDS is based solely on clinical criteria, which have been established for the six major types of EDS.
- Major and minor criteria have been established for each type; the presence of one or more major criteria is highly indicative and warrants laboratory confirmation if possible.
- A minor criterion is less specific, but the presence of one or more minor criteria contributes to the diagnosis of a specific type; in the absence of a major criterion, minor criteria are not sufficient to establish a diagnosis.
- Positive family history is a minor criterion for all forms.
- Skin hyperextensibility (**Figure 224-1**) should be tested at a site not subjected to mechanical forces or scarring, and measured by pulling up the skin until resistance is felt.
- Joint hypermobility should be assessed using the Beighton scale. A score of 5 or greater defines hypermobility:
    - Passive dorsiflexion of the fifth finger >90° (one point if present, 2 points if bilateral).
    - Passive flexion of thumb to the forearm (one point if present, 2 points if bilateral).

  - Hyperextension of the elbow beyond 10° (one point if present, 2 points if bilateral).
  - Hyperextension of the knee beyond 10° (one point if present, 2 points if bilateral).
  - Ability to place the palms on the floor with extension of the knees (one point if present).
- Easy bruising is defined as spontaneous ecchymosis, frequently located in the same areas, and causing a brownish discoloration.

CLINICAL FEATURES

- Classic EDS.
  - Skin hyperextensibility, widened atrophic scars (tissue fragility), and joint hypermobility are the major criteria (**Figures 224-1** to **224-3**).

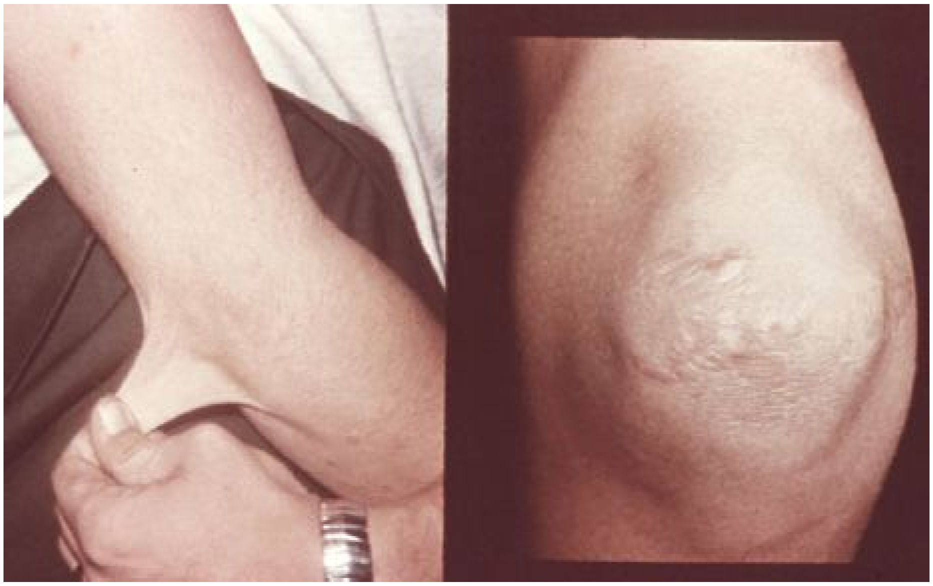

FIGURE 224-3 Hyperextensibility of the skin (left) and atrophic scarring of the knee in a patient with the classic form of Ehlers-Danlos syndrome. (*Used with permission from Cleveland Clinic Children's Photo Files*.)

  - Dermatologic features predominate, although the range of these manifestations varies greatly.
  - Minor criteria include:

  - Smooth, velvety skin.
  - Molluscoid pseudotumors—Fleshy lesions associated with scars (**Figure 224-4**).

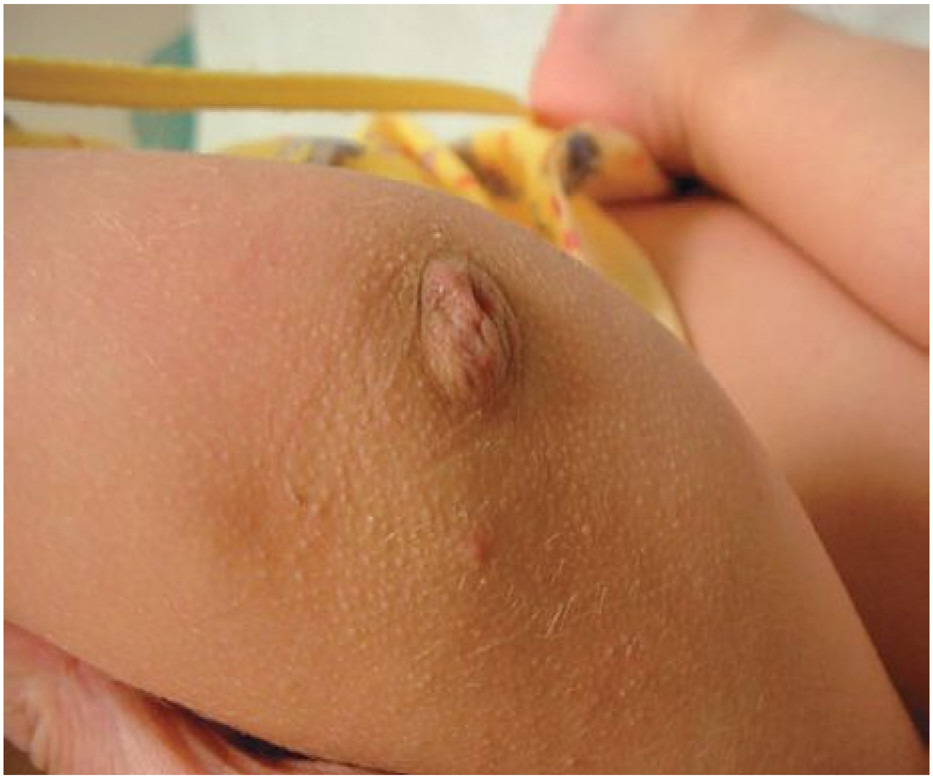

FIGURE 224-4 Small fleshy pseudotumor on the elbow of a girl with Ehlers-Danlos syndrome. These represent calcified herniations of fat through the dermis. (*Used with permission from Weinberg S, Prose NS, Kristal L: Color Atlas of Pediatric Dermatology, 4th edition: www.accesspediatrics.com. Figure 11-10. New York: McGraw-Hill, 2009.*)

  - Subcutaneous spheroids—Small, firm, cyst-like nodules along shins or forearms.
  - Muscle hypotonia, delayed gross motor development.
  - Easy bruising.
  - Complications of hypermobility (dislocations or sprains).
  - Manifestations of tissue extensibility and fragility (hiatal hernia, prolapsed pelvic organ, premature arthritis, and cervical insufficiency).[4]

- Hypermobility EDS.

  - Often presents with joint pain, joint dislocations, and inability to walk. Skin manifestations are less prominent.
  - Major criteria include generalized joint hypermobility and skin involvement (hyperextensibility and/or smooth velvety skin).
  - Minor criteria include recurring joint dislocations as well as chronic joint and limb pain.

- Vascular EDS.
  - Most severe form of EDS.[4,5]
  - Major criteria for diagnosis include:
    - Arterial, intestinal, or uterine fragility or rupture.
    - Easy bruising.
    - Thin, translucent skin.
    - Characteristic facial features (thin, delicate, and pinched nose, hollow cheeks, prominent staring eyes).
    - Occurs in <30 percent of patients and not prominent in children.

- Minor criteria:
  - Small joint hypermobility.
  - Gingival recession.
  - Spontaneous pneumothorax/hemothorax.
  - Tendon or muscle rupture.
  - Early-onset varicose veins.
  - Carotid-cavernous fistula.
  - Talipes equinovarus (clubfoot).
  - Acrogeria (**Figure 224-5**).

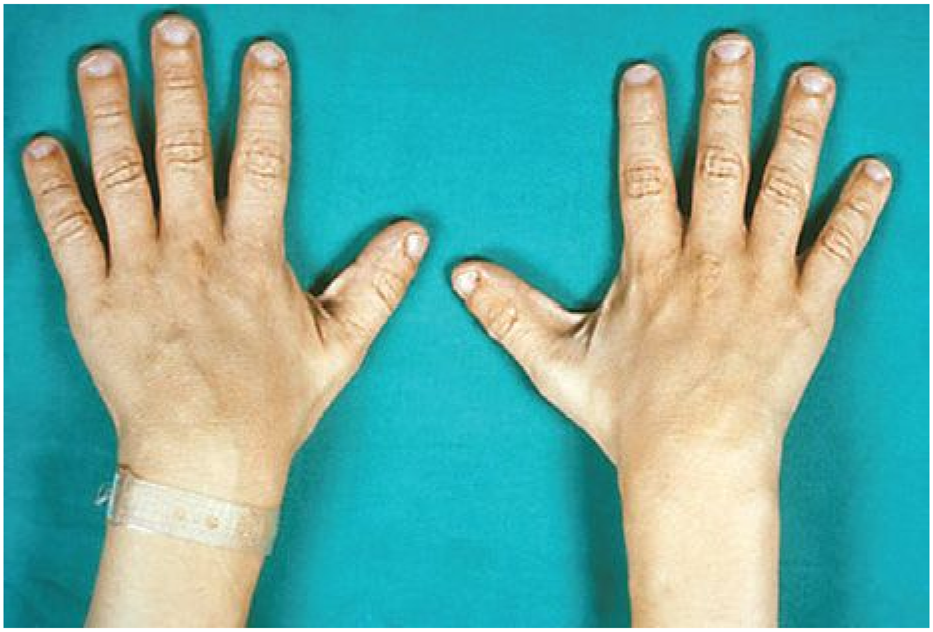

FIGURE 224-5 Acrogeria (fragile, thin, prematurely aging skin) in a child with the vascular form of Ehlers-Danlos syndrome. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- The vascular form of EDS is severe and it is important to identify patients early for management.[3,6–8]
- Kyphoscoliotic EDS.
  - Characterized by marked muscular hypotonia at birth, joint hypermobility, progressive scoliosis, and optic globe fragility.
  - Vascular involvement, such as mitral valve prolapse and aortic root dilatation, has been described.
- Arthrochalasia EDS.
  - Characterized by severe general joint hypermobility with recurrent subluxations, congenital hip dislocation, skin hyperextensibility, and tissue fragility, including atrophic scars.
- Dermatosparaxis EDS.
  - Characterized by severe skin fragility, sagging and redundant skin, easy bruising, and large hernias.

LABORATORY TESTING

- Genetic and biochemical testing for collagen type V abnormalities may be performed to aid in the diagnosis of classic EDS.
- There is currently no molecular test to diagnose hypermobility EDS.
- Biochemical and gene testing for known molecular defects of type III collagen from cultured fibroblasts and/or identification of mutations in COL3A1 can confirm the diagnosis of vascular EDS.

IMAGING

- Plain radiographs may reveal calcified nodules along the shin or forearms corresponding to the subcutaneous spheroids.
- Echocardiogram should be performed to identify mitral valve prolapse and aortic dilatation.

DIFFERENTIAL DIAGNOSIS

- Marfan syndrome may present with similar cardiovascular manifestations. Other manifestations of Marfan are usually present and can serve to differentiate from EDS (see Chapter 223, Marfan Syndrome).
- Osteogenesis imperfecta—May manifest with similar features, but blue sclerae and bone fractures of osteogenesis imperfecta help to differentiate (see Chapter 225, Osteogenesis Imperfecta).
- Autosomal dominant cutis laxa—Usually characterized by abnormalities limited to the skin, although visceral organs may also be involved rarely.
- Familial joint hypermobility—Can be difficult to differentiate from the hypermobility form of EDS. The diagnostic criteria from hypermobility type of EDS can help in differentiating these.

- Non-accidental trauma—Should always be considered when there is easy bruising in early childhood (see Chapter 8, Child Physical Abuse)

MANAGEMENT

- All patients should receive genetic counseling about the mode of inheritance of their EDS.
- Management of most skin and joint problems should be conservative and preventive. Joint hypermobility and pain in EDS usually does not require surgical intervention.
- For patients with vascular EDS:
    - Special surgical care is required because of increased tissue friability.
    - Patients should be advised to avoid contact sports especially if they have cardiac problems.
    - Elevated blood pressure should be aggressively treated with beta-blockers, given the risk of arterial dissection.
    - Women with vascular EDS should be counseled about the risk of uterine, intestinal, and arterial rupture. Pregnancy is associated with up to a 25 percent mortality rate; however, successful childbirth is possible.[4,5,9]

NONPHARMACOLOGIC

Physical therapy to strengthen muscles is helpful.

MEDICATIONS

- Beta-blocker therapy for patients with cardiac complications, especially aortic root dilatation, is often prescribed. SOR C

SURGERY

- Surgical intervention should be considered on an individual basis.
- The instability of joints, leading to subluxations and joint pain, often require surgical intervention in patients.
- Surgical repair and tightening of joint ligaments can be performed, but ligaments frequently will not hold sutures.
- Risk of complications in patients with EDS include decreased strength of the tissues, which makes the tissue less suitable for surgery; the fragility of the blood vessels, which can cause problems during surgery; and wound healing is often delayed or incomplete.
- Surgery requires careful tissue handling and a longer post-operative immobilization.
- Local anesthetics have less effect in EDS.
- Patients should generally be referred to specialized surgical centers who have experience with EDS. Wound healing and rupture of visceral organs during surgery is a concern.
- In the vascular form of EDS, arterial aneurysms are difficult to manage surgically as the vessels are often friable and not amenable to anastomosis.[3]

REFERRAL

- Referral to dermatology for skin biopsy to confirm the diagnosis of vascular EDS.
- Cardiology, orthopedic surgery, general surgery, and physical therapy as needed.

PROGNOSIS

- Prognosis varies according to type of EDS.

- Vascular EDS is associated with a 25 percent risk of significant complication by the age of 25 years; >80 percent will have a complication by the age of 40 years. Most vascular complications consist of arterial dissections. Vascular events typically occur between the third and fifth decade. Median age of survival is 48 years. Most deaths are related to arterial rupture.

FOLLOW-UP

Close multispecialty follow-up is often required. This may include orthopedic surgery, general surgery, dermatology, and physiotherapy as needed.

225 OSTEOGENESIS IMPERFECTA

Elumalai Appachi, MD, MRCP

PATIENT STORY

A newborn infant is being evaluated by the pediatrician in the hospital. On physical exam, the infant is noted to have blue sclerae and deformities in the legs (**Figure 225-1**). X-rays of the long bones of the legs reveal multiple fractures (**Figure 225-2**). Prenatal ultrasound screening in the second trimester showed bowing of long bones, fractures, and shortened limbs, suspicious for osteogenesis imperfecta (OI). The infant is treated with supportive care and a referral to genetics and orthopedics is made. The diagnosis of OI is formally established by identifying mutations in type 1 collagen.

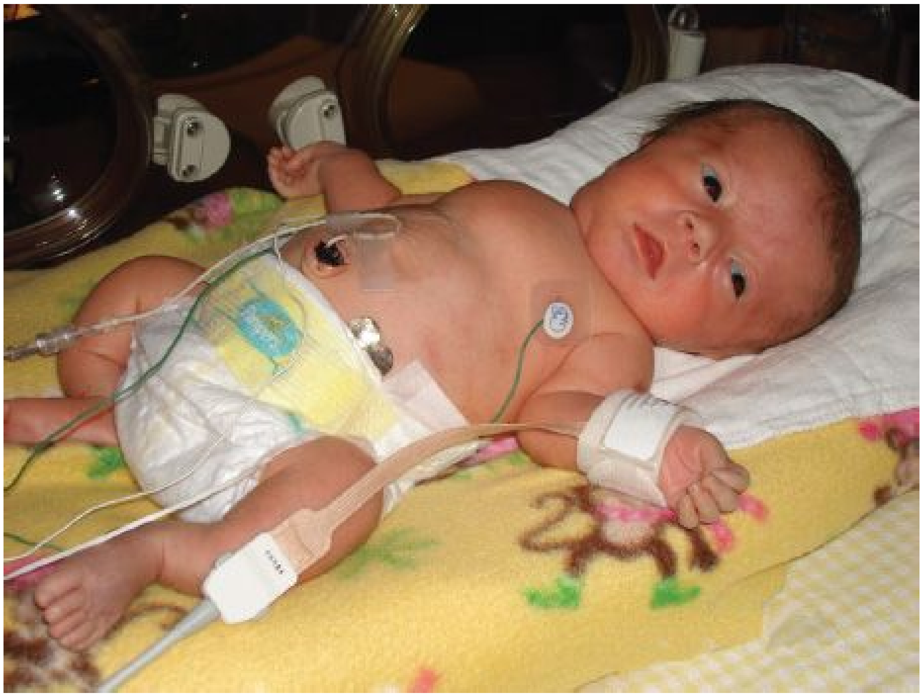

FIGURE 225-1 Blue sclerae and leg deformities in a 3-day-old infant with osteogenesis imperfecta. The diagnosis was suspected before birth based on bony abnormalities seen during prenatal ultrasound imaging. (*Used with permission from Betsy Tapani*.)

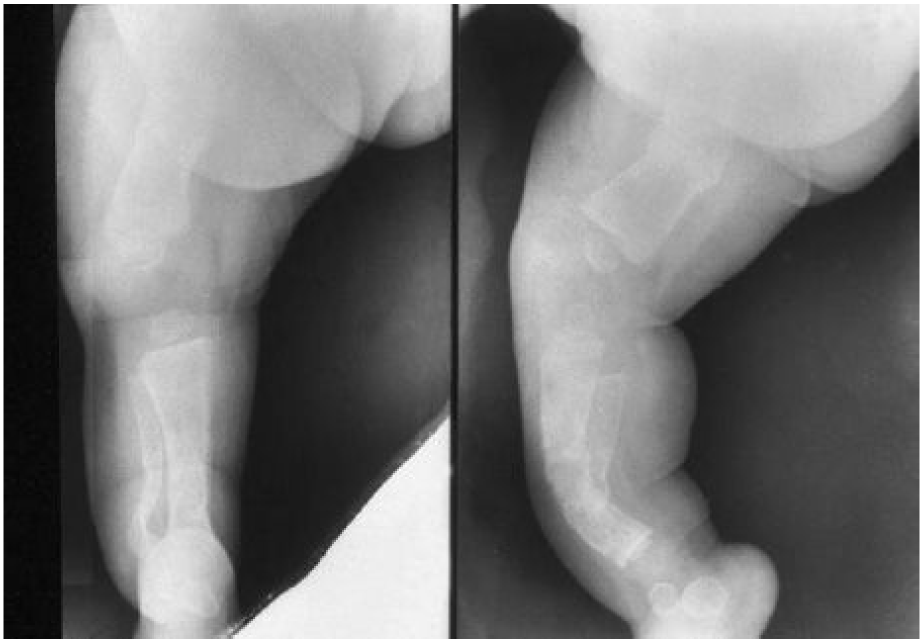

FIGURE 225-2 Multiple fractures present at birth in a newborn with osteogenesis imperfecta. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

INTRODUCTION

Osteogenesis imperfecta (OI) is a genetic disorder characterized by fragility of the skeletal system, and resulting in frequent fractures. The four major types of OI are caused by structural or quantitative defects in type 1 collagen, which is the primary component of the extracellular matrix of bone and skin protein.

SYNONYMS

Brittle bone disease (type 1 OI), Osteogenesis imperfecta congenita (type 3 OI).

EPIDEMIOLOGY

- Overall incidence of OI is 1 in 20,000 births. The number of individuals affected by OI in the US is estimated to be between 20,000 and 50,000.[1]
- Eight types of OI have been described and are classified according to clinical presentation, radiographic findings, mode of inheritance, and molecular findings.
- Types 1 through 4 of OI are the most common; types 5 to 8 are very rare.[2]
- Type 1 is the most common form and is inherited in an autosomal dominant pattern. Type 4 is also inherited in an autosomal dominant pattern. Type 2 and Type 3 are usually the result of new mutations.
- Type 2 is the most severe form; 50 percent of cases are stillborn.
- The autosomal dominant forms of OI (types 1 and 4) occur equally in all racial and ethnic groups, and recessive forms (types 2 and 3) occur predominantly in ethnic groups with consanguineous marriages.

ETIOLOGY AND PATHOPHYSIOLOGY

- OI types 1 through 4 are the result of mutations of genes that code for type I collagen, while types 5 to 8 are caused by mutations of other less-well characterized genes.
- Types 1 and 4 are inherited in an autosomal dominant pattern and are caused by mutations in COL1A1 and COL1A2 genes that code for the alpha-1 and alpha-2 chains of type 1 collagen.
- Collagen structural defects are predominantly of two types:

1. Eighty percent are point mutations causing substitutions of helical glycine residues or crucial residues in the C-propeptide by other amino acids.
2. Twenty percent are single exon splicing defects.

- The clinically mild OI type 1 has a quantitative defect, with null mutations in one a1(I) allele leading to a reduced amount of normal collagen.[3]
- Types 2 and 3 may be inherited in a recessive pattern and most cases are related to new point mutations of COL1A1 or COL1A2.
- The collagen structural mutations cause OI bone to be globally abnormal. The bone matrix contains abnormal type I collagen fibrils and relatively increased levels of types III and V collagen.

RISK FACTORS

- Affected parent for OI types 1 and 4.
- Consanguineous marriage for OI types 2 and 3.

DIAGNOSIS

- The diagnosis is made based on clinical grounds in most cases.
- Collagen and genetic testing are available to help to make the diagnosis in difficult cases.

CLINICAL FEATURES

- Fragile bones, blue sclerae, and early deafness are the hallmark features of OI (**Figure 225-1**).
- Common presenting features include bone fragility, repeated fractures with minimal trauma, and easy bruisability.

- Deafness may be a presenting feature of children with type 1 OI.
- Prenatal ultrasound screening in the second trimester may show bowing of long bones, fractures, shortened limbs, and other bone abnormalities.
- The majority of fractures occur during childhood.
- The blue sclerae is due to thinning of the sclera.
- Some patients have short stature and develop hearing loss later in life.
- Specific features are specific to the types of OI:
    - Osteogenesis Imperfecta Type 1 (Mild).
        - Major features include blue sclerae, recurrent fractures in childhood, easy bruising, joint laxity, and hearing loss (30 to 60%), which often develops in the 2nd or 3rd decade.
        - Fractures result from mild to moderate trauma, are uncommon at birth, and decrease after puberty.
        - Deformities of bones are uncommon.
        - Short stature, compared with family members, may or may not be present.
        - Differentiation from nonaccidental trauma can be challenging.
    - Osteogenesis Imperfecta Type 2 (Perinatal Lethal).
        - Most severe form of OI.
        - Lethal in utero or in the majority of newborns because of respiratory insufficiency.
        - Extreme fragility of the skeleton and other connective tissues.
        - Multiple intrauterine fractures of long bones are evident, which have a crumpled appearance on radiographs.
        - Limbs are short and bowed, and legs are held abducted at right angles to the body creating a frog-leg position.
        - Multiple rib fractures create a beaded appearance and the small thorax contributes to respiratory insufficiency.
        - A large, soft skull and open fontanelles are common.
    - Osteogenesis Imperfecta Type 3 (Severe, Progressive Deforming).
        - Nonlethal form but patients have severe physical disability.
        - Usually presents in the newborn period with multiple fractures.
        - Infants have low birth weight and in utero fractures are common.

- There is relative macrocephaly, triangular facies and blue sclera (**Figure 225-3**).

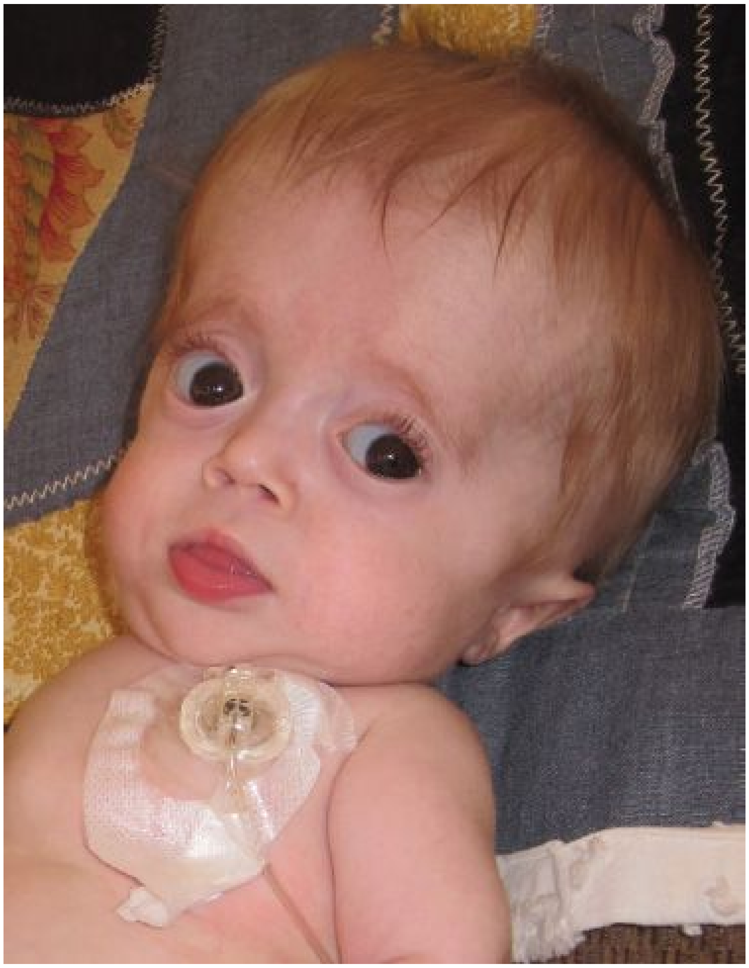

FIGURE 225-3 Blue sclerae, macrocephaly, and triangular facies in a 10-month-old infant with osteogenesis imperfecta type 3. (*Used with permission from Betsy Tapani*.)

- Postnatally, fractures occur from inconsequential trauma and heal with deformity.
- Disorganization of the bone matrix results in a “popcorn” appearance at the metaphyses.
- The rib cage has flaring at the base and pectal deformity is frequent.
- Almost all patients have scoliosis and vertebral compression.
- Pulmonary function can be affected due to associated scoliosis.
- Extreme short stature is common (**Figure 225-4**).

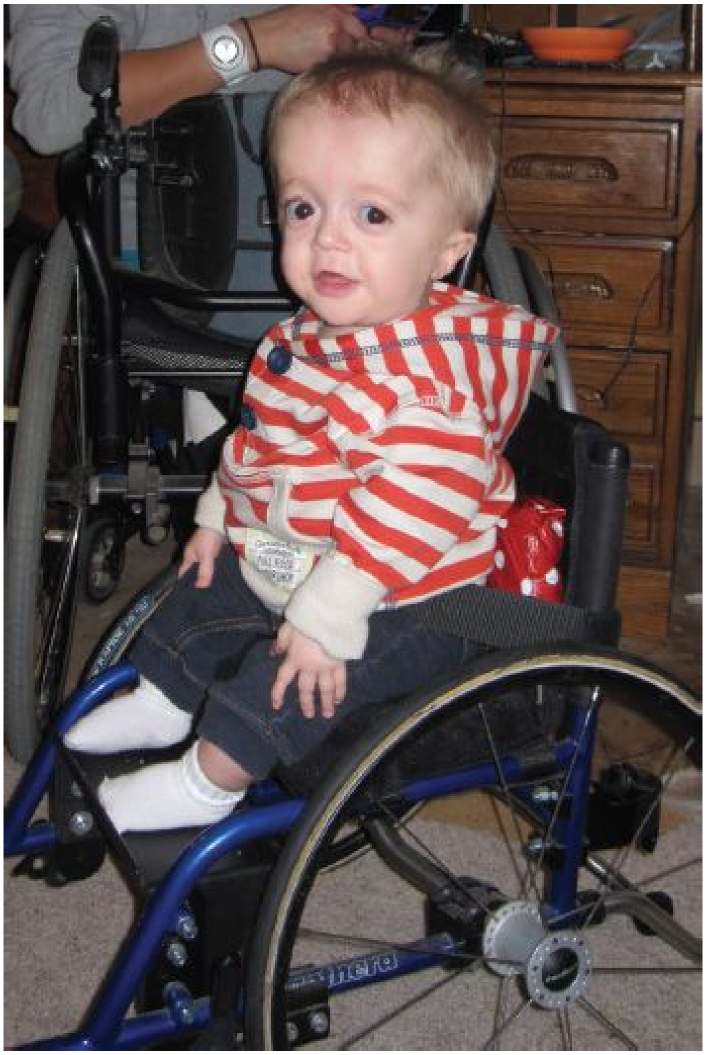

FIGURE 225-4 Happy 2-year-old boy with osteogenesis imperfecta type 3. His measured height is well below the normal for his age. He successfully uses a wheelchair for mobility. He is greatly loved by his family. (*Used with permission from Betsy Tapani*.)

- Osteogenesis Imperfecta Type 4 (Mild to Moderately Severe).
  - Marked variability in clinical findings.
  - In utero fractures can occur.
  - Bowing of the tibia is the hallmark of this type of OI and can occur even without fractures.
  - Children require orthopedic and rehabilitation intervention, but they are usually able to attain community ambulation skills.

    - Fracture rates decrease after puberty. X-ray findings show osteoporotic and have metaphyseal flaring and vertebral compressions.
    - Short stature is common, like in other types of OI.
  - Osteogenesis Imperfecta Type 5 (Hyperplastic Callus) and Type 6 (Mineralization Defect).
    - These types of OI are similar clinically to type 4, but they have distinct findings on bone histology.
    - Type 5 patients also have hyperplastic callus, calcification of the interosseous membrane of the forearm, and a radiodense metaphyseal band.
    - The absence of a collagen defect supports the distinct grouping; the genetic etiology is unknown.
  - Osteogenesis Imperfecta Types 7 and 8 (Recessive Forms).
    - Caused by null mutations in proteins involved in posttranslational modifications of type I procollagen.
    - Clinically overlap types 2 and 3, but have distinct features including white sclerae, rhizomelia, and small to normal head circumference. Rhizomelia is a disproportion in the length of the most proximal segment of the limbs (upper arms and thighs).
    - Surviving children have severe osteochondrodysplasia with extreme short stature.

LABORATORY TESTING

- Collagen synthesis and DNA analyses can be obtained to identify mutations.

IMAGING

- Routine radiologic testing is done to identify fractures and bony deformities (**Figures 225-2** and **225-5**).

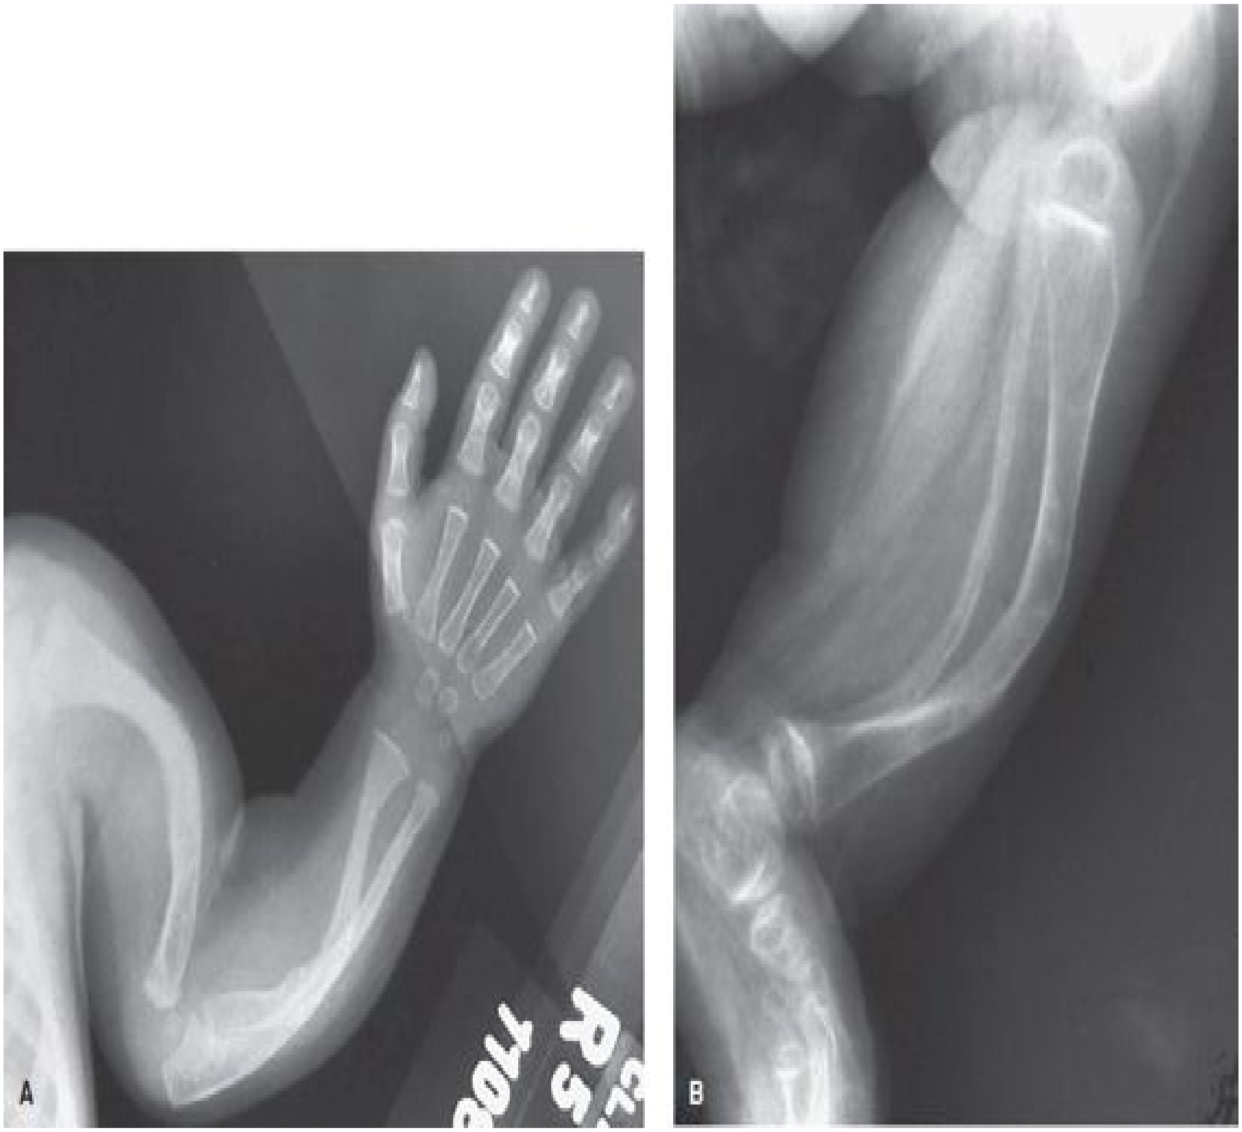

FIGURE 225-5 Severe deformities and multiple fractures of the long bones in a child with osteogenesis imperfecta before the advent of bisphosphonate therapy. **A**. Arms. **B**. Legs. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Dual energy x-ray absorptiometry may offer more evidence for OI.

DIFFERENTIAL DIAGNOSIS

- Child Abuse—Nonaccidental trauma can be challenging to distinguish from OI. Examination of psychosocial factors, along with other evidence of nonaccidental trauma (retinal hemorrhage, intracranial hemorrhage) can help in distinguishing these entities from child abuse (see Chapter 8, Child Physical Abuse).
- Rickets—Can cause similar bone fractures. Rickets can be distinguished from OI based on history, characteristic investigations (elevated alkaline phosphatase and parathyroid hormone levels). Typical radiologic features are also helpful in distinguishing these entities (see Chapter 198, Rickets).
- Osteoporosis—Very rare in children.

MANAGEMENT

- There is no cure for OI, although gene therapy is under investigation.
- Management is directed toward improving joint mobility and muscle strength.

NONPHARMACOLOGIC

- Physical therapy, directed toward improvement of joint mobility and muscle strength development is critical (**Figure 225-6**).

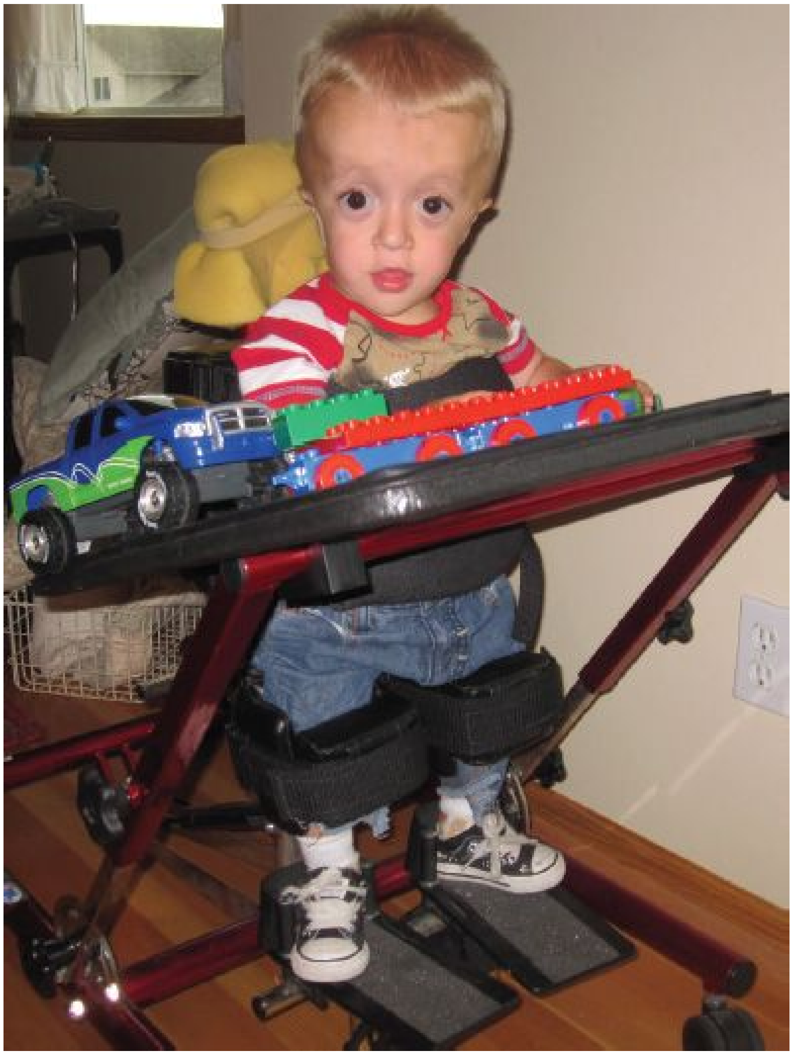

FIGURE 225-6 A 3-year-8-month-old boy with osteogenesis imperfecta is using a special device as part of his home physical therapy to improve his motor function and balance. (*Used with permission from Betsy Tapani*.)

- Occupational therapy should aim to improve function in daily living, social integration, and educational achievement.
- Caution should be taken with physical and occupational therapy to avoid causing fractures in more severe forms. Risks may outweigh potential benefits in some cases.
- Treatment may be required, as necessary and appropriate, for hearing loss and for neurological, and cardiorespiratory complications.

MEDICATIONS

- Bisphosphonates are used in OI type 3 and in more severe presentations of other forms, to reduce the incidence of fractures and improve bone quality.[4]
- Intravenous and oral forms of bisphosphonates have been shown to result in improvement in clinical symptoms (less pain), increased mobility, and reduction in fracture frequency in children with OI.[5–7]
- The use of pamidronate (a bisphosphonate) can lead to metaphyseal bands, known as "zebra lines." These lines are not problematic but produce an interesting pattern on radiographs (**Figure 225-7**).

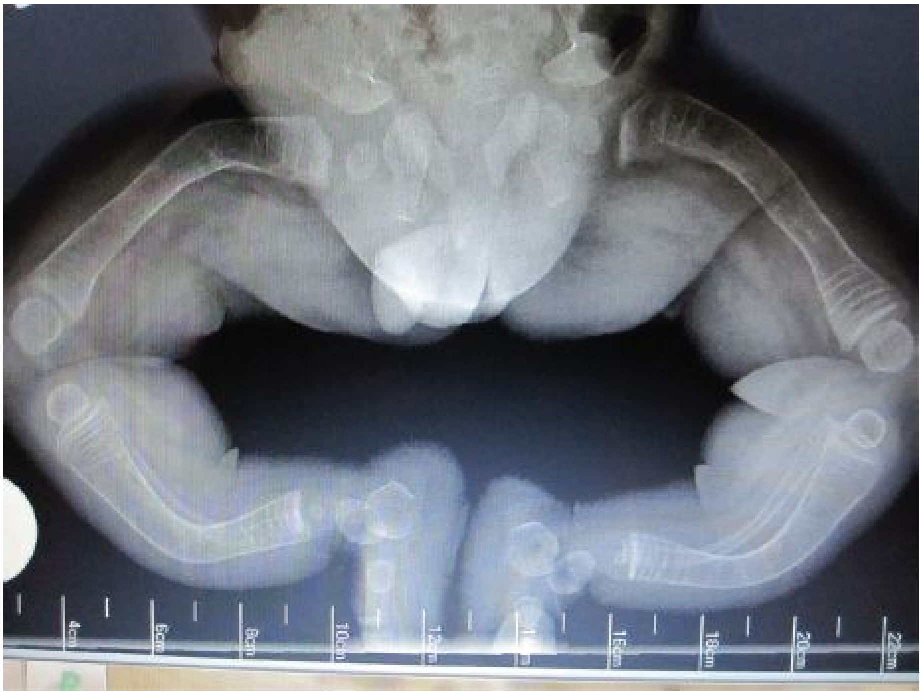

FIGURE 225-7 Leg bowing and metaphyseal bands in an 8-month-old child with osteogenesis imperfecta undergoing pamidronate therapy to prevent fragility fractures. This child received many cycles of pamidronate, resulting in metaphyseal bands, known as "zebra lines." (*Used with permission from Betsy Tapani*.)

- A Cochrane review concluded that oral or intravenous bisphosphonates equally increase bone mineral density in children with OI; it is unclear whether either treatment decreases fractures.[8]

- Gene therapy and bone marrow transplantation are under investigation.[9]

SURGERY

- Surgical procedure that involves internally splinting the long bones by insertion of a metal rod is recommended to control repeated fractures and to improve bone deformities that interfere with function (**Figure 225-8**).

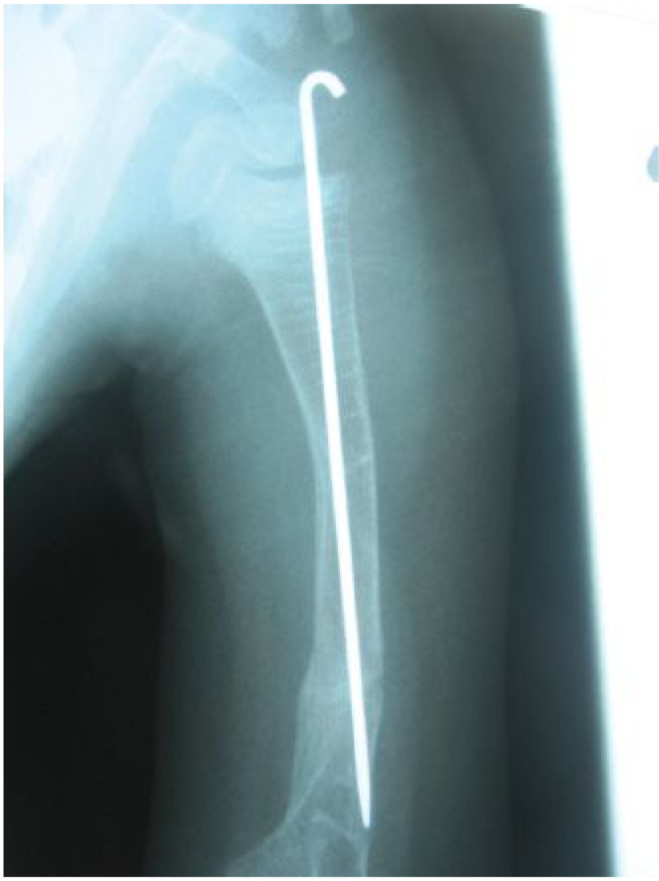

FIGURE 225-8 A metal rod has been inserted into the humerus of a 2-year-old boy with osteogenesis imperfecta to control repeated fractures and to improve bone deformities that interfere with function. (*Used with permission from Betsy Tapani*.)

- Posterior spinal fusion—for severe scoliosis may be required.
- Limb lengthening procedures and correction of angular deformities may be required.[7,10,11]

REFERRAL

- Genetics referral may be required if the diagnosis is in doubt, to better classify the type of OI, and for genetic counseling.
- Orthopedic, pulmonary, and neurology referrals may be needed depending on the clinical spectrum of involvement and the severity of the findings.
- Audiology referral is important for patients with hearing deficits and for monitoring and screening.

PREVENTION AND SCREENING

- Genetic counseling is indicated for families with OI.
- Chorionic villous sampling may be analyzed for abnormal collagen or collagen mutations.

PROGNOSIS

- The prognosis for an individual with OI varies greatly, depending upon the type of OI and severity of symptoms. In general, the prognosis improves if the child survives beyond age 10 years.
- Type 1—Life expectancy similar to that of the general population.
- Type 2—Poor prognosis.
- Type 3—Life expectancy is reduced significantly as a result of concurrent problems such as respiratory infection and skull fractures.

FOLLOW-UP

- Audiological follow-up is important for children with OI.

- Orthopedic follow-up is indicated for most patients with OI.

ACKNOWLEDGEMENT

We greatly thank Betsy Tapani for the photographs and radiographs of her son with osteogenesis imperfecta (**Figures 225-1**, **225-3**, **225-4**, **225-6** to **225-8**). One can learn more about their family story at http://www.oif.org/site/PageServer?pagename=meetbrennan.

The Osteogenesis Imperfecta Foundation has been of great help to Betsy and her family and she is committed to giving to those parents who face similar challenges.

226 NOONAN SYNDROME

Elumalai Appachi, MD, MRCP

PATIENT STORY

A 3-year-old boy is brought to see his pediatrician for a health maintenance visit. During the exam, the pediatrician notes that the child's face lacks expression, has a short neck with excessive skin, a low hairline, low set ears, and a short broad nose (**Figure 226-1**). The child is appropriate for weight but his height is well below the third percentile. An audible systolic ejection murmur is heard. The pediatrician refers the child to a pediatric cardiologist who makes the diagnosis of pulmonic stenosis from physical exam and echocardiogram. Based on these findings, the pediatrician and cardiologist make a clinical diagnosis of Noonan syndrome, which is confirmed by genetic testing. A multidisciplinary approach to the child's care is planned.

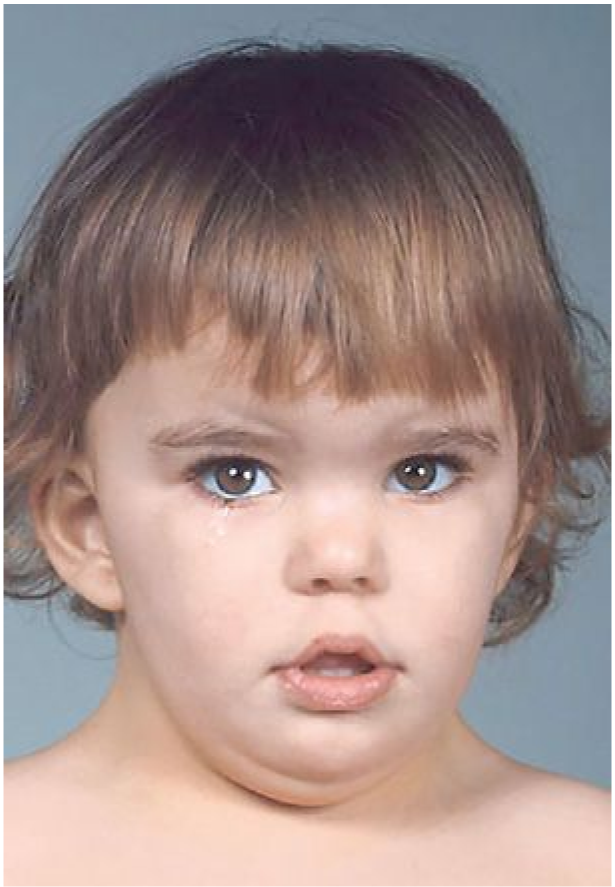

FIGURE 226-1 Distinctive facial features, including a short neck with excessive skin, a low hairline, low set ears, and a short broad nose, in a boy with Noonan syndrome. This child also has hypertelorism (widely spaced eyes). The lack of facial expression resembling a myopathy has also been described in these patients. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

INTRODUCTION

Noonan syndrome is an autosomal dominant, variably expressed, multisystem disorder characterized by distinctive facial features, developmental delay, learning difficulties, short stature, congenital heart disease, renal anomalies, lymphatic malformations, and bleeding difficulties. Mutations that cause Noonan syndrome alter genes encoding proteins with roles in the RAS–MAPK pathway, leading to pathway dysregulation.

SYNONYMS

Male Turner syndrome.

EPIDEMIOLOGY

- First described by Jacqueline Noonan, who reported nine patients with pulmonary stenosis, short stature, chest deformities, and mild developmental delay.[1,2]
- Estimated prevalence is 1 in 1000 to 2500.[2]
- Although this syndrome was first described in males who had the Turner syndrome phenotype, it is now recognized in females as well.
- Autosomal dominant condition with complete penetrance but variable expressivity.
- Congenital heart disease present in 80 to 90 percent of patients.
- After trisomy 21, Noonan syndrome is the second most common syndromic cause of congenital heart disease.

ETIOLOGY AND PATHOPHYSIOLOGY

- Autosomal dominant inheritance.
- Eight genes in the RAS–MAPK signaling pathway cause Noonan syndrome or closely related conditions (*PTPN11*, *SOS1*, *KRAS*, *NRAS*, *RAF1*, *BRAF*, *SHOC2*, and *CBL*).

- The RAS–MAPK pathway is a well-studied, widely important signal transduction pathway through which extracellular ligands—such as some growth factors, cytokines, and hormones—stimulate cell proliferation, differentiation, survival, and metabolism.
- Noonan syndrome has been linked to the chromosomal band 12q24.1 and *PTPN11*, which encodes the protein SHP2. Because SHP2 has essential roles in signal transduction pathways that control several developmental processes, including cardiac semilunar valvulogenesis, *PTPN11* was deemed an excellent candidate gene.
- Studies suggest that 50 percent of cases of Noonan syndrome are caused by missense, gain of-function mutations in *PTPN11*.[3,4]

RISK FACTORS

- Autosomal dominant and the risk for having an affected child is 50 percent.

DIAGNOSIS

Diagnosis is made from the key clinical features and genetic testing.

CLINICAL FEATURES

- Facial features, especially early in life, most often lead to the clinical diagnosis of Noonan syndrome. Wide-spaced and prominent eyes, epicanthal folds, ptosis, and down-slanting palpebral fissures are common. Other features include hypertelorism (widely spaced eyes), low set posteriorly rotated ears, distinctive upper lip, short neck with excessive skin, and low posterior hairline (**Figure 226-1**).[2]

- During adolescence, the face shape becomes an inverted triangle, wide at the forehead and tapered to a pointed chin. The eyes become less prominent, the neck is longer, and there is accentuation of skin webbing or prominence of the trapezius muscle (**Figures 226-2** and **226-3**).

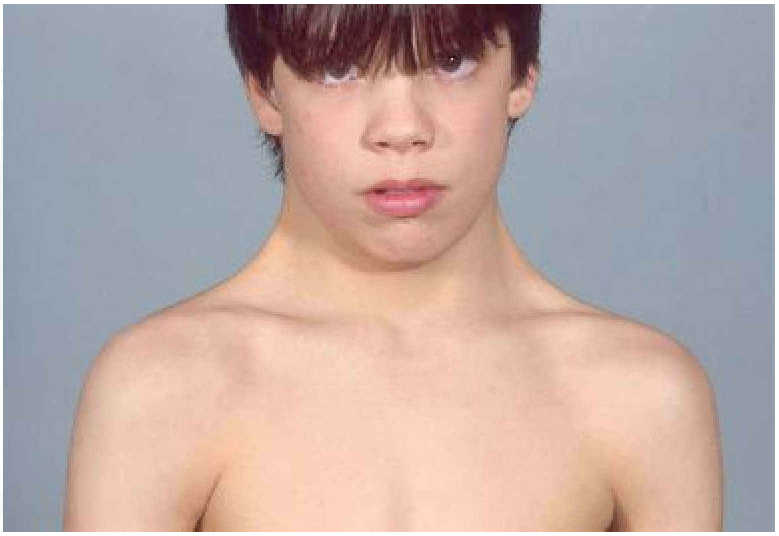

FIGURE 226-2 Hypertelorism, pointed chin, accentuation of skin webbing in the neck and prominence of the trapezius muscle in an adolescent boy with Noonan syndrome. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

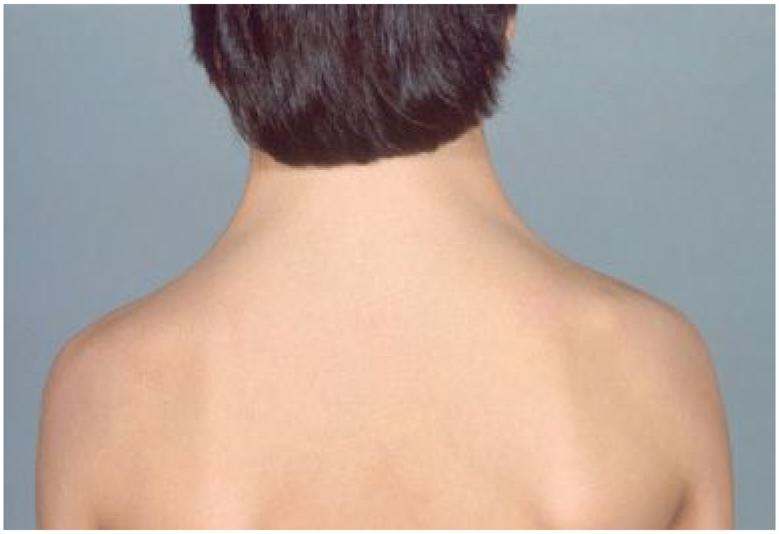

FIGURE 226-3 Prominence of the trapezius muscle and webbed neck in the same boy as in Figure 226-2. (*Used with permission from Cleveland Clinic Children's Hospital Photo Files*.)

- Multiple cardiovascular conditions occur in Noonan syndrome. The most common are pulmonary stenosis (often with dysplastic valves; 50 to 60%), hypertrophic cardiomyopathy (20%), and secundum atrial septal defect (6 to 10%).[5,6,7]
- Short stature is present in 50 to 75 percent of patients, who may have growth hormone deficiency, neurosecretory dysfunction, and growth hormone resistance. Mean age at puberty is delayed compared to general population.[8]
- Most infants with Noonan syndrome have feeding difficulties that can lead to failure to thrive. Poor suck, prolonged feeding time, or recurrent vomiting have been reported and about 25 percent of infants need to be fed by tube for 2 weeks or longer. Gastroesophageal reflux is also common.[6,8]
- Up to 80 percent of boys diagnosed with Noonan syndrome have unilateral or bilateral cryptorchidism. Male gonadal dysfunction has been reported and is suggested to be caused by primary Sertoli cell dysfunction rather than cryptorchidism.
- An estimated 30 percent of children have a spinal deformity with surgical correction recommended in two thirds of cases. Chest deformity (superior pectus carinatum and inferior pectus excavatum), widely spaced nipples, cubitus valgus, and genu valgum have also been reported.
- Though several hematological abnormalities, including transient monocytosis, thrombocytopenia, and myeloproliferative disorders, have been seen, the most common hematologic disorders are abnormalities of bleeding caused by coagulation defects. Hematological cancers, including juvenile myelomonocytic leukemia, acute myelogenous leukemia, and B-cell acute lymphoblastic leukemia have been reported.
- Lymphatic abnormalities, most commonly peripheral lymphedema, are present in less than 20 percent of individuals but can cause substantial morbidity. Peripheral lymphedema can occur in infants and resolves in the first few years of life or it can develop in adolescence or adulthood.
- In most affected individuals, intelligence is within the normal range, with intelligence quotient generally varying between 70 and 120.

- Roughly 10 percent of affected individuals have auditory deficits in the low frequency range caused by sensorineural hearing loss and 25 percent have deficits in the high frequency range. Inner ear structural abnormalities, including temporal bone abnormalities, have been reported.
- Language impairments are more common in patients with the disease than in the general population and, when present, are associated with a high risk of reading and spelling difficulties.
- Up to 95 percent of affected individuals will have at least one characteristic eye finding including strabismus, refractive errors, amblyopia, or nystagmus. 2/3 of patients develop anterior chamber abnormalities including cataracts. Fundal changes, including optic head drusen, optic disk hypoplasia, colobomas, and myelinated nerves, occur in 20 percent of patients.
- Abnormal pigmentation can occur, including multiple pigmented nevi, café-au-lait spots, and lentigines. Keratosis pilaris of the upper arms and face is common and can impede hair and eyebrow growth. Hair is often thick and curly, although thin, sparse hair has also been reported.

LABORATORY TESTING

- Genetic testing is widely available and chip-based sequencing, which enables the simultaneous assessment of all genes related to diseases caused by changes in RAS, has reduced the cost compared with individual sequencing of each gene. Positive genetic testing can confirm the diagnosis but negative testing cannot exclude the diagnosis.
- Screening CBC with differential and prothrombin time/activated partial thromboplastin should be obtained at the time of diagnosis and after 6 to 12 months of age if the initial screen was performed in infancy.

IMAGING

- Echocardiogram and electrocardiogram should be obtained at the time of diagnosis.

- Renal ultrasound should be obtained on all patients at the time of diagnosis.

DIFFERENTIAL DIAGNOSIS

- Leopard Syndrome—Autosomal dominant disorder with lentigines, electrocardiogram abnormalities, hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, and deafness. Many affected individuals have hypertrophic cardiomyopathy. Is mainly caused by PTPN11 missense mutations and, less often, by RAF1 mutations.
- Cardiofaciocutaneous syndrome—Presents with multiple congenital anomalies and intellectual disability, failure to thrive and short stature, congenital heart defects, and a characteristic facial appearance. Patients have a rounder, more bulbous nasal tip, wider nasal base, fuller lips, and coarser facial features. They also often have follicular hyperkeratosis, sparse eyebrows and lashes, and ichthyosis (see Chapter 171, Ichthyosis). They also develop moderate intellectual disability.[9] Molecular gene testing will distinguish this from Noonan syndrome.
- Costello Syndrome—Infants with high birthweight and delayed growth, developmental delay, coarse facial features, wide nasal bridge, loose and soft skin, increased pigmentation over time, deep palmar and plantar creases, facial or perianal papillomata, premature ageing and hair loss, moderate intellectual disability, flexion or ulnar deviation of the wrist and fingers, and cardiac abnormalities (most commonly pulmonic stenosis and hypertrophic cardiomyopathy).
- Turner syndrome—Only girls are affected and chromosomal analysis helps in the diagnosis. Patients typically have left-sided heart lesions (compared with right-sided lesions in Noonan syndrome), have no or arrested pubertal development, and have gonadal dysgenesis.[10]
- Aarskog syndrome—X-linked disorder, which can cause similar phenotypic features as Noonan syndrome, but caused by FGD1 mutations. These patients do not have congenital heart disease and

affected boys have a shawl scrotum (scrotum surrounds the penis like a shawl).

MANAGEMENT

- Multidisciplinary approach with many subspecialists involved in the care of these patients is essential.

NONPHARMACOLOGIC

- Developmental screening yearly.
- Cardiac evaluation by a cardiologist at the time of diagnosis, including an electrocardiogram and echocardiogram.
- Neuropsychological testing.
- Growth should be monitored closely. Children with growth failure and delayed puberty should be referred to a pediatric endocrinologist.
- Routine ophthalmological and auditory evaluations.
- Blood work including coagulation studies every 6 to 12 months and prior to surgical procedures.
- Spine exams yearly.

MEDICATIONS

- Therapeutic interventions for growth failure includes growth hormone therapy.[11] SOR Ⓒ
- Thyroid hormone replacement should be provided for hypothyroidism.
- Estrogen or testosterone therapy should be provided for pubertal delay.

SURGERY

- Orchiopexy by age 1 year for persistent cryptorchidism.
- Cardiac surgery for congenital heart defects when needed.

REFERRAL

- Genetics consultation and follow-up.
- Cardiac evaluation by a cardiologist.
- Children with evidence of delayed puberty (no breast development in girls by the age of 13 years or no testicular enlargement in boys by 14 years of age) should be referred to a pediatric endocrinologist.
- Pediatric gastroenterology/nutrition consultation for feeding difficulties/recurrent vomiting.
- Pediatric Surgery and preoperative evaluation of bleeding risk; hematology consultation as needed for management of bleeding risk.

PREVENTION AND SCREENING

- Prenatal screening is done when prenatal ultrasound shows features suggestive of Noonan syndrome.[12]

PROGNOSIS

- Prognosis depends on the severity of the cardiac lesions.

FOLLOW-UP

- Regular detailed follow-up with a multidisciplinary approach is often needed to address the medical and developmental complications of Noonan syndrome.

227 PHACE SYNDROME

Carla Torres-Zegarra, MD
Joan Tamburro, DO
Allison Vidimos, MD

PATIENT STORY

A 2.5-year-old girl who was diagnosed with PHACE syndrome at 5 months of age is brought to her dermatologist for a routine follow-up visit. She had presented with multiple hemangiomas on her face, chest, and right arm, microphthalmia, corneal hazing, and a sternal pit. The dermatologist recognized the associated findings as concerning for PHACE syndrome. Work-up at that time revealed moderate to severe dysgenesis of the anterior segment of her right eye and elevated intraocular pressure. An MRI/MRA of her brain showed hypoplasia of the right cerebellum and multiple arterial anomalies (**Figures 227-1** and **227-2**). The facial hemangiomas were treated locally with sequential laser treatments and eventually required removal of a hypertrophic scar on her upper lip. She is doing well clinically. She continues to have residual hemangiomas on her face and arm, microphthalmia, and a sternal pit (**Figures 227-3** and **227-4**).

INTRODUCTION

Hemangiomas are the most common benign tumor in infancy. Associations between infantile hemangiomas with anomalies in the brain, cerebral vasculature, cardiovascular system, eyes, and chest wall have led to the designation of PHACE syndrome, which is defined by the presence of a large, segmental hemangioma, more commonly found on the face or head, associated with one or more congenital malformations, most commonly structural or cerebrovascular anomalies of the brain and cardiovascular system. In 1996, Frieden proposed an acronym for this syndrome as shown in the following:[1]

P—Posterior fossa malformations, that is, Dandy Walker malformation (**Figure 227-1**).
H—Hemangiomas, usually large, segmental, “plaque-like” lesions (**Figure 227-5**).

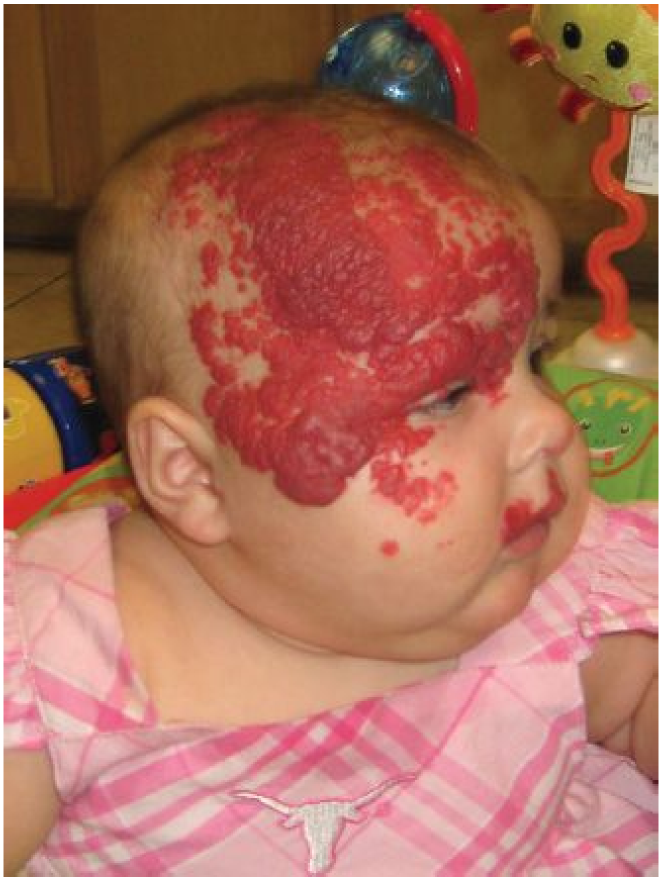

FIGURE 227-5 Large segmental hemangioma on the face of a 5-month-old girl with PHACE syndrome before onset of propranolol therapy. (*Used with permission from AngelPHACE.com*.)

A—Arterial anomalies (**Figure 227-2**).
C—Cardiac anomalies and coarctation of the aorta.
E—Eye abnormalities, that is, microphthalmos (**Figure 227-3**), exophthalmos, colobomas, retinal vascular abnormalities, optic nerve

atrophy, iris hypertrophy, or hypoplasia. A coloboma is a hole in one of the structures of the eye that can cause blindness (**Figure 227-6**).

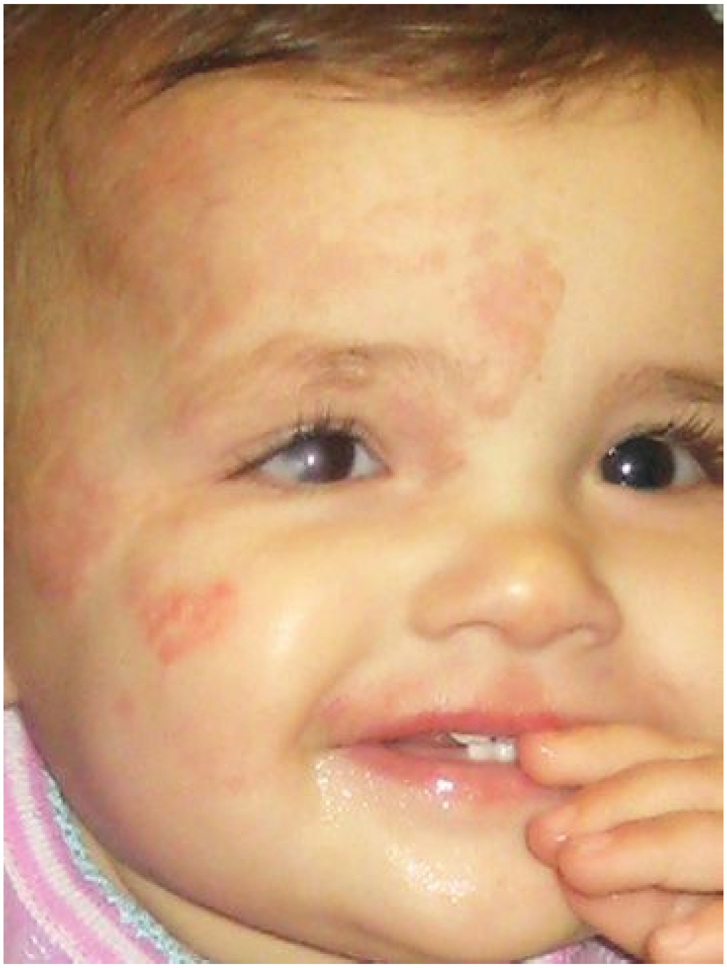

FIGURE 227-6 This infant girl from **Figure 227-5** has a coloboma (hole) of the cornea of the right eye. While she can detect some light she does not have useful vision in that eye. (*Used with permission from AngelPHACE.com*.)

Ventral anomalies, such as sternal cleft or pits and supraumbilical raphe may also be associated (**Figure 227-4**).

SYNONYMS

PHACES syndrome, PHACES association, Pascual Castroviejo type II syndrome, Sternal malformation/vascular dysplasia association, Cutaneous hemangioma: vascular anomaly complex.

EPIDEMIOLOGY

- There is significant female predominance in PHACE syndrome, with 80 percent of affected children being females.
- Seventy percent of cases only have one extracutaneous manifestation.
- Although uncommon, incidence probably exceeds that of Sturge Weber syndrome (SWS).[2]
- PHACE syndrome is probably still under-recognized since it rarely presents with all associated features.
- Most affected infants are born at term with normal birth weight, which is in contrast to infants with non-PHACE associated infantile hemangiomas, who have a greater incidence of prematurity and low birth weight.[3]

ETIOLOGY AND PATHOPHYSIOLOGY

- The precise pathogenesis of PHACE syndrome is unknown.
- Female predominance was thought to be due to an X-linked dominant condition, which is lethal in males, but this has recently been questioned.[4]
- The structural anomalies found in association with PHACE syndrome suggests that the timing of these errors in morphogenesis occurs early, probably between 6 to 8 weeks of gestation, prior to or during vasculogenesis.
- Both HOX and Eph genes have been linked to capillary, sternal, ocular, neural, and thyroid development and may have an important role in PHACE syndrome.

- The long-term outcome is unclear, mostly due to under diagnosis and lack of data.
- In patients with PHACE syndrome, there is an increase risk of stroke during the 1st year of life due to progressive vasculopathy.

RISK FACTORS

- Size and distribution of the facial hemangiomas appear to play an important role in the development of PHACE syndrome.
- Segmental infantile hemangiomas are more likely to be associated extracutaneous manifestations than localized infantile hemangiomas.[2,5]
- One study found that 2.3 percent of infants with a facial hemangioma developed at least one extracutaneous feature of PHACE, while 20 percent of those with segmental facial hemangiomas developed one or more PHACE anomalies.[2]

DIAGNOSIS

CLINICAL FEATURES

- The hallmark of PHACE syndrome is a large, segmental hemangioma, which is usually on the face or head (**Figure 227-5**). The hemangioma is likely to enlarge during the first year of life (**Figure 227-7**).

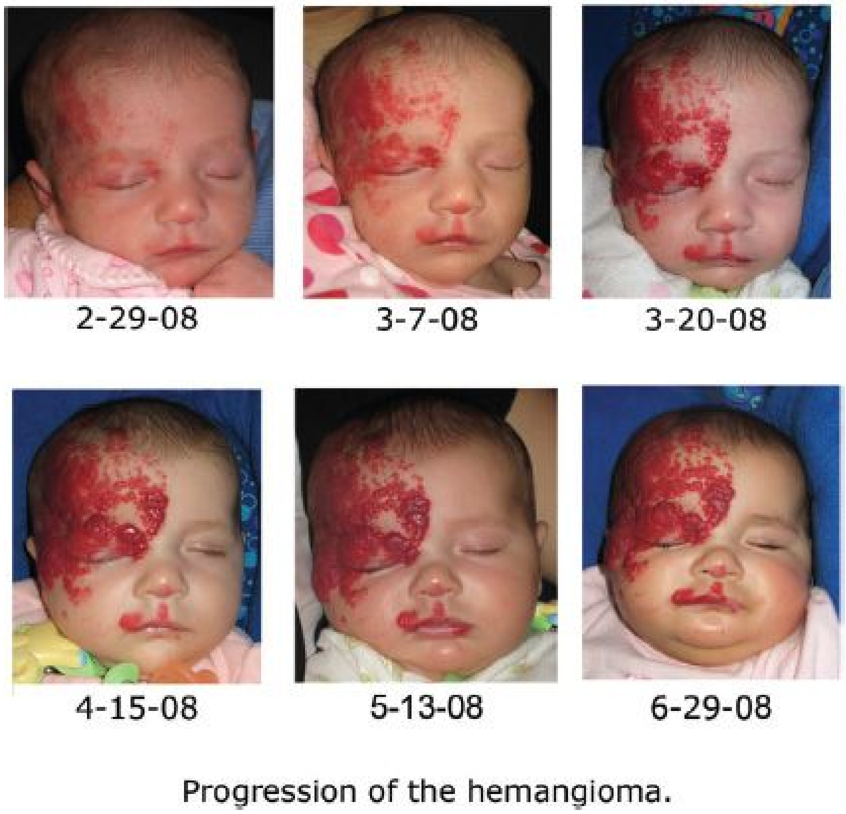

FIGURE 227-7 Progression of a large segmental hemangioma in an infant with PHACE syndrome. (*Used with permission from AngelPHACE.com*.)

- Awareness of this entity and early recognition is crucial.
- The diagnosis should be considered when large “plaque-like” segmental hemangiomas are present.
- There is a wide spectrum of features associated with PHACE syndrome which include:[1,6]
  - Large facial hemangiomas (**Figure 227-5**).
  - Posterior fossa malformations including Dandy Walker malformations (**Figure 227-1**).
  - Arterial anomalies (**Figure 227-2**).
  - Cardiac or aortic malformations.
  - Unusual ophthalmologic abnormalities (**Figures 227-3** and **227-6**).
  - Ventral defects such as sternal clefting, supraumbilical raphe, and sternal pits (**Figure 227-4**).

- Cerebral vascular malformations are the most common extracutaneous manifestations of PHACE syndrome; predominant involvement of the arterial system is unique and serves to distinguish this from other neurocutaneous syndromes.
- Most infants have a normal neurologic exam; thus screening for abnormalities should not be based on the presence of neurologic findings.
- Coarctation of the aorta is the most important cardiac finding in these patients.
- Commonly reported ophthalmologic anomalies include microphthalmia, optic nerve hypoplasia, persistent fetal vasculature, and morning glory disc abnormalities.
- Although sternal clefting and/or supraumbilical abdominal raphe are most commonly reported ventral developmental defects, subtle features such as sternal pits, dimples, and papules can be seen.

IMAGING

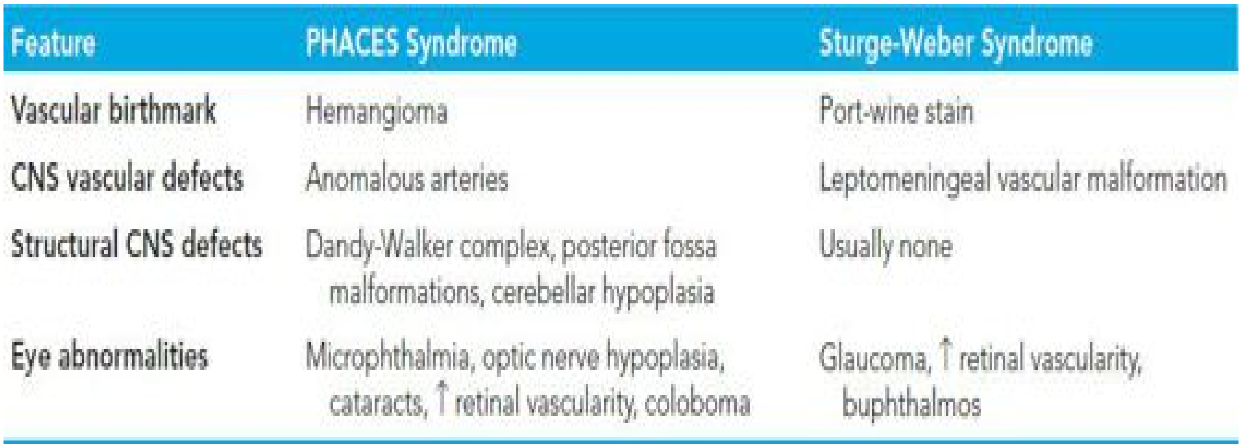
- A variety of imaging studies are used for the evaluation of PHACE syndrome, including:
    - Magnetic resonance imaging and magnetic resonance angiography of the brain to evaluate for posterior fossa and arterial malformations.
    - Echocardiogram to evaluate cardiac anomalies.
    - Ultrasound and/or computed tomography to delineate internal organ involvement where indicated.

DIFFERENTIAL DIAGNOSIS

- Early in the course the hemangioma may be mistaken for a port-wine stain, concerning for SWS. However, a port-wine stain does not proliferate or regress like hemangiomas do (see Chapter 93, Childhood Hemangiomas and Vascular Malformations).

- Differences between PHACE syndrome and SWS are listed in the **Table 227-1** (see Chapter 207, Sturge Weber).

TABLE 227-1 Differences in Features Between PHACE Syndrome and Sturge-Weber Syndrome



Feature	PHACES Syndrome	Sturge-Weber Syndrome
Vascular birthmark	Hemangioma	Port-wine stain
CNS vascular defects	Anomalous arteries	Leptomeningeal vascular malformation
Structural CNS defects	Dandy-Walker complex, posterior fossa malformations, cerebellar hypoplasia	Usually none
Eye abnormalities	Microphthalmia, optic nerve hypoplasia, cataracts, ↑ retinal vascularity, coloboma	Glaucoma, ↑ retinal vascularity, buphthalmos

MANAGEMENT

- Although it is recommended that all infants with characteristic features of segmental facial hemangiomas undergo thorough evaluation of the brain, heart, and eyes, there are little data to guide the management, risks, prognosis, or anticipatory guidance.[3]
- Infants and children suspected of having PHACE syndrome should undergo a thorough ophthalmologic examination for potential features.
- Brain imaging studies (MRI and MRA) are recommended for all infants with segmental facial hemangiomas.
- Echocardiography is recommended to rule out aortic arch and other abnormalities associated with this syndrome.
- Treatment of hemangiomas can include observation, propranolol, and laser, depending on the stage of the lesion and location. SOR Ⓒ
- Although propranolol is now the treatment of choice for large segmental hemangiomas (**Figure 227-8**), there is at least theoretical concern that this

drug could cause infarcts if stenotic vessels are present as a part of this syndrome. Thus, it is recommended that cardiac and neuroimaging be completed before propranolol therapy is considered in an infant at risk for PHACE syndrome.[3] SOR Ⓒ

The difference in a year:
The difference in a year:

FIGURE 227-8 Regression of a large segmental hemangioma in an infant with PHACE syndrome after nearly 11 months of propranolol therapy.

Initially prednisolone was being used simultaneously but that was stopped approximately halfway through the treatment with the propranolol. Note the presence of a coloboma of the right eye. (*Used with permission from AngelPHACE.com*.)

- Aspirin has been advocated for patients with PHACE due to increased risk of stroke during infancy. However, data regarding its benefits are lacking. SOR C

REFERRAL

- Infants suspected of having PHACE syndrome should be referred to centers that have experience with the manifestations and are able to provide a multi-disciplinary approach to the diagnosis and management.
- If a PHACE center is not available, referrals to separate specialists can be made:
  - Pediatric dermatologists are likely to be experienced in the use of propranolol for hemangioma treatment. Other dermatologists especially in academic centers should be able to manage this therapy as well.
  - Referrals to neurologists, cardiologists, and ophthalmologists may be needed.

PROGNOSIS

- Long-term studies on neurologic or cardiac outcomes are not currently available.
- A PHACE registry has been established to promote further understanding of this disorder.
- Prognosis for the facial hemangioma is usually excellent, especially with propranolol therapy (**Figures 227-8** and **227-9**).

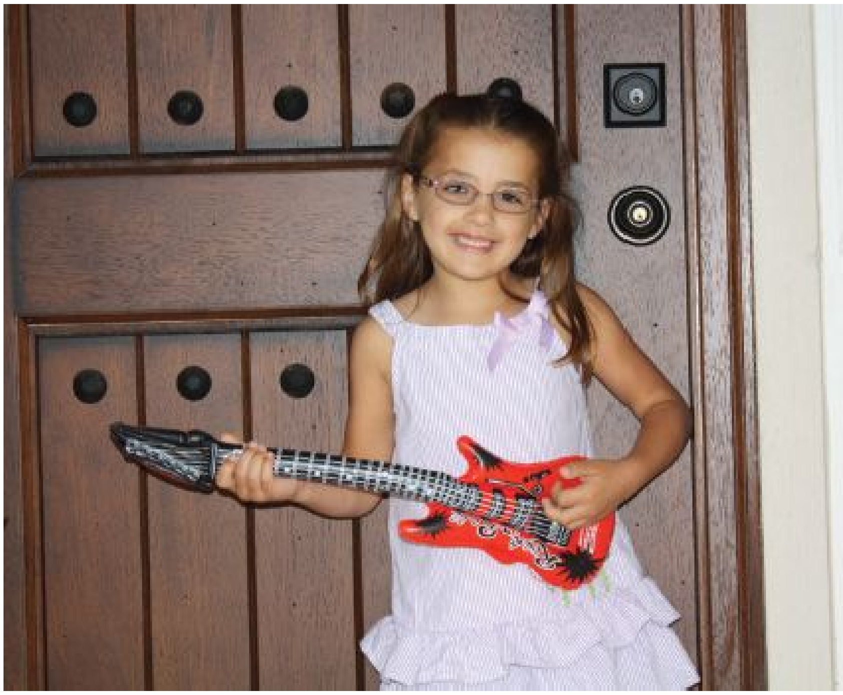

FIGURE 227-9 The girl from Figures 227-5 to 227-8 on her first day of Kindergarten showing almost complete regression of the hemangioma. (*Used with permission from AngelPHACE.com*.)

FOLLOW-UP

- Follow-up should be determined by the clinical features that are present after the initial work-up has been performed
- There are no standard recommendations for the need or frequency of reimaging if manifestations are detected.

PATIENT EDUCATION

The results of propanolol therapy for the facial hemangioma can be very impressive (**Figures 227-8** and **227-9**). Showing the photos in this chapter to the parents of affected children can provide hope for improvement.

Continuity of care with appropriate medical providers is essential to the management of this syndrome.

228 INCONTINENTIA PIGMENTI

Carla Torres-Zegarra, MD
Elumalai Appachi, MD, MRCP

PATIENT STORY

A 6-day-old girl is brought by her parents to the emergency department for a rash on her arms and chest. The parents noted that over the past 3 days, the baby has had intermittent episodes of right eye deviation and upper extremity stiffening. These episodes lasted approximately 30 seconds, occurred approximately 3 times per day and were associated with cyanosis. The family history was notable for seizures in a maternal aunt. On physical examination the infant was quiet, seemingly withdrawn with stable vital signs. The infant had erythematous papules and vesicles, some of which had eroded with crusting on the arms and anterior chest (**Figure 228-1**). A direct fluorescent antibody test and culture from the lesions were negative for herpes simplex virus. Skin biopsy of the lesions showed spongiotic dermatitis with many eosinophils and large dyskeratotic cells. Based on the skin lesions and the neurological manifestations, the infant was diagnosed with incontinentia pigmenti. Genetic, neurologic, and ophthalmology consults were obtained.

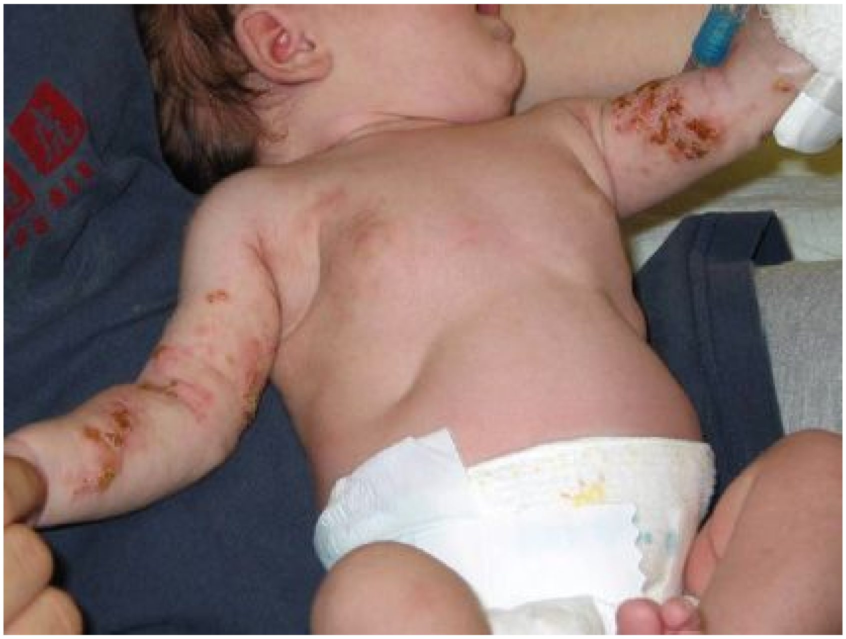

FIGURE 228-1 Papular and vesicular lesions, many of which are hyperkeratotic, on the upper extremities and trunk of a neonate with incontinentia pigmenti. (*Used with permission from Camille Sabella, MD*.)

INTRODUCTION

- Incontinentia pigmenti (IP) is an X-linked dominant systemic disease, usually lethal in males, and characterized by skin involvement at birth in 50 percent of cases. IP is a rare genodermatosis that presents in the neonatal period.
- The disease involves tissues of ectodermic and mesodermic origin including cutaneous tissue, teeth, eyes and the central nervous system (CNS), amongst other organs.[1]

SYNONYMS

Bloch-Sulzberger syndrome.

EPIDEMIOLOGY

- The incidence of IP is 1 case per 40,000.[1] It is more common in Caucasians than other ethnicities.
- Because IP is an X-linked dominant disease, affected male fetuses usually do not survive, and therefore over 97 percent of living affected individuals are female.
- IP has high penetrance. Most persons with IP begin to express the phenotype within a few months of birth.[2]

ETIOLOGY AND PATHOPHYSIOLOGY

- This X-linked dominant disorder is caused by mutations in the gene known as NEMO (NF-kappa essential modulator, also known as IKK-gamma). The gene NEMO encodes a protein that regulates the function of various chemokines, cytokines, and adhesion molecules, and is essential for protection against tumor necrosis factor induced apoptosis, inflammatory, and immune response[3].
- With this mutated gene, endothelial cells and other cells throughout the body can overexpress chemotactic factors specific for eosinophils, explaining why serum eosinophilia is common in IP patients.
- The epidermal skin lesions also show extensive involvement of eosinophils. It appears that the eosinophils, combined with other factors, lead to extensive inflammation, affecting not only the skin, but also endothelial cells.
- It is believed that this inflammation leads to vaso-occlusion, which results in ischemia, causing both the retinal and neurologic manifestations of IP.

RISK FACTORS

- Family history appears to be the only known risk factor for IP.
- Living males are likely to be affected with Klinefelter syndrome, where an extra X chromosome is present (XXY).

DIAGNOSIS

CLINICAL FEATURES

- Skin manifestations are prominent and develop in four stages:[4]
    - Stage 1—Erythematous papules and vesicles (Bullous stage) that appear in crops in linear streaks along the lines of Blaschko (lines along which skin and appendages, such as hair, melanocytes, and eccrine glands migrate during embryogenesis; **Figures 228-2** to **228-4**). Presentation is usually at birth or within the neonatal period. Each crop typically lasts 1 to 2 weeks.

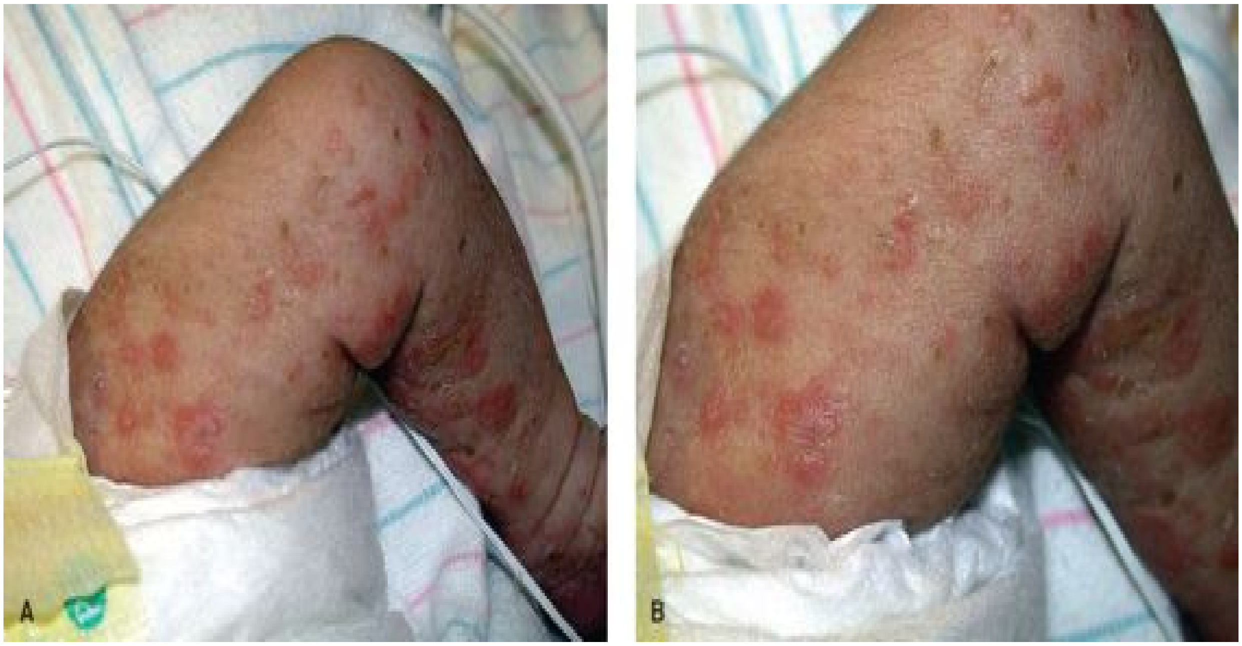

FIGURE 228-2 Erythematous papules and vesicles in a linear pattern in an infant with incontinentia pigmenti (**A**) and on close-up view (**B**).

Hyperkeratotic papules and plaques are also evident. (*Used with permission from Eric Kraus, MD.*)

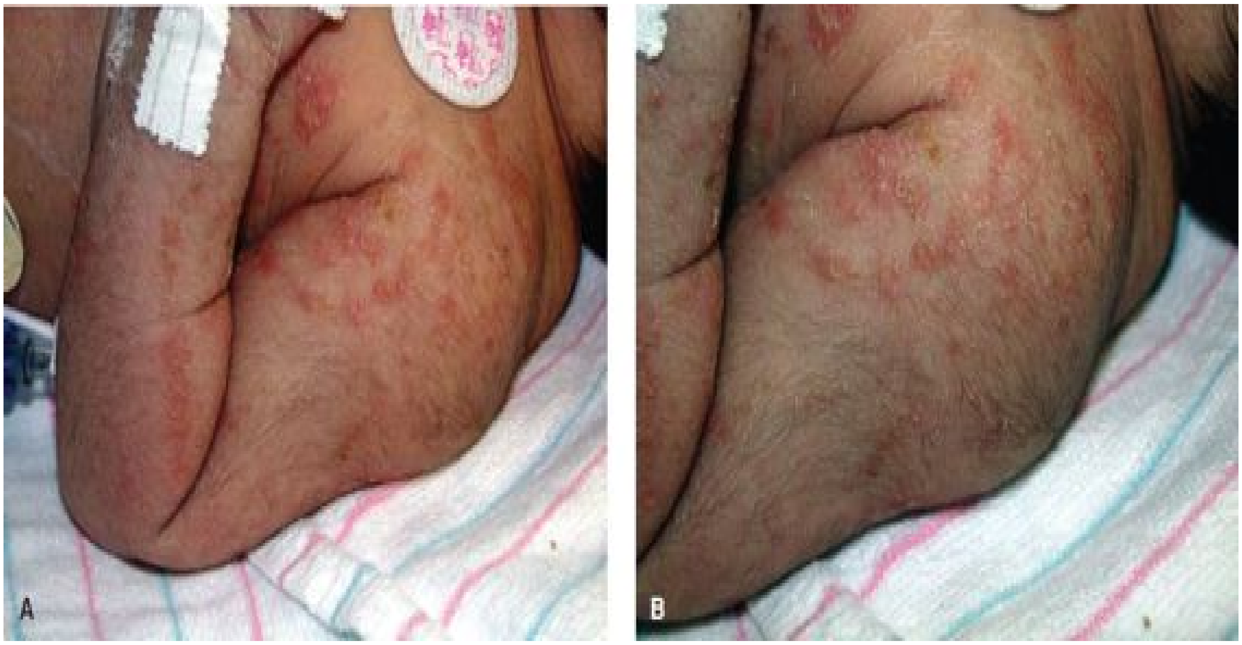

FIGURE 228-3 Crops of vesicular and crusted lesions on the upper extremity and chest of the same infant as in Figure 228-2 (**A**) and on close-up view (**B**). Note the linear distribution of the lesions on the lower arm. (*Used with permission from Eric Kraus, MD.*)

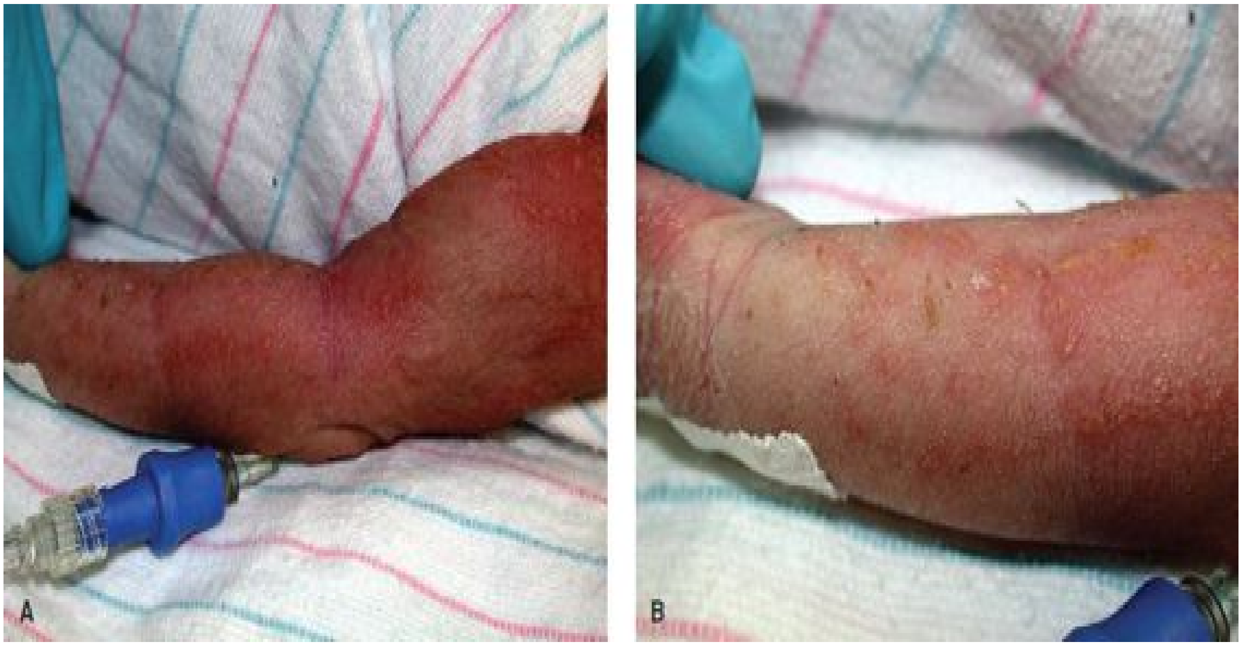

FIGURE 228-4 Linear erythematous papules and vesicles in the same infant (**A**). Note the vesicular and crusting appearance of some of the lesions on the close-up view (**B**). (*Used with permission from Eric Kraus, MD.*)

  - Stage 2—“Verrucous stage” that consists of hyperkeratotic warty papules or plaques in linear or swirling patterns (**Figures 228-1** and **228-2**). This stage usually last weeks to months.
  - Stage 3—Streaks of hyperpigmentation develop in a “marble cake” or swirled pattern typically occuring at 3 to 6 months of age, often begins to fade in adolescents, but can persist into adulthood (**Figure 228-5**).

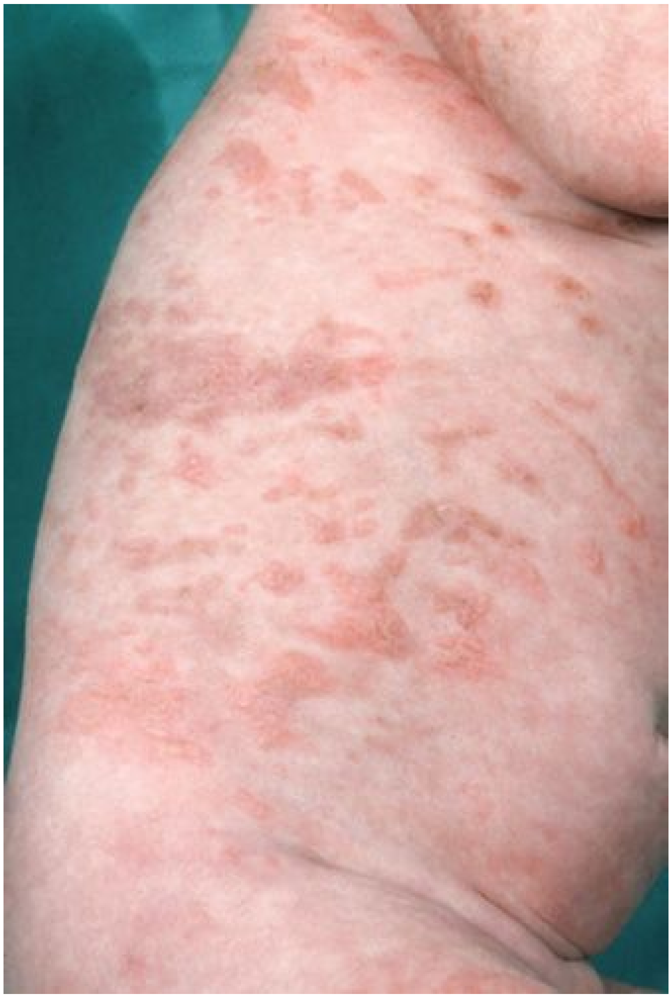

FIGURE 228-5 Hyperpigmentation plaques in a “marble cake” pattern in an infant with Incontinentia pigmenti. (*Used with permission from Cleveland Clinic Children’s Photo Files.*)

  - Stage 4—By the second or third decade of life, the hyperpigmented streaks become hypopigmented and atrophic.

- All stages may be present simultaneously, and may also occur in utero. Additional cutaneous changes include patchy alopecia, woolly-hair nevus, and nail dystrophy.
- Systemic abnormalities occur in nearly 80 percent of patients and include:
  - Dental abnormalities (i.e., adontia or conical deformities of the teeth).
  - Ocular problems (strabismus, cataracts, and retinal vascular changes leading to blindness).
  - Neurologic abnormalities (seizures, intellectual disability, mental retardation, and spastic paralysis).
  - Structural malformations (less frequently).
- In 1993, Landy and Donnai proposed a set of clinical diagnostic criteria for IP.[5]The criteria focus on whether or not the suspected patient has a first-degree relative with IP. If this relative exists, then only one of the following is needed for diagnosis of IP:
  - History or evidence of typical skin lesions.
  - Pale, hairless, atrophic linear skin streaks.
  - Dental anomalies.
  - Retinal disease.
  - Multiple male miscarriages.
- If a first-degree relative with IP cannot be established, then diagnostic criteria are separated into major and minor categories.
  - Major criteria—Skin lesions that occur in stages from infancy to adulthood.
    - Erythematous lesions followed by vesicles anywhere on the body (sparing the face), usually in a linear distribution.
    - Hyperpigmented streaks and whorls respecting Blaschko lines, occurring mainly on the trunk and sparing the face, fading in adolescence.
    - Pale, hairless, atrophic linear streaks or patches.
  - Minor criteria:
    - Hypodontia or anodontia (partial or complete absence of teeth), microdontia (small teeth), or abnormally shaped teeth.

  - Alopecia, wiry coarse hair.
  - Mild nail ridging or pitting, hypertrophied, or curved nails.
  - Retinal abnormalities.
- If a first-degree relative with IP cannot be established, one major criteria and two or more minor criteria are needed for diagnosis. If none of the minor criteria are present, then a diagnosis other than IP should be considered.

LABORATORY TESTING

- The clinical diagnosis is confirmed with skin biopsy that demonstrates spongiotic dermatitis with many eosinophils and large dyskeratotic cells during the vesicular stage.
- Peripheral eosinophilia typically is present in early infancy.[2,3]
- Molecular-based diagnosis is available to detect mutations in NEMO (NF-kappaB essential modulator) that occur in 85 percent of affected patients.[2,4]

IMAGING

- Generally, brain imaging, such as an MRI, should be obtained to investigate the vaso-occlusive consequences of IP in the brain.
- Electroencephalogram should be obtained if seizures are present.

DIFFERENTIAL DIAGNOSIS

- Erythema toxicum neonatorum—A self-limited neonatal macular or papular rash usually appearing at 2 days of life (see Chapter 92, Normal Skin Changes [newborn]).
- Herpes simplex virus infection—Vesicular lesions on erythematous base often appearing in crops. Needs to be excluded in any infant who has

vesicular lesions by direct testing of the lesions for the virus (see Chapter 114, Herpes Simplex and Chapter 187, Congenital and Perinatal Infections).

- Diffuse cutaneous mastocytosis—The affected infants develop urticaria when exposed to hot water or other physical stimuli (see Chapter 134, Urticaria and Angioedema). They may also get bullous mastocytosis, which can crust in a manner very similar to IP (**Figure 228-6**). A biopsy can differentiate between these 2 diagnoses.

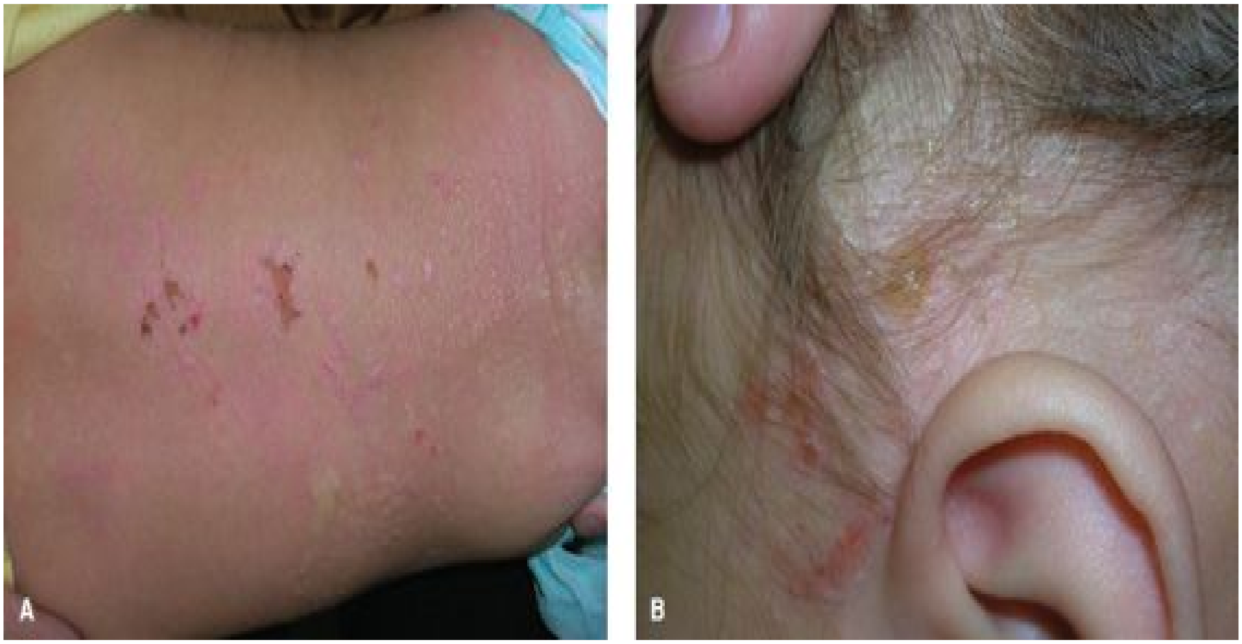

FIGURE 228-6 Bullous mastocytosis in a 9-month-old infant presenting with wheals, bullae, and crusts on the (**A**) back and (**B**) scalp. (*Used with permission from Richard P. Usatine, MD.*)

- Hypomelanosis of Ito.[6] Lesions are hypopigmented, rather than hyperpigmented, macules arranged in sharply demarcated whorls, streaks, and patches over the body, extremities (**Figure 228-7**) and face that follow the lines of Blaschko. There are no papules, vesicles or crusts as seen in IP (see Chapter 167, Vitiligo and Hypopigmentation).

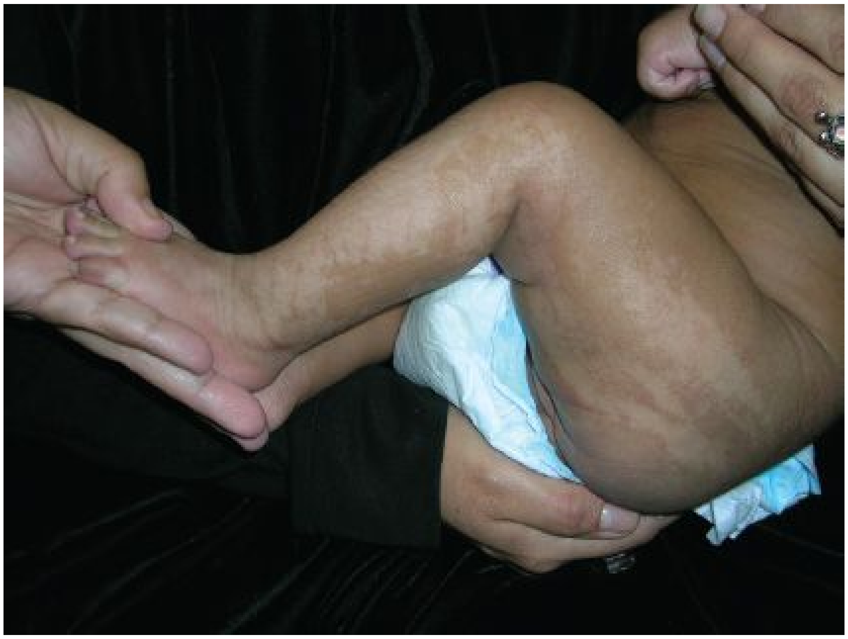

FIGURE 228-7 Hypomelanosis of Ito in a 2-month-old infant showing linear and whorled hypopigmentation from the buttocks down to the foot. These areas of hypopigmentation extend up the trunk and down the arm on the same side of the body. They follow Blaschko lines. (*Used with permission from Richard P. Usatine*, *MD*.)

MANAGEMENT

- There is no cure or specific treatment. Genetic therapies are not currently available; management is aimed at managing the presenting signs and symptoms.
- Local care of the skin manifestations is needed to prevent infection or excessive scarring.
- The skin abnormalities of IP usually disappear by adolescence or adulthood without treatment.
- Diminished vision may be treated with corrective lenses, medication, or, in severe cases, surgery.
- A dental specialist may treat dental problems.

- Neurological symptoms such as seizures, muscle spasms, or mild paralysis may be controlled with medication and/or medical devices, and with the advice of a neurologist.
- Developmental therapy may be needed for those with developmental delay.

REFERRAL

- Because IP is a multisystemic disease, dermatologic, genetic, ophthalmic, neurologic, and dental consultations should be obtained upon diagnosis.

PREVENTION AND SCREENING

- If a proband is identified, clinical examination of family members and genetic testing of the mother is warranted.
- If a female has IP (IKBKG mutation), the risk of conceiving a fetus with IP is 50 percent. However, most affected males die in utero, meaning that an affected mother has a near 33 percent probability of giving birth to either an affected female, unaffected female, or unaffected male.
- In parents without IP or an IP-related IKBKG mutation that have had a child with IP, the risk of a subsequent child having IP is less than 1 percent.[7]
- Prenatal diagnosis of fetuses with a family history of IP is possible via DNA analysis obtained by amniocentesis or chorionic villus sampling.

PROGNOSIS

- Although the skin abnormalities usually regress, and sometimes disappear completely, the prognosis is dependent upon residual neurological impairment.

- Survival in male patients may be related to genetic heterogeneity or postzygotic mosaicism. In polymerase chain reaction analysis of samples from 18 boys with clinical and histologic features of IP, 15 had the normal NEMO allele in leukocyte DNA, whereas three had both the normal NEMO allele and the NEMO mutation that occurs in the majority of girls with IP, confirming postzygotic mosaicism.[4]

FOLLOW-UP

Follow-up is contingent on the affected systems.

PATIENT EDUCATION

- Families should be educated as to the genetics of the disorder and genetic counseling should be provided for all affected families.

229 SUBSTANCE ABUSE DISORDER

Richard P. Usatine, MD
Heidi Chumley, MD
Kelli Hejl Foulkrod, MS

PATIENT STORY

A young mother and her four children are being seen in a free clinic within a homeless shelter for various health reasons (**Figure 229-1**). The woman is currently clean and sober, but has a long history of cocaine use and addiction (**Figure 229-2**). Her children span the ages of 3 months to 5 years. She was recently living with her mother after the birth of her youngest child, but was kicked out of her mother’s home when she began to use cocaine once again. The patient gave written consent to the photograph and when she was shown the image on the digital camera she noted how depressed she looked. She asked for us to tell the viewers of this photograph that these can be the consequences of drug abuse—being depressed, homeless, and a single mom. Only time will reveal the effect of this situation on her four children. They are at risk for so many problems including neglect, abuse, behavioral issues and being placed in foster care. They are also at higher risk of developing substance abuse disorder. Being the health care provider for these children requires understanding the disease of addiction and the consequences of this on the family.

FIGURE 229-1 A cocaine-addicted mother with her children in a homeless shelter. Her drug addiction resulted in their homelessness. (*Used with permission from Richard P. Usatine, MD*.)

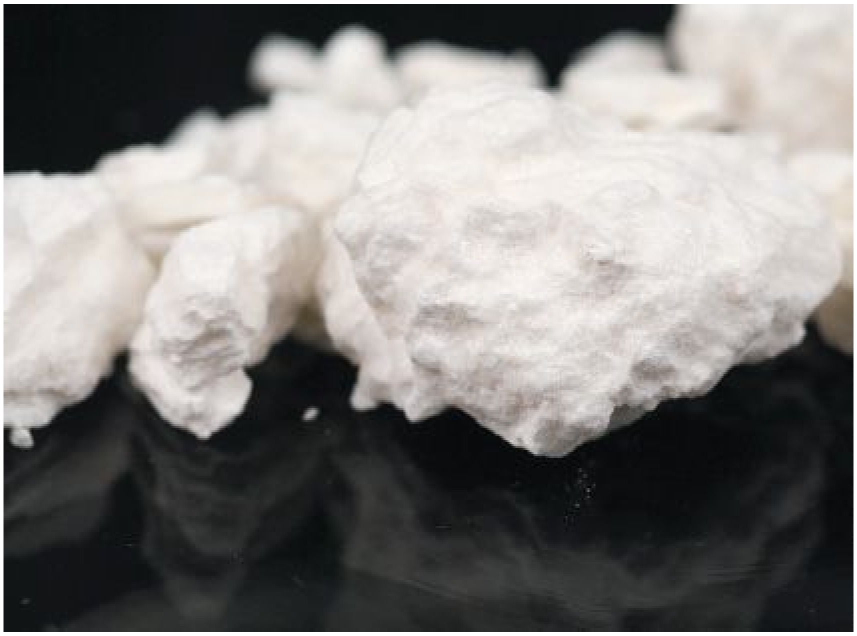

FIGURE 229-2 Purified cocaine. (*Used with permission from DEA*.)

INTRODUCTION

Addiction occurs when substance use has altered brain function to an extent that an individual loses a degree of control over his or her behaviors. Addiction is an epigenetic phenomenon. Many genes influence the brain functions that affect behavior and genetic variants. These genes differ in their susceptibility to environmental conditions, which trigger the changes in brain circuitry, and contribute to the development of addiction. Addiction must be recognized and treated as a chronic illness with an interprofessional team and social support.

EPIDEMIOLOGY

- An estimated 69.6 million Americans age 12 years or older were current users of a tobacco product in 2010. This represents 27.4 percent of the population in that age range. In addition, 58.3 million persons (23% of the population) were current cigarette smokers, 13.2 million (5.2%) smoked cigars, 8.9 million (3.5%) used smokeless tobacco, and 2.2 million (0.8%) smoked tobacco in pipes.[1]
- An estimated 22.6 million Americans age 12 years or older were current illicit drug users in 2010. This represents 8.9 percent of the population in that age range.[1]
- Marijuana was the most commonly used illicit drug (17.4 million users; **Figures 229-3** and **229-4**). It was used by 76.8 percent of current illicit drug users. Among current illicit drug users, 60.1 percent used only marijuana, 16.7 percent used marijuana and another illicit drug, and the remaining 23.2 percent used only an illicit drug other than marijuana.[1]

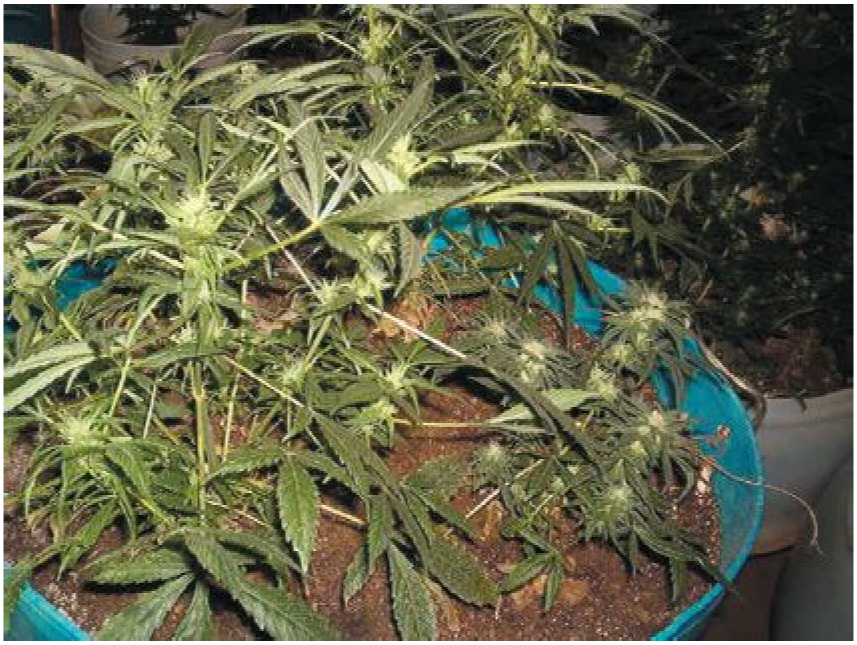

FIGURE 229-3 Home-grown marijuana plant. (*Used with permission from DEA*.)

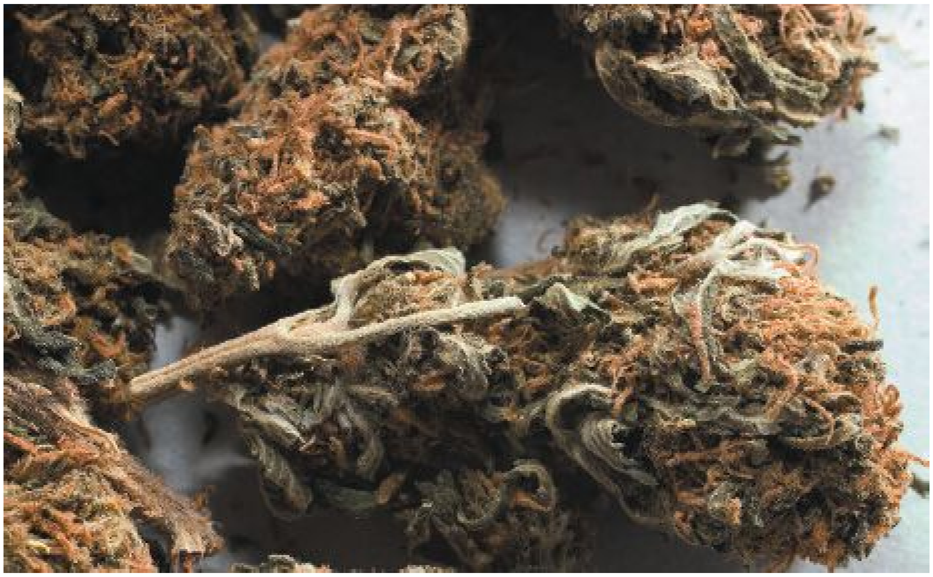

FIGURE 229-4 Marijuana ready to be smoked. (*Used with permission from DEA*.)

- There were 1.5 million persons who were current cocaine users in 2010.[1]
- There were 353,000 persons who were current methamphetamine users in 2010 (**Figure 229-5**).[1]

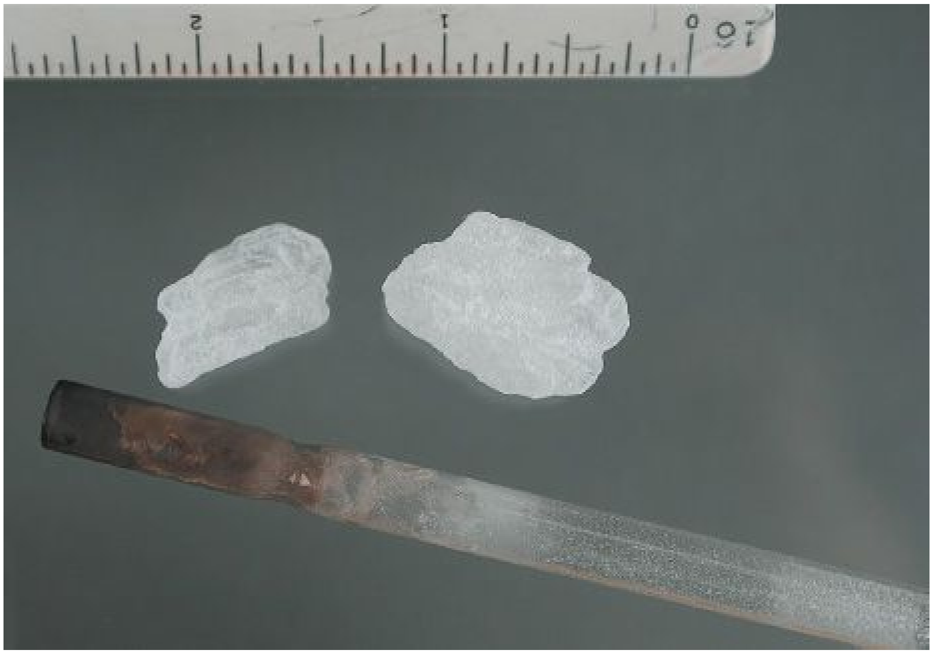

FIGURE 229-5 Methamphetamine ice with pipe. (*Used with permission from DEA*.)

- Hallucinogens were used by 1.2 million persons (0.5%) in 2010, including 695,000 (0.3%) who had used ecstasy (**Figure 229-6**).[1]

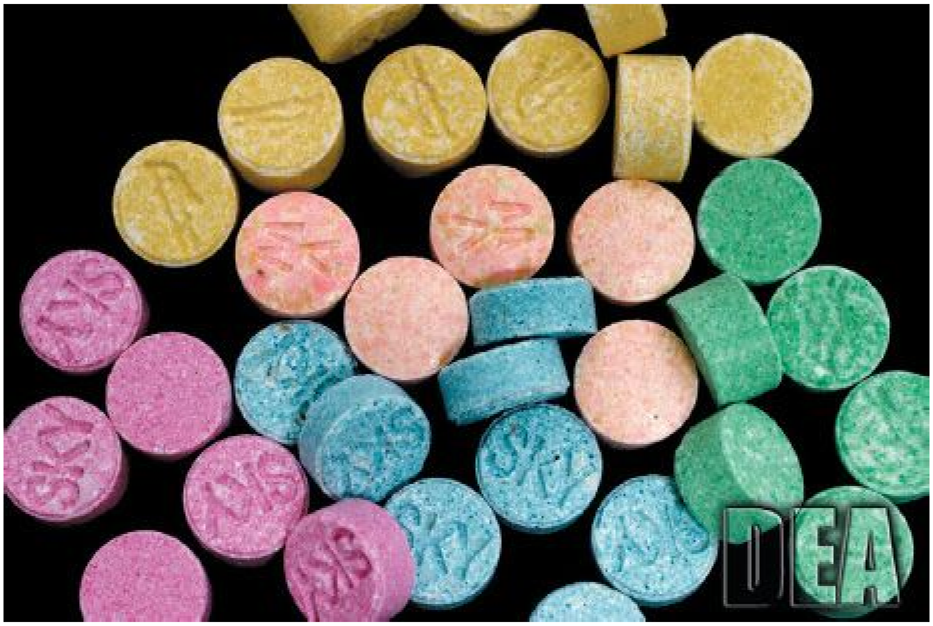

FIGURE 229-6 Ecstasy tablets used at raves where people dance all night long and some collapse in dehydration. (*Used with permission from DEA*.)

- In 2010, 140,000 persons used heroin for the first time (**Figure 229-7**).[1]

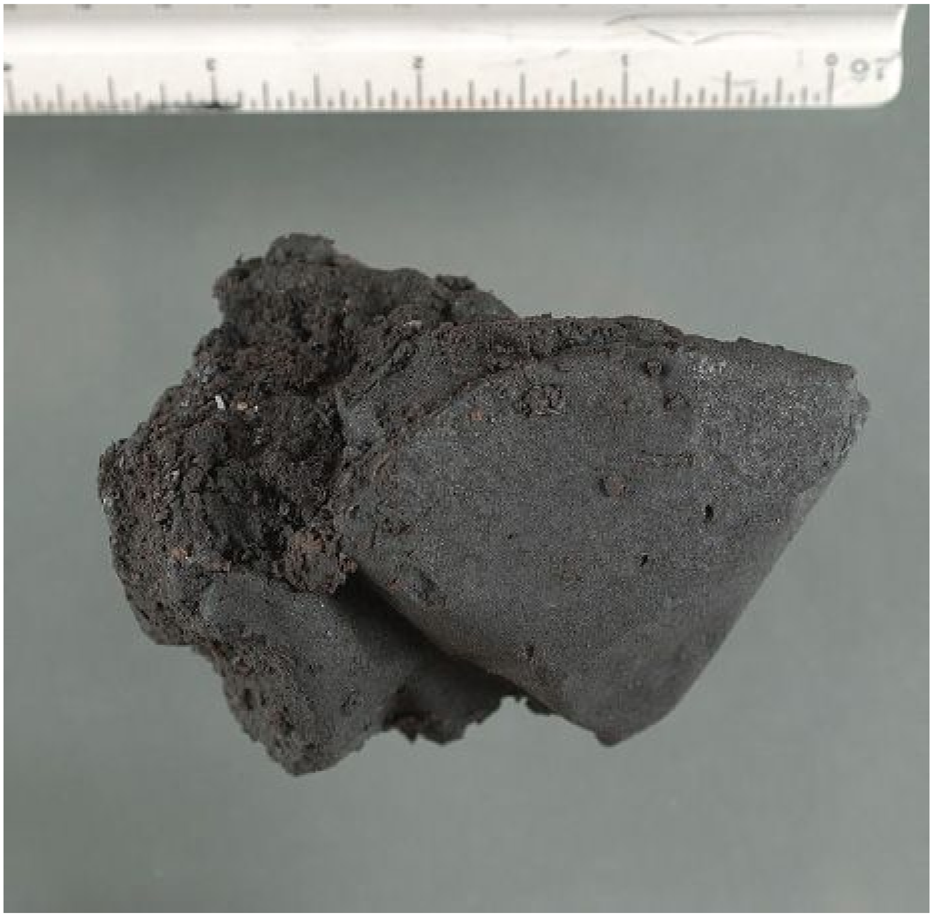

FIGURE 229-7 Black tar heroin for injection. (*Used with permission from DEA.*)

- There were 9 million people age 12 years or older (3.6%) who were current users of illicit drugs other than marijuana in 2010. Most (7 million, 2.7%) used psychotherapeutic drugs nonmedically (including prescription drugs). Of these, 5.1 million used pain relievers, 2.2 million used tranquilizers, 1.1 million used stimulants, and 374,000 used sedatives.[1]
- Among persons who used pain relievers nonmedically in the past 12 months, 55 percent reported that the source of the drug was from a friend or relative for free. Another 17.3 percent reported that they got the drug from a physician. Only 4.4 percent obtained the pain relievers from a

drug dealer or other stranger, and only 0.4 percent reported buying the drug on the Internet.[1]

ASSOCIATION WITH CIGARETTE AND ALCOHOL USE

- In 2010, the rate of current illicit drug use was 8.5 times higher among youths age 12 to 17 years who smoked cigarettes in the past month (52.9%) than it was among youths who did not smoke cigarettes in the past month (6.2%).[1]
- Past month illicit drug use was also associated with the level of past month alcohol use. Among youths age 12 to 17 years in 2010 who were heavy drinkers (i.e., drank 5 or more drinks on the same occasion [i.e., at the same time or within a couple of hours] on each of 5 or more days in the past 30 days), 70.6 percent were also current illicit drug users, which was higher than among nondrinkers (5.1%).[1]

ETIOLOGY AND PATHOPHYSIOLOGY

- “Drug addiction is a brain disease. Although initial drug use might be voluntary, drugs of abuse have been shown to alter gene expression and brain circuitry, which in turn affect human behavior. Once addiction develops, these brain changes interfere with an individual’s ability to make voluntary decisions, leading to compulsive drug craving, seeking and use.”[2]
- Addiction is a polygenic disorder. Many genes have direct or indirect influences on neurotransmitters, drug metabolic pathways, and behavioral patterns. For example, variants of receptors for dopamine or opiates influences perceived reward.[3]
- Epigenetic mechanisms, external influences that trigger changes in gene expression, are believed to play a role through modulation of reward and

emotion.[3] As such, both genetics and environment/learned behaviors can increase a person's risk for substance abuse.

- Family, twin, and adoption studies convincingly demonstrate that genes play an important role in the development of alcohol dependence, with heritability estimates in the range of 50 to 60 percent for both men and women. Important genes include those involved in alcohol metabolism, and those involved in γ-aminobutyric acid (GABA), endogenous opioid, dopaminergic, cholinergic, and serotonergic transmission.[4]
- Several drinking behaviors, including alcohol dependence,; history of blackouts, age at first drunkenness, and level of response to alcohol are associated with single-nucleotide polymorphisms (SNPs) within 1 of 4 GABA receptor genes on chromosome 5q.[5]
- Comorbid mental health issues and chronic pain disorders are highly prevalent among persons with substance abuse disorders. Commonly, a person begins using drugs to self-treat feelings of depression and symptoms of pain.
- The medical consequences of addiction are far reaching and very costly to society. Cardiovascular disease, stroke, cancer, HIV/AIDS, hepatitis, and lung disease can all be increased by drug abuse. Some of these effects occur when drugs are used at high doses or after prolonged use. Some consequences occur after just one use.[2]
- Classes of substances that are frequently abused and involved in addiction include:
    - Depressants—Alcohol, sedatives, hypnotics, opioids, and anxiolytics.
    - Stimulants—Cocaine, amphetamines, and nicotine.
    - Hallucinogens—Cannabis, phencyclidine (PCP), and lysergic acid diethylamide (LSD).

Toxic inhalants.

- The onset of drug effects is approximately:
    - Seven to ten seconds for inhaling or smoking.
    - Fifteen to thirty seconds for intravenous injection.
    - Three to five minutes for intramuscular or subcutaneous &injection.
    - Three to five minutes for intranasal use (snorting).

RISK FACTORS

- Family history.
- Personal history of prior addiction.

DIAGNOSIS

The diagnosis of a substance use disorder is based on a pathological pattern of behaviors related to use of the substance.[6] The DSM V uses 11 criteria to make this diagnosis. One example of these criteria is the following 11 symptoms for alcohol abuse disorder. If one substitutes other substances like cannabis or cocaine the same criteria still apply.

Alcohol abuse disorder is diagnosed when there is a problematic pattern of alcohol use leading to clinically significant impairment or distress, manifested by at least two of the following, occurring within a 12-month period:

1. Alcohol is often taken in larger amounts or over a longer period than was intended.
2. There is a persistent desire or unsuccessful efforts to cut down or control alcohol use.
3. A great deal of time is spent in activities necessary to obtain alcohol, use alcohol, or recover from its effects.
4. Craving, or a strong desire or urge to use alcohol.
5. Recurrent alcohol use resulting in a failure to fulfill major role obligations at work, school, or home.
6. Continued alcohol use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of alcohol.
7. Important social, occupational, or recreational activities are given up or reduced because of alcohol use.
8. Recurrent alcohol use in situations in which it is physically hazardous.

9. Alcohol use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by alcohol.
10. Tolerance, as defined by either of the following:
    - A need for markedly increased amounts of alcohol to achieve intoxication or desired effect.
    - A markedly diminished effect with continued use of the same amount of alcohol.
11. Withdrawal, as manifested by either of the following:
    - The characteristic withdrawal syndrome for alcohol (refer to Criteria A and B of the criteria set for alcohol withdrawal).
    - Alcohol (or a closely related substance, such as a benzodiazepine) is taken to relieve or avoid withdrawal symptoms.

Severity is graded based on the number of symptoms present:

Mild: Presence of 2–3 symptoms.
Moderate: Presence of 4–5 symptoms.
Severe: Presence of 6 or more symptoms.[6]

CLINICAL FEATURES VISIBLE WITH SUBSTANCE ABUSE

- With intoxication, the following signs may be visible:
    - Via stimulants—Dilated pupils and increase in blood pressure, respiratory rate, pulse, and body temperature.
    - Via depressants—Decrease in blood pressure, respiratory rate, pulse, and body temperature. Opioids produce pinpoint pupils. Alcohol intoxication produces dilated pupils.
    - Withdrawal develops with decline of substance in the central nervous system (CNS). Withdrawal reactions vary by the substance used. Alcohol withdrawal is one of the most deadly and dangerous types of withdrawal.

LABORATORY TESTING

- All injection-drug users and persons engaged in high-risk sexual activities should be screened for HIV (with consent), hepatitis B and hepatitis C, and syphilis (rapid plasma reagin [RPR]).
- Persons who have multiple sex partners or use sex to obtain drugs are at high risk for sexually transmitted infections (STIs) and should be tested.
- Urine screen for common drugs of abuse may reveal other drugs not admitted to in the history. Most laboratories can differentiate prescription from nonprescription drugs (i.e., opiates) upon request. Substances have different physiologic half-lives in the body and show up for varying amounts of time in the urine. Marijuana has a long excretion half-life and may be detectable for 1 month after its use. Other substances may last for only days.

DIFFERENTIAL DIAGNOSIS

Substance abuse disorders coexist with and complicate the course and treatment of numerous psychiatric conditions.

- Mood/anxiety disorders—Especially depression, bipolar affective disorder, panic disorder, and generalized anxiety disorder. Persons with addictions can develop the symptoms of these disorders from the drugs of abuse. However, mood and anxiety disorders can predate the use of drugs, and some of the motivation for drug use can stem from the desire to self-treat these psychological conditions. It is best to evaluate persons when they are off the drugs whenever possible.
- Schizophrenia—Although drugs can cause temporary psychosis and paranoia, if these symptoms persist after the drugs are stopped for some time, consider schizophrenia and other causes of psychosis.
- Personality disorders—These are a complicated set of disorders that can coexist and be confused with substance abuse disorder. A person in the midst of their addiction may appear to have an antisocial personality disorder when committing crimes to get money for expensive drugs. It is

best to not use this diagnosis unless the behaviors continue when the person is off the drugs.

MANAGEMENT

- Recognize addiction (dependence). One simple mnemonic device is the “three C’s of addiction”:
    - **C**ompulsion to use.
    - Lack of **C**ontrol.
    - **C**ontinued use despite adverse consequences.
- Use the “5 *A*s”—Ask, Advise, Assess, Assist, and Arrange—to help smokers who are willing to quit. This model can be applied to any substance of abuse.[7]
- Offer counseling and pharmacotherapy to aid your patients to quit smoking.
- Use the CAGE[7] questionnaire when asking about alcohol use:
    - Cut down (Have you ever felt you should *cut* down on your drinking?).
    - Annoyed (Have people *annoyed* you by criticizing your drinking?).
    - Guilty (Have you ever felt bad or *guilty* about your drinking?).
    - Eye opener (Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover?).

Interpreting the results: one positive suggests at risk, two positives suggest abuse, and three or four positives suggest dependence. This is just a screening tool, and further evaluation is always needed.

- Recommend 12-step programs. These have been very effective for millions of people worldwide.
- Refer to substance abuse programs. Such programs include hospital-and community-based programs. Some programs include detoxification and others require the patient to have gone through detoxification before starting the program. There are residential treatment units, outpatient

programs, and ongoing self-help programs. Learn about the programs in your community and work with them.

- When prescribing opioid analgesics for chronic pain consider the outcomes in four domains, or the "4 *A*s." Is the patient:
    - Receiving adequate Analgesia?
    - Experiencing improvements in Activities of daily life?
    - Experiencing any Adverse effects?
    - Demonstrating Aberrant medication-taking behaviors that may be linked to addiction?[8]
- When patients are exhibiting aberrant drug-taking behaviors, consider the following:
    - They may have an addiction.
    - They may not be getting adequate pain relief taking the drug as prescribed.
    - They may have a comorbid mental illness.
    - They may intend to distribute pain medications illegally.[9]
- Help your patients acknowledge that they have a problem and offer them help in a nonjudgmental manner.
- Enlist parents and family members to help.
- Demonstrate genuine concern and care; suspend judgment and you will have a higher chance of succeeding to help your patients overcome addiction.
- Advanced brain imaging and genetic tests are helping us to understand the physiologic basis of addiction and will ultimately provide us with better treatments for the medical disease of addiction.

PERSONS IN RECOVERY

- Be careful how you prescribe medications to persons in recovery. A "simple" prescription for hydrocodone (Vicodin) postoperatively can start a recovered person down the road of active addiction.

- Avoid giving opioids and benzodiazepines whenever there are good alternatives. Use NSAIDs for pain if possible. Use selective serotonin reuptake inhibitors (SSRIs), other antidepressants, or buspirone for anxiety if a medication is needed.
- If an opioid is needed, work with the patient to monitor the amount and manner of use. Involving a third person or sponsor to help meter out the dose may prevent relapse.
- Be upfront and honest about a shared goal to avoid relapse.

FOLLOW-UP

- Follow-up is critical to the treatment of all types of substance abuse. Substance abuse is a chronic condition (similar to hypertension or diabetes mellitus) and requires ongoing intervention to maintain sobriety.
- The frequency and intensity of follow-up depends on the substance, the addiction, and the patient.
- Do not give up on patients who relapse because it often takes more than 1 attempt before long-term cessation can be achieved.

PATIENT EDUCATION

Explain to patients that addiction is a disease and not a failing of their moral character. Inform patients about the existing treatment programs in their community and offer them names and phone numbers so that they may get help. If your patient is not ready for help today, give the numbers and names for tomorrow. Speak about the value of 12-step programs because these are effective and everyone can afford a 12-step program (they are free). There are 12-step programs in the community for everyone, including nonsmokers and agnostics.

PATIENT RESOURCES

- Alcoholics Anonymous (AA)—Meetings and the Big Book are free. The Big Book is online for free in three languages. **www.alcoholics-anonymous.org/**.
- Narcotics Anonymous (NA)—Meetings are free. The *Basic Text* costs $10; it is similar to the AA big book, but the language is more up to date and readable. **http://www.na.org/**.
- Cocaine Anonymous (CA)—Meetings are free. Their first book *Hope, Faith and Courage: Stories from the Fellowship of Cocaine Anonymous* was published in 1994 and sells for $10. **www.ca.org**.
- Crystal Meth Anonymous (12-step meetings)—**www.crystalmeth.org**.

PROVIDER RESOURCES

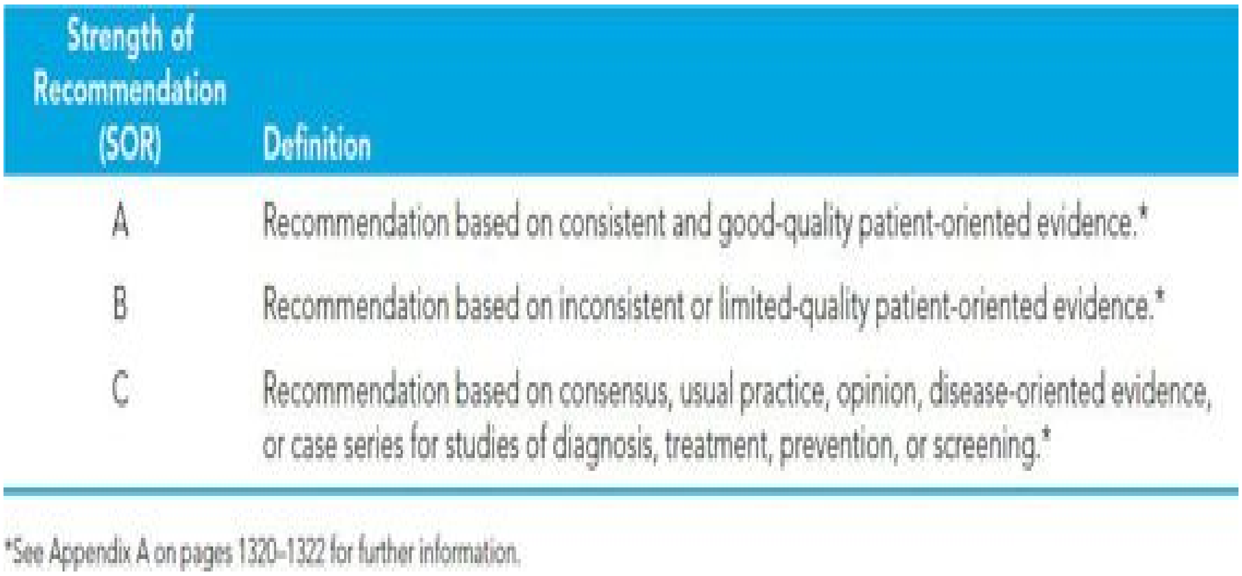
APPENDIX



Strength of Recommendation (SOR)	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series for studies of diagnosis, treatment, prevention, or screening.*

*See Appendix A on pages 1320–1322 for further information.

APPENDIX A INTERPRETING EVIDENCE-BASED MEDICINE

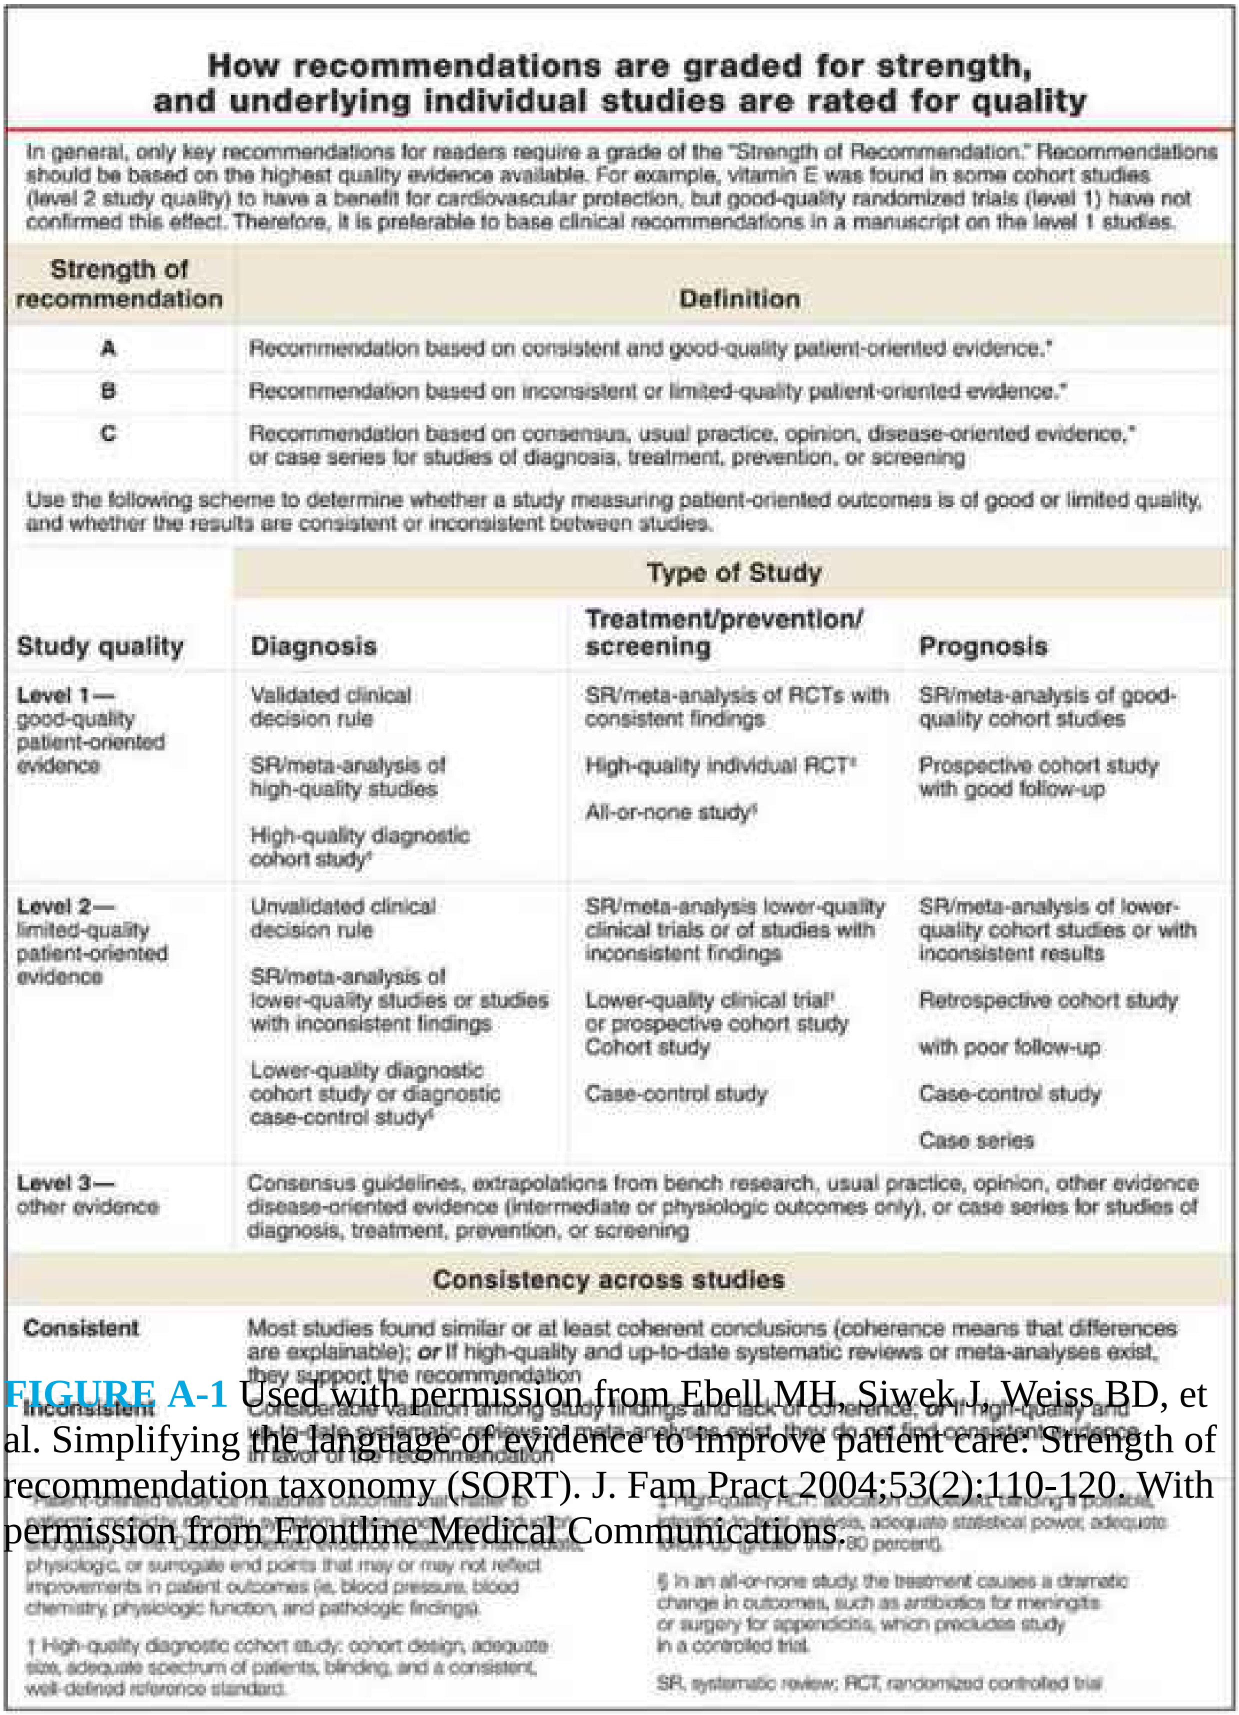
Mindy A. Smith, MD, MS

“Evidence-based medicine—is this something new?” asked my father, incredulously. “What were you practicing before?”

Like my father, our patients assume that we provide recommendations to them based on scientific evidence. The idea that there might not be relevant evidence or that we might not have access to that evidence has not even occurred to most of them. This is certainly not to imply that such evidence is the be-all and end-all of medical practice or that our patients would follow such recommendations blindly—rather, for me, it is a starting point from which to begin rational testing or outline a possible therapeutic plan.

The first time that I recall the term *evidence-based medicine* (EBM) being discussed was in the early 1990s.[1,2] It seemed that we would need to develop skills in evaluating the published literature and determining its quality, validity, and relevance to the care of our patients. As a teacher and researcher, I was intrigued by the challenges of critically appraising articles and teaching this newfound skill to others. As a clinician, however, I was most interested in answering clinical questions and doing so in a compressed time frame. I need rapid access to tools or sources that provided summary answers to those questions tagged to information about the quantity and quality of the evidence and the consistency of information across studies.

There seemed to be many systems for rating literature but few that met the needs of the busy practitioner trying to make sense of individual clinical trials and the hundreds of both evidence-based and consensus-based guidelines that seemed to spring up overnight. In 2004, the editors of the U.S. family medicine and primary care journals and the Family Practice Inquiries Network published a paper on a unified taxonomy called *Strength of Recommendation* (SOR) Taxonomy that seemed to fit the bill (**Figure A-1**).[3] This taxonomy made use of existing systems for judging study quality while incorporating the concept of patient-oriented (e.g., mortality, morbidity, symptom improvement) rather than disease-oriented (e.g., change in blood pressure, blood chemistry) outcomes as most relevant. SOR Ⓐ recommendation is one based on consistent, good-quality patient-oriented evidence; SOR Ⓑ is a recommendation based on inconsistent or limited-quality patient-oriented evidence; and SOR Ⓒ is a recommendation based on consensus, usual practice, opinion, disease-oriented evidence, or case series (**Figures A-1** and **A-2**).



How recommendations are graded for strength, and underlying individual studies are rated for quality

In general, only key recommendations for readers require a grade of the "Strength of Recommendation." Recommendations should be based on the highest quality evidence available. For example, vitamin E was found in some cohort studies (level 2 study quality) to have a benefit for cardiovascular protection, but good-quality randomized trials (level 1) have not confirmed this effect. Therefore, it is preferable to base clinical recommendations in a manuscript on the level 1 studies.

Strength of recommendation	Definition
A	Recommendation based on consistent and good-quality patient-oriented evidence.*
B	Recommendation based on inconsistent or limited-quality patient-oriented evidence.*
C	Recommendation based on consensus, usual practice, opinion, disease-oriented evidence,* or case series for studies of diagnosis, treatment, prevention, or screening

Use the following scheme to determine whether a study measuring patient-oriented outcomes is of good or limited quality, and whether the results are consistent or inconsistent between studies.

	Type of Study		
Study quality	**Diagnosis**	**Treatment/prevention/ screening**	**Prognosis**
Level 1— good-quality patient-oriented evidence	Validated clinical decision rule SR/meta-analysis of high-quality studies High-quality diagnostic cohort study†	SR/meta-analysis of RCTs with consistent findings High-quality individual RCT‡ All-or-none study§	SR/meta-analysis of good-quality cohort studies Prospective cohort study with good follow-up
Level 2— limited-quality patient-oriented evidence	Unvalidated clinical decision rule SR/meta-analysis of lower-quality studies or studies with inconsistent findings Lower-quality diagnostic cohort study or diagnostic case-control study§	SR/meta-analysis lower-quality clinical trials or of studies with inconsistent findings Lower-quality clinical trial‡ or prospective cohort study Cohort study Case-control study	SR/meta-analysis of lower-quality cohort studies or with inconsistent results Retrospective cohort study with poor follow-up Case-control study Case series
Level 3— other evidence	Consensus guidelines, extrapolations from bench research, usual practice, opinion, other evidence disease-oriented evidence (intermediate or physiologic outcomes only), or case series for studies of diagnosis, treatment, prevention, or screening		

Consistency across studies	
Consistent	Most studies found similar or at least coherent conclusions (coherence means that differences are explainable); ***or*** if high-quality and up-to-date systematic reviews or meta-analyses exist, they support the recommendation
Inconsistent	Considerable variation among study findings and lack of coherence; ***or*** if high-quality and up-to-date systematic reviews or meta-analyses exist, they do not find consistent evidence in favor of the recommendation

* Patient-oriented evidence measures outcomes that matter to patients: morbidity, mortality, symptom improvement, cost reduction, and quality of life. Disease-oriented evidence measures intermediate, physiologic, or surrogate end points that may or may not reflect improvements in patient outcomes (ie, blood pressure, blood chemistry, physiologic function, and pathologic findings).

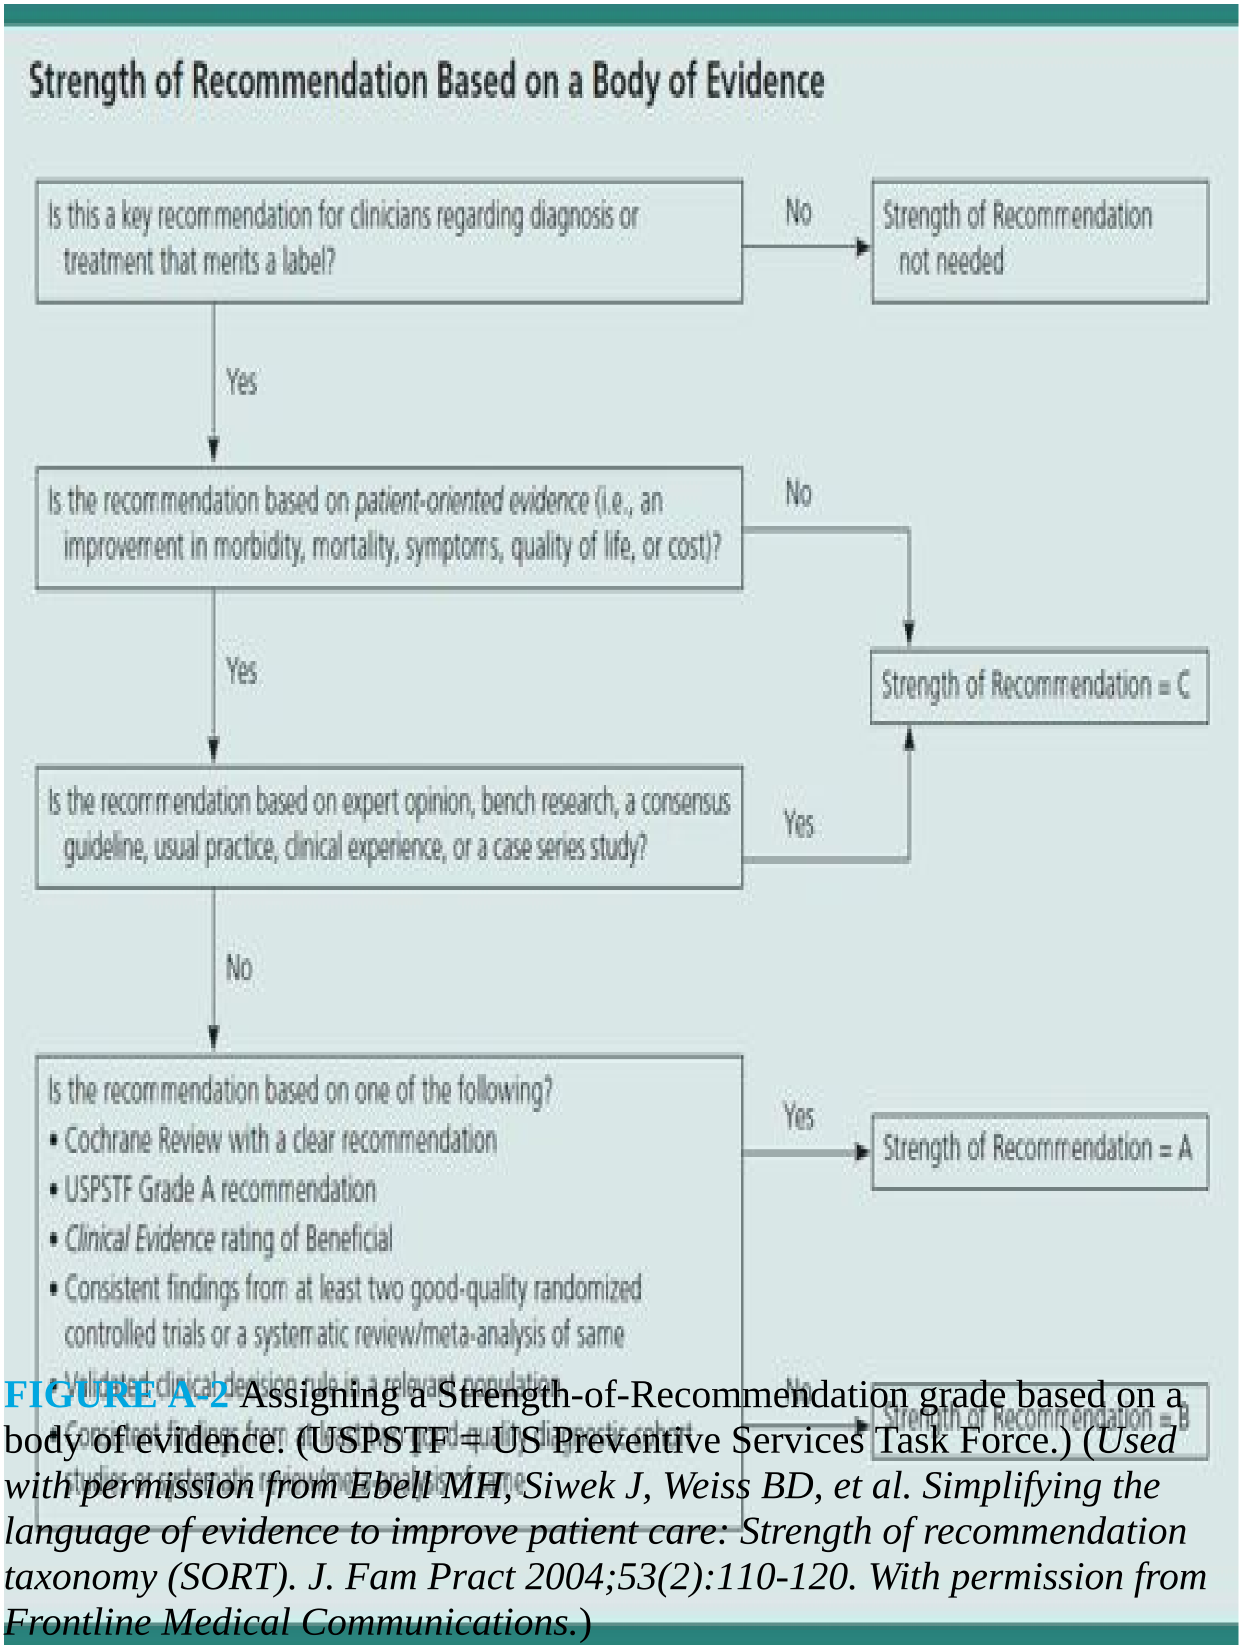
† High-quality diagnostic cohort study: cohort design, adequate size, adequate spectrum of patients, blinding, and a consistent, well-defined reference standard.

‡ High-quality RCT: allocation concealed, blinding if possible, intention-to-treat analysis, adequate statistical power, adequate follow-up (greater than 80 percent).

§ In an all-or-none study the treatment causes a dramatic change in outcomes, such as antibiotics for meningitis or surgery for appendicitis, which precludes study in a controlled trial.

SR, systematic review; RCT, randomized controlled trial

FIGURE A-1 Used with permission from Ebell MH, Siwek J, Weiss BD, et al. Simplifying the language of evidence to improve patient care: Strength of recommendation taxonomy (SORT). J. Fam Pract 2004;53(2):110-120. With permission from Frontline Medical Communications.



Strength of Recommendation Based on a Body of Evidence
Is this a key recommendation for clinicians regarding diagnosis or treatment that merits a label?
No
Strength of Recommendation not needed
Yes
Is the recommendation based on *patient-oriented evidence* (i.e., an improvement in morbidity, mortality, symptoms, quality of life, or cost)?
No
Yes
Strength of Recommendation = C
Is the recommendation based on expert opinion, bench research, a consensus guideline, usual practice, clinical experience, or a case series study?
Yes
No
Is the recommendation based on one of the following?
• Cochrane Review with a clear recommendation
• USPSTF Grade A recommendation
• *Clinical Evidence* rating of Beneficial
• Consistent findings from at least two good-quality randomized controlled trials or a systematic review/meta-analysis of same
• Validated clinical decision rule in a relevant population
• Consistent findings from at least two good-quality diagnostic cohort studies or systematic review/meta-analysis of same
Yes
Strength of Recommendation = A
No
Strength of Recommendation = B

FIGURE A-2 Assigning a Strength-of-Recommendation grade based on a body of evidence. (USPSTF = US Preventive Services Task Force.) (*Used with permission from Ebell MH, Siwek J, Weiss BD, et al. Simplifying the language of evidence to improve patient care: Strength of recommendation taxonomy (SORT). J. Fam Pract 2004;53(2):110-120. With permission from Frontline Medical Communications.*)

In this book, we made a commitment to search for patient-oriented evidence to support the information that we provide in each of the chapter sections (i.e., epidemiology, etiology and pathophysiology, risk factors, diagnosis, differential diagnosis, management, prevention, prognosis, and follow-up) and to provide a SOR rating for that evidence whenever possible. The bulleted format within these divisions would allow the practitioner to quickly find answers to their clinical questions while providing some direction about how confident we were that a recommendation had high-quality patient-oriented evidence to support it.

For example, a parent of a child with suspected sinusitis asks about the need for treating with antibiotics rather than saline nose spray and decongestants? As noted in Chapter 26, Sinusitis, under Medications, there is strong data (SOR A) that antihistamines and decongestants confer no benefit in symptom relief in children and are associated with significant toxicity. Data are absent with regard to saline nose spray for sinusitis in children. Using antibiotics, there is modest potential benefit (about 10% decrease in clinical failure rate) and risks of harm (primarily diarrhea in just under half [44%] but also skin rash, headache, dizziness, and fatigue; although few discontinue medications because of these).

The physician armed with this information can discuss the options with the parent and explore potential benefits and risks. Particularly in difficult cases where there are multiple options, the clinician's experience and the patient preferences are important aspects of shared decision-making. One definition of EBM is, "The integration of best research evidence with clinical expertise and patient values."

Several other concepts are used throughout the book that can assist practitioners in using evidence-based information and explaining that information to patients. Risk reductions from medical treatments are often presented in relative terms—the *relative risk reduction* (RRR) or the difference in the percentage of adverse outcomes between the intervention group and the control group divided by the percentage of adverse outcomes in the control group. These numbers are often large and use of them not only causes us to overestimate the importance of a treatment but misses its clinical relevance. A more meaningful term is the *absolute risk reduction* (ARR)—the risk difference between the two groups. This number can then be used to obtain a *number needed to treat* (NNT)—the number of patients that would need to be treated (over the same time as used in the treatment trial) to prevent 1 bad outcome or produce 1 good outcome. This is calculated as 100 percent divided by the ARR. NNT is more easily understood by us and our patients. See the NNT example in **Box A-1**.

Another term that is used in this book is the *likelihood ratio* (LR). This number, based on the sensitivity and specificity of a diagnostic test, is used to determine the probability of a patient with a positive test (LR+) having the disease or the probability of the patient with a negative test (LR+) not having the disease in question. The LR is defined as the likelihood that a given test result would be expected in a patient with the target disorder compared to the likelihood that the same result would be expected in a patient without the target disorder.[4] The number obtained for the LR+ [Sensitivity/(100 – Specificity)] or the LR–[(100 – Sensitivity)/Specificity] can be multiplied by the pretest probability of disease to determine the posttest probability of disease. A nomogram (one can be found by visiting the website mentioned in reference 6) can be used to more easily work with these numbers to convert a pretest probability into a posttest probability. A LR+ over 10 is considered strong evidence to rule in disease while a LR–of less than 0.1 is strong evidence to rule out disease.

We are both privileged and cursed with practicing medicine in an information-rich environment. We have designed our *Color Atlas* to link evidence to clinical recommendations so that we can provide our patients the best science available. When the evidence is lacking, we make that clear and encourage you to engage in frank and honest discussions that lead to the shared responsibility for decisions. Our patients are justified in expecting science along with humanism—can we give them anything less?

BOX A-1 NNT Example

If a new drug was released for the treatment of pain and a randomized controlled trial found that the 70 percent of the treated group reported significant pain control (based on the defined end point) and 20 percent of the placebo group reported significant pain control this would produce an absolute risk reduction (ARR) of 50 percent. In this case, the NNT would be 100%/50% = 2. On average, only 2 patients would need to be treated for 1 patient to receive the defined pain control benefit. If the ARR was only 10 percent (30% of the intervention group and 20 percent of the control group benefitted), then the NNT = 10 or 10 patients would need treatment on average for 1 to receive benefit.

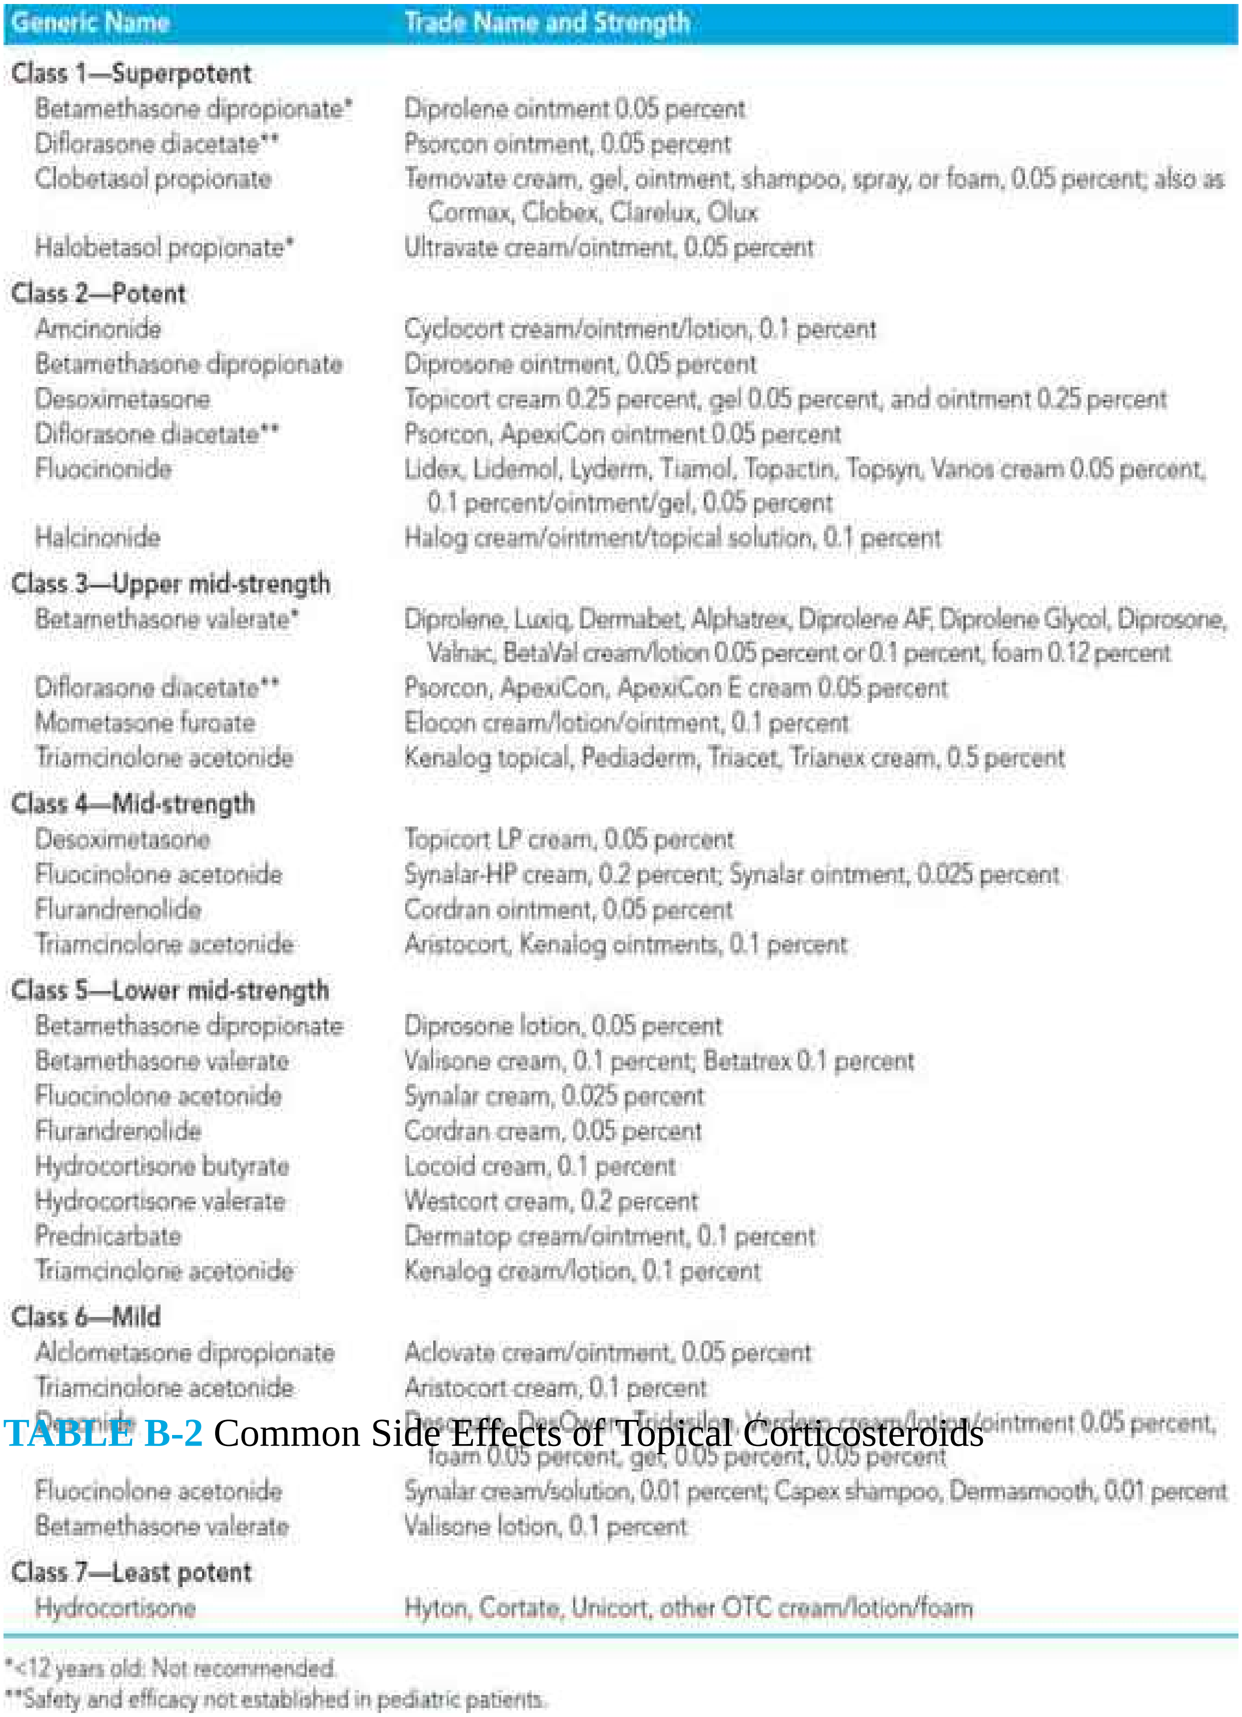
APPENDIX B USE OF TOPICAL AND INTRALESIONAL CORTICOSTEROIDS

TABLE B-1 Corticosteroid Potency Chart

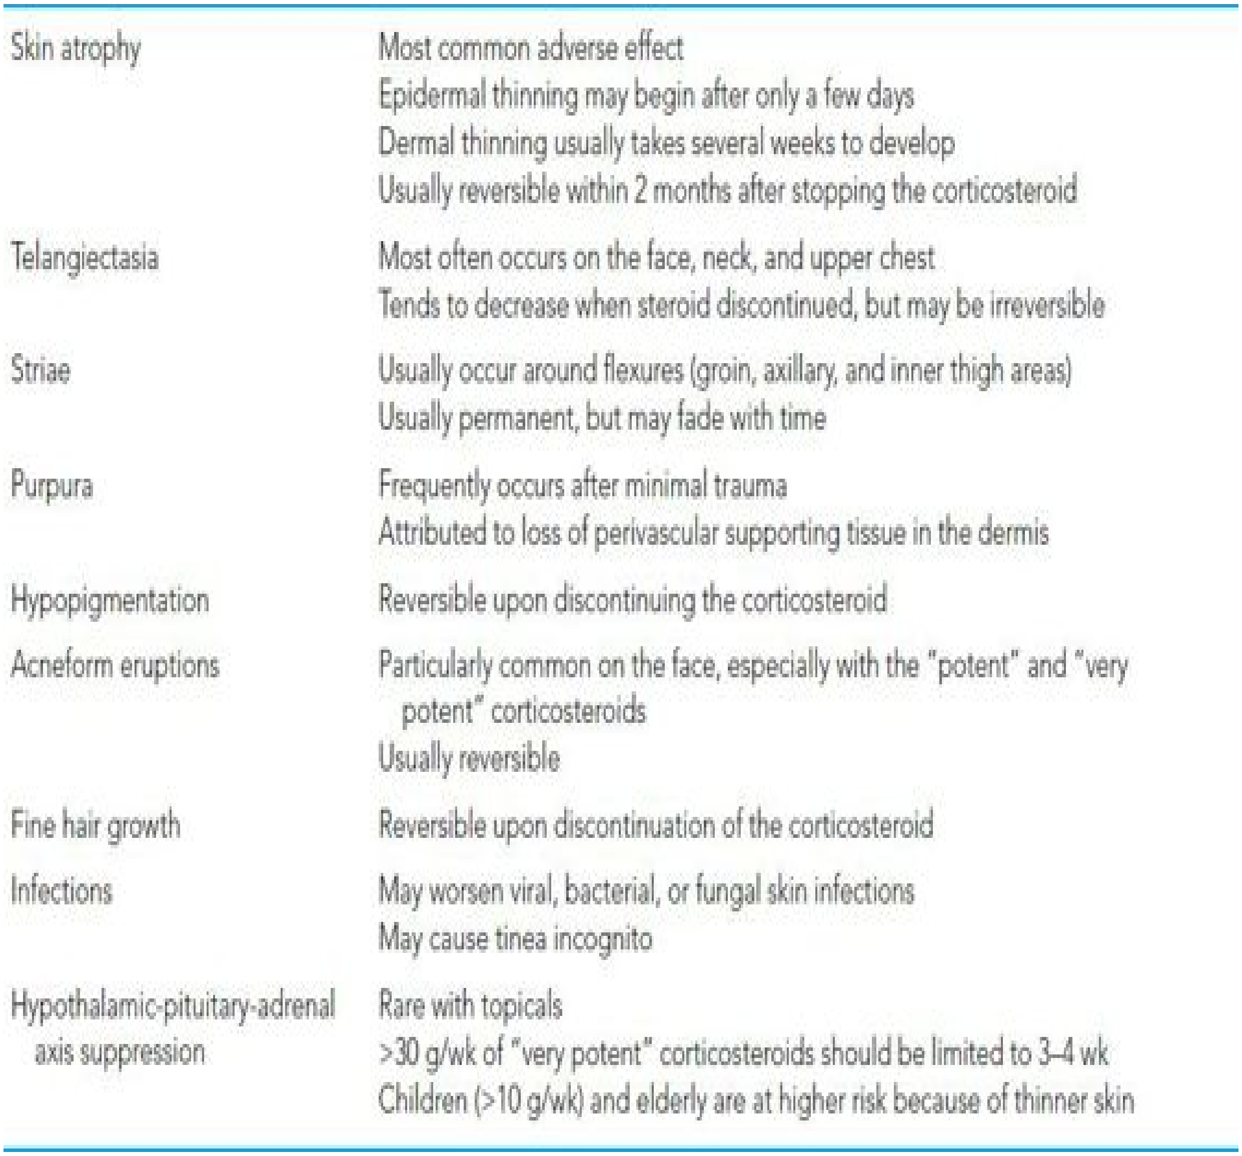


Generic Name	Trade Name and Strength
Class 1—Superpotent	
Betamethasone dipropionate*	Diprolene ointment 0.05 percent
Diflorasone diacetate**	Psorcon ointment, 0.05 percent
Clobetasol propionate	Temovate cream, gel, ointment, shampoo, spray, or foam, 0.05 percent; also as Cormax, Clobex, Clarelux, Olux
Halobetasol propionate*	Ultravate cream/ointment, 0.05 percent
Class 2—Potent	
Amcinonide	Cyclocort cream/ointment/lotion, 0.1 percent
Betamethasone dipropionate	Diprosone ointment, 0.05 percent
Desoximetasone	Topicort cream 0.25 percent, gel 0.05 percent, and ointment 0.25 percent
Diflorasone diacetate**	Psorcon, ApexiCon ointment 0.05 percent
Fluocinonide	Lidex, Lidemol, Lyderm, Tiamol, Topactin, Topsyn, Vanos cream 0.05 percent, 0.1 percent/ointment/gel, 0.05 percent
Halcinonide	Halog cream/ointment/topical solution, 0.1 percent
Class 3—Upper mid-strength	
Betamethasone valerate*	Diprolene, Luxiq, Dermabet, Alphatrex, Diprolene AF, Diprolene Glycol, Diprosone, Valnac, BetaVal cream/lotion 0.05 percent or 0.1 percent, foam 0.12 percent
Diflorasone diacetate**	Psorcon, ApexiCon, ApexiCon E cream 0.05 percent
Mometasone furoate	Elocon cream/lotion/ointment, 0.1 percent
Triamcinolone acetonide	Kenalog topical, Pediaderm, Triacet, Trianex cream, 0.5 percent
Class 4—Mid-strength	
Desoximetasone	Topicort LP cream, 0.05 percent
Fluocinolone acetonide	Synalar-HP cream, 0.2 percent; Synalar ointment, 0.025 percent
Flurandrenolide	Cordran ointment, 0.05 percent
Triamcinolone acetonide	Aristocort, Kenalog ointments, 0.1 percent
Class 5—Lower mid-strength	
Betamethasone dipropionate	Diprosone lotion, 0.05 percent
Betamethasone valerate	Valisone cream, 0.1 percent; Betatrex 0.1 percent
Fluocinolone acetonide	Synalar cream, 0.025 percent
Flurandrenolide	Cordran cream, 0.05 percent
Hydrocortisone butyrate	Locoid cream, 0.1 percent
Hydrocortisone valerate	Westcort cream, 0.2 percent
Prednicarbate	Dermatop cream/ointment, 0.1 percent
Triamcinolone acetonide	Kenalog cream/lotion, 0.1 percent
Class 6—Mild	
Alclometasone dipropionate	Aclovate cream/ointment, 0.05 percent
Triamcinolone acetonide	Aristocort cream, 0.1 percent
Desonide	Desonate, DesOwen, Tridesilon, Verdeso cream/lotion/ointment 0.05 percent, foam 0.05 percent, gel, 0.05 percent, 0.05 percent
Fluocinolone acetonide	Synalar cream/solution, 0.01 percent; Capex shampoo, Dermasmooth, 0.01 percent
Betamethasone valerate	Valisone lotion, 0.1 percent
Class 7—Least potent	
Hydrocortisone	Hyton, Cortate, Unicort, other OTC cream/lotion/foam

*<12 years old: Not recommended.

**Safety and efficacy not established in pediatric patients.

TABLE B-2 Common Side Effects of Topical Corticosteroids



Skin atrophy	Most common adverse effect Epidermal thinning may begin after only a few days Dermal thinning usually takes several weeks to develop Usually reversible within 2 months after stopping the corticosteroid
Telangiectasia	Most often occurs on the face, neck, and upper chest Tends to decrease when steroid discontinued, but may be irreversible
Striae	Usually occur around flexures (groin, axillary, and inner thigh areas) Usually permanent, but may fade with time
Purpura	Frequently occurs after minimal trauma Attributed to loss of perivascular supporting tissue in the dermis
Hypopigmentation	Reversible upon discontinuing the corticosteroid
Acneform eruptions	Particularly common on the face, especially with the "potent" and "very potent" corticosteroids Usually reversible
Fine hair growth	Reversible upon discontinuation of the corticosteroid
Infections	May worsen viral, bacterial, or fungal skin infections May cause tinea incognito
Hypothalamic-pituitary-adrenal axis suppression	Rare with topicals >30 g/wk of "very potent" corticosteroids should be limited to 3–4 wk Children (>10 g/wk) and elderly are at higher risk because of thinner skin

TABLE B-3 Intralesional Steroids—Concentrations for Injection

Condition	Concentration of Triamcinolone Acetonide Solution (mg/mL)
Acne (**Figure B-1**)	2 to 2.5
Alopecia areata (**Figure B-2**)	5 to 10
Granuloma annulare	5 to 10
Psoriasis	5 to 10
Hypertrophic lichen planus	5 to 10
Prurigo nodularis	10
Hidradenitis suppurativa	10
Keloids and hypertrophic scars (**Figure B-3**)	10 to 40

Use a 27-gauge or 30-gauge needle when injecting intralesional steroids to minimize pain. Steroid dilutions can be made with sterile saline for injection. The injection hurts less than when diluting the steroid with lidocaine. A Luer-Lok syringe is helpful to avoid the needle from popping off during the injection. For further information on performing intralesional injections see Usatine R, Pfenninger J, Stulberg D, Small R. *Dermatologic and Cosmetic Procedures in Office Practice*. Philadelphia, PA: Elsevier; 2012. This text and accompanying videos can also be purchased as an electronic application at **http://www.usatinemedia.com**.

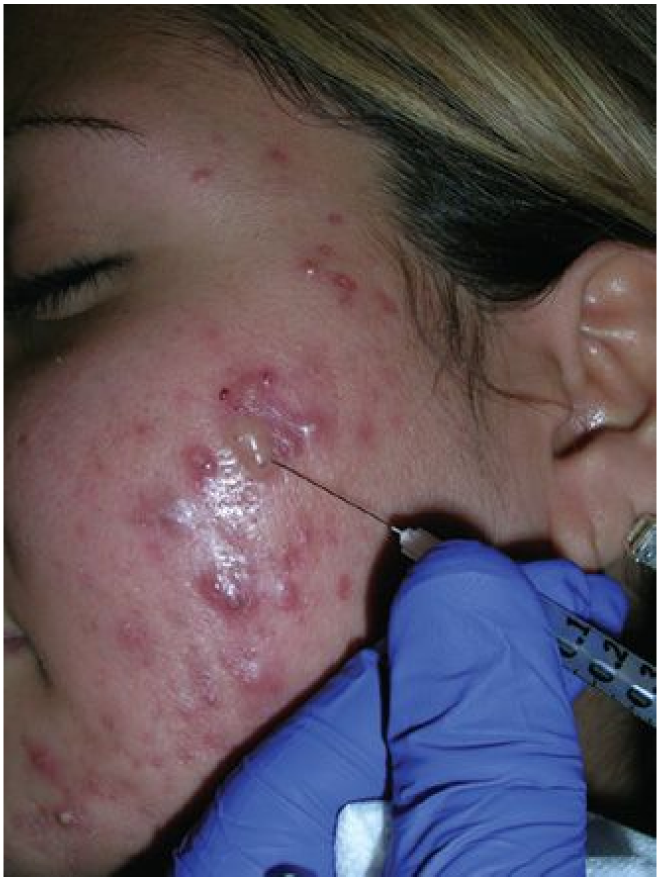


FIGURE B-1 Injecting painful cystic acne with 2 mg/mL triamcinolone using a 30-gauge needle. (*Used with permission from Richard P. Usatine, MD*.)

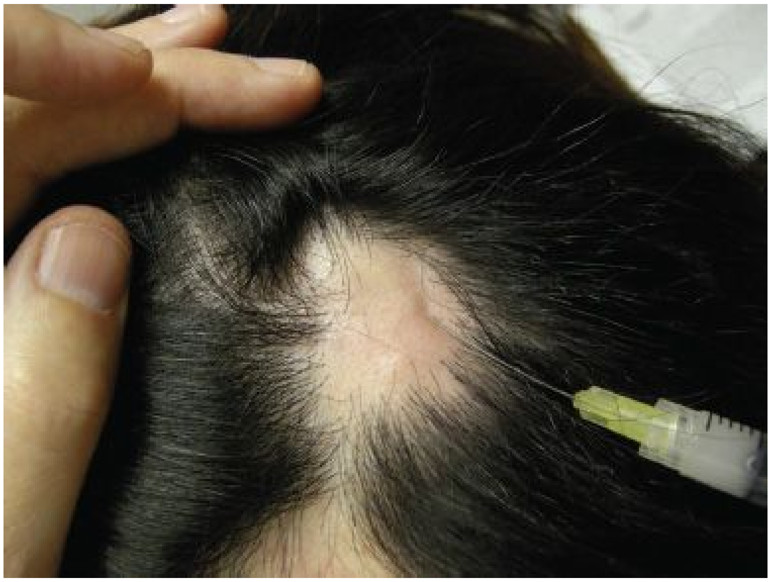

FIGURE B-2 Injecting alopecia areata with 5 mg/mL triamcinolone using a 27-gauge needle on a Luer-Lok syringe. (*Used with permission from Richard P. Usatine, MD.*)

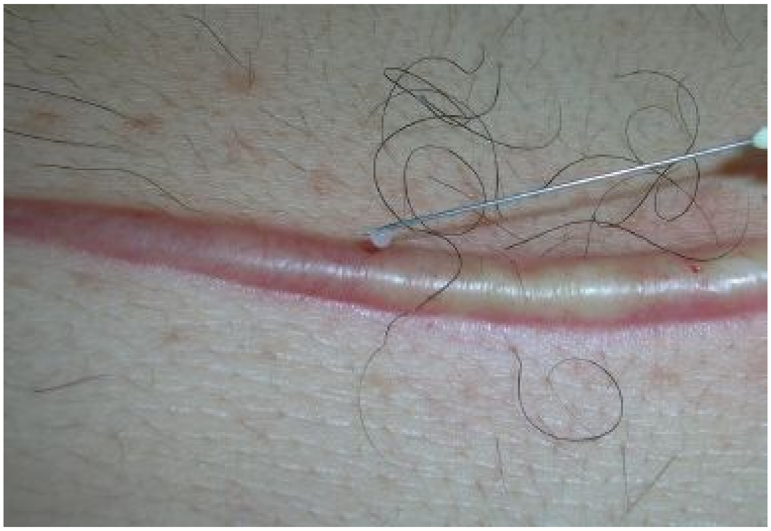

FIGURE B-3 Injecting a hypertrophic scar with 10 mg/mL triamcinolone using a 27-gauge needle on a Luer-Lok syringe. (*Used with permission from Richard P. Usatine, MD.*)

Erythema ab igne
  - differential diagnosis of, 962–963, 962f
  - epidemiology of, 959

Erythema dyschromicum perstans, 963, 963f, 964f

Erythema infectiosum, 644–646, 644f, 645f

Erythema marginatum, in acute rheumatic fever, 269, 270f

Erythema migrans, in Lyme disease, 1063f, 1064, 1064f. *See also* Lyme disease

Erythema multiforme, 867–872, 885
  - diagnosis of, 868f, 869–871, 869f, 888, 888f
  - differential diagnosis of, 763, 764f, 871
  - epidemiology of, 867–868, 872
  - etiology and pathophysiology of, 867f, 868–869
  - fundamentals of, 867
  - management of, 871
  - patient education on, 872
  - prognosis and follow-up of, 872

Erythema nodosum, 873–876
  - diagnosis of, 873f, 874–875
  - differential diagnosis of, 875, 875f
  - epidemiology of, 873
  - from Epstein Barr virus, 1069, 1069f

  - etiology and pathophysiology of, 873–874, 873f
  - fundamentals of, 873
  - in latent TB infection, 1081, 1081f (*See also* Tuberculosis (TB))
  - management of, 875–876
  - patient education on, 876
  - patient story of, 873, 873f
  - prevention of, 876
  - prognosis and follow-up of, 876
  - risk factors for, 873f, 874
  - in sarcoidosis, 861, 862
- Erythema nodosum leprosum, 875, 875f
- Erythematotelangiectatic rosacea, 585, 585f. *See also* Rosacea
- Erythema toxicum neonatorum, 556–560
  - diagnosis of, 557f, 558
  - differential diagnosis of, 558–559
  - epidemiology of, 557
  - etiology and pathophysiology of, 558
  - management of, 559
  - patient education on, 560
  - prognosis in, 560
- Erythrasma, 606–608
  - diagnosis of, 606–607, 606f, 607f, 709, 710f
  - differential diagnosis of, 607
  - epidemiology, etiology and pathophysiology of, 606, 606f
  - management of, 607–608
  - patient education on, 608
  - patient story of, 606, 606f
  - prognosis and follow-up of, 608
  - risk factors for, 606
- Erythroderma, in toxic shock syndrome, 1074, 1074f
- Erythrodermic psoriasis. *See also* Psoriasis
  - diagnosis of, 775, 776f, 778

  management of, 783
Escherichia coli gastroenteritis, 1038–1040
Escherichia coli O157:H7 gastroenteritis, 1038–1040
Esophageal disorders
  differential diagnosis of, 350–351
  epidemiology of, 350
  etiology and pathophysiology of, 350
  fundamentals of, 349–350
  management of, 351
  patient education on, 352
  patient stories of, 349, 349f
  prevention and screening for, 351
  prognosis in, 351
  risk factors for, 350
Esophageal foreign body, in acute upper airway obstruction, 184t, 185f
Esotropia
  accommodative, 99, 100f
  congenital/infantile, 98, 98f
Ethmoidal sinusitis, orbital cellulitis from, 119–122, 119f, 121f. *See also* Orbital cellulitis
EV71 enterovirus hand foot mouth syndrome, 648
Evidence-based medicine (EBM), 1320–1322
  absolute risk reduction in, 1320
  history of, 1320
  likelihood ratio in, 1320–1322
  number needed to treat in, 1320, 1321f
  relative risk reduction in, 1320
  Strength of Recommendation Taxonomy in, 1320, 1321f, 1322f
Exophthalmos, in hyperthyroidism, 1123, 1123f, 1125, 1125f
Exotropia, 98–103, 100f. *See also* Strabismus
Extensive myelination of nerve fiber layer, 106t, 111f
Extremely low birth weight, 12

Eyelid ecchymosis, 124f
Eyes, widely spaced, in Noonan syndrome, 1298f, 1299, 1299f
Eye trauma (hyphema), 123–125. *See also* Hyphema
